Traffic emissions significantly contribute to regional air pollution. Meteorology, traffic characteristics, road design and side structure affect near-road air quality by modifying dispersion of emissions (Hagler et al., 2010). Urban areas typically consist of street canyons where pollutant concentrations can be several times higher than in open areas due to reduced exchange of air and dispersion of pollutants inside the canyon. To obtain more detailed assessment of physical and chemical characteristics and source contributions of fine-particles in urban environment, an advanced measurement method was developed as part of the MMEA (Measurement, Monitoring and Environmental Assessment) program.

Three weeks street canyon campaign was performed in December 2010 in Helsinki. Mobile laboratory Sniffer (Pirjola et al., 2004) was driven on a 20 km route in the city center during the morning and afternoon rush hours, occasionally also at noon. The main street Mannerheimintie was driven back and forth always 5 times. Similarly, the measurements were carried out in side streets and background locations up to the shore. A special attention was given for the urban microenvironments close to the high traffic density street. Stationary measurements were conducted in four measurement stations by HSY, along the driving route.

The spatially and temporally high-resolution data included number concentration and size distribution of particles larger than 3 nm (ELPI, CPC and SMPS) as well as black carbon (Aethalometer) in PM_1 size fraction. Also continuously measured were NO, NO_2, NOx, CO, CO_2, PM_1, $PM_{2.5}$, meteorological and geographical parameters. A thermodenuder was used for volatility studies of particles.

Figure 1 shows the contour plot of the average total number concentration during the rush hours on 2 Dec, 2010. Temporal concentrations were highly variable. Meteorological conditions as well as traffic characteristics and urban planning was shown to have strong effect on the measured air quality.

Within a microenvironment where Mannerheimintie can be considered as an avenue canyon, the wake interference flow is produced (Vardoulakis et al., 2003). The windward concentrations of NO_x were around 26-59% of the leewind concentrations. Rather similar results (55%) were also predicted by a street canyon model OSPM (Berkowicz, 2000).

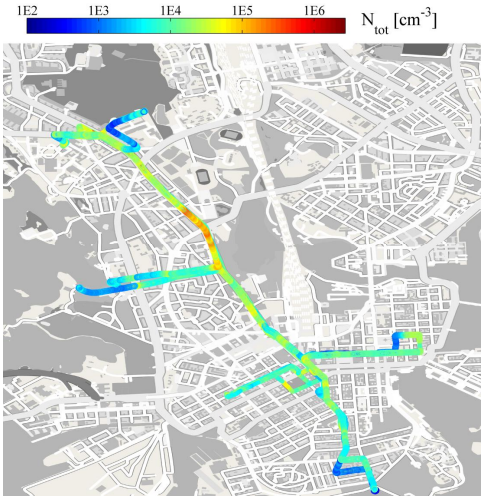

Figure 1. The map of downtown of Helsinki. The colour bar indicates the particle number concentration on Mannerheimintie and on the nearby streets.

More detailed analysis showed that the surrounding built environment combined to the predominant wind conditions changed the dispersion around the high traffic density streets markedly. The comparison of the stationary measurements to mobile measurements corresponded well promoting the mobile measurement method in an urban air quality studies.

MMEA is supported by Tekes (the Finnish Funding Agency for Technology and Innovation) and coordinated by the Finnish energy and environment cluster - CLEEN Ltd.

Spatial and Seasonal Variations of Black Carbon and NO_2 Concentrations in an Urban Environment and correlation with UFP concentrations at selected locations

Martine Van Poppel[1], Christina Matheeussen[2], Patrick Berghmans[1]

[1]VITO - Flemish Institute for Technological Research, 2400 Mol, Belgium
[2]Flemish Environmental Agency, 2000 Antwerp, Belgium

Keywords: Black Carbon, NO2, UFP, traffic.
Presenting author email: martine.vanpoppel@vito.be

Traffic is one of the main sources of BC (black carbon), UFP (Ultrafine Particles) and NO_2 in urban environments. In addition, BC and UFP are considered to have a larger health impact (per mass) as compared to PM (Particulate Matter). Therefore, it is important to know the spatial variation in order to assess people's exposure and related health impact.

The results presented in this paper are part of a larger multidisciplinary study dealing with health impact of traffic related air pollution (UFP, BC, NO_2) on school children. To assess the exposure of the children, air quality measurements were performed at two school locations, at 40 home location and during 'in transport'. This paper focuses on the seasonal and spatial variation of UFP, BC and NO_2 at school and home locations.

Monitoring of UFP, BC and NO_2 was performed during summer (May – June 2011) and winter (November – December 2011). At two school locations BC, NO_2 and UFP were measured. BC and NO_2 measurements were performed at 8 locations simultaneously during 5 consecutive weeks resulting in 40 locations sampled. During each week, UFP measurements were performed at one of these locations. The locations represent the home locations of the children. In addition, measurements were performed during the entire monitoring campaign at an urban location of the AQ monitoring network. These data were used to rescale BC and NO_2 concentrations that were measured consecutively. The locations are characterised by different exposure to traffic. Two rural locations were included to estimate the regional background contribution. NO_2 was monitored using diffusive sampling tubes. BC was measured using µ-Aethalometer (AethLabs). UFP number concentrations were measured using CPC (TSI type 3783 and 3786) and Nanocheck (Grimm). During a limited period of the monitoring campaign at the school locations, BC concentrations were compared to EC analysed on filter samples using TOT (Thermo Optical Transmission).

BC concentrations measured in summer are less than 1 µg/m^3 at rural location and range from 1 to 3 µg/m^3 at the urban locations. Highest concentrations are measured at locations with more traffic. Similar trends are observed for NO_2. Weekly average concentrations of NO_2 measured in the urban locations range from 17 – 48 µg/m^3.

Weekly average NO_2 and BC concentrations show a good correlation (Figure 1) and a spatial variation of a factor 3 during summer. Correlation of BC with UFP are higher at street locations as compared to background locations.

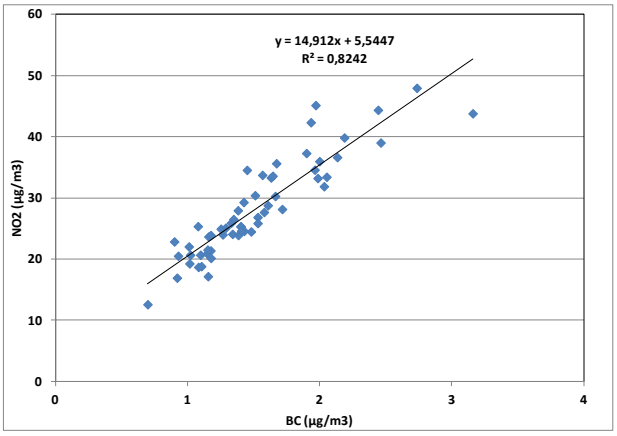

Figure 1. Weekly average BC and NO_2 concentrations at different locations in Antwerp in summer.

Preliminary results of the summer campaign show a high spatial variation for BC and NO_2 and the added value of a dense (temporary) monitoring network to asses more accurate real exposure in health-related studies.

Results of the winter campaign will be further discussed in the paper.

This work was funded by the Flemish Environmental Agency.

WG03S3O. Characterisation Techniques for Organic Aerosol

Studying Atmospheric Aerosols by Acoustic Levitation: Linking Head Space Solid-Phase Micro-Extraction (HS-SPME) with Gas Chromatography-Mass Spectrometry (GC-MS).

S. Almabrok, G. Marston and C. Pfrang

Department of Chemistry, University of Reading, P.O. Box 224, RG6 6AD Reading, Berkshire, UK
Keywords: Solid-Phase Micro-extraction, Acoustic Levitation, α-Pinene, Ozone.
Presenting author email: s.h.almabrok@reading.ac.uk

Climate change is one of the most important global environmental problems affecting natural ecosystems, food production, availability of fresh water as well as human health.(1) In acoustic levitation, a sound wave is generated between a piezoelectric transducer and a flat or concave reflector; therefore, by altering the distance between transducer and reflector a standing wave can be created and small samples of solids or liquids can be levitated.(2) This study has been conducted to improve our understanding of the reactions of O_3 and NO_3 with a range of terpenes found in the Earth's atmosphere and of the formation and properties of associated organic aerosols. For these investigations, a combination of acoustic levitation with gas chromatography-mass spectrometry (GC-MS) has been achieved by head space solid-phase micro-extraction (HS-SPME). The experimental set-up is illustrated in Fig. 1 (a-b).

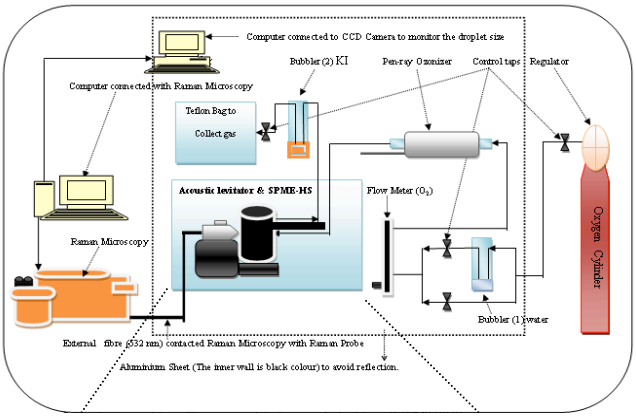

Figure 1 (a): Experimental set-up for the acoustic levitator with HS-SPME-GC-MS analysis.

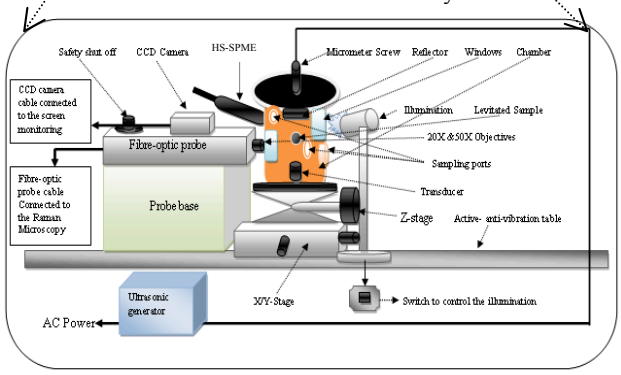

Figure 1 (b): Set-up for the combination of the acoustic levitator with HS-SPME (zoom into Fig. 1 (a)).

Fig. 2 shows the mass spectrum for a levitated droplet of pure α- pinene obtained by using HS-SPME-GC-MS under the following conditions: 174 ml/min flow of N_2, 5 min extraction time, and using a 100 µm polydimethylsiloxane (PDMS) coated fibre. Oxidation of acoustically levitated droplets of α-pinene and d-limonene has been studied in an environmental chamber that allowed control of the gas-phase surroundings and relative humidity. Several products could be identified mostly by comparison with reference samples in the same conditions including verbenone, verbenol, pinocarveol, carvone, carveol, norpinoaldehyde and pinonaldehyde (see example in Fig. 3).

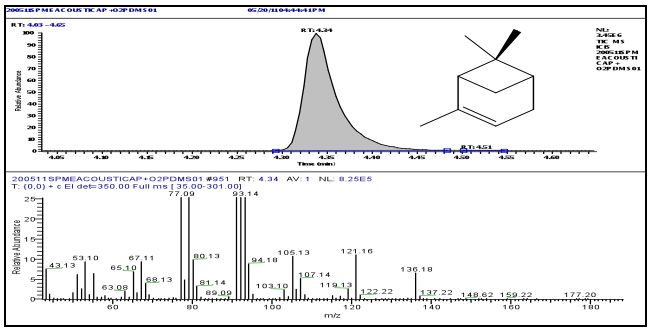

Figure 2: HS-SPME-GC-MS result for a levitated droplet of pure α-pinene (GC on top; MS below).

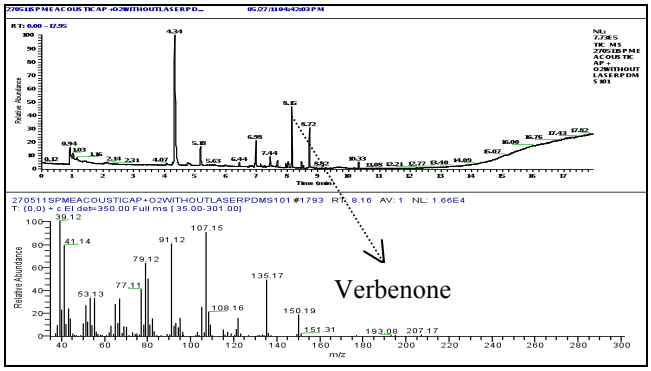

Figure 3: HS-SPME-GC-MS result for a levitated droplet of α-pinene after oxidative ageing (MS for the product verbenone).

Aerosols of biological origin such as bacteria and spores are gaining increasing attention in the research field of cloud microphysics. Their ability to act as heterogeneous ice nuclei has been shown in various laboratory studies; however, their atmospheric relevance in aerosol-cloud interactions is debatable. This is partly due to the lack of understanding of the actual processes driving water and ice nucleation on biological particles (e.g. Möhler *et al.*, 2008), but also to the challenging identification of these particles in the field (Pratt *et al.*, 2009). Both objectives were tackled in the framework of the BIO05 and BIO06 campaigns at the AIDA facility at the Karlsruhe Institute of Technology, Germany. The ice nucleation behavior of bacterial species such as *Pseudomonas syringae* and *Pseudomonas fluorescence* was studied with focus on differences in the physico-chemical properties between the individual, intact cells, bacteria strains and their residuals. The latter are a product of the aerosol generation process and smaller in size than the intact cells.

This study focuses on mass spectrometric measurements of the chemical composition of the laboratory generated bacterial cells and their residues. Three different aerosol mass spectrometers were applied featuring the analysis of single particles: a TSI Aerosol Time-of-Flight Mass Spectrometer (ATOFMS), Aerodyne's C-ToF-AMS with Light Scattering Probe (LSP) for single particle detection, and the Aircraft-based Laser ABlation Aerosol MAss spectrometer (ALABAMA), developed by MPI Mainz (Brands *et al.*, 2011). The ATOFMS and ALABAMA both use laser ablation to evaporate and ionize the particles for mass spectrometric detection (LDI), whereas the C-ToF-AMS uses thermal vaporization with subsequent electron impact for ionization. All three instruments allow a size resolved analysis of the particles' chemical composition, i.e. mass spectra from intact cells and their residues are separated. Both were represented as two distinct modes in the measured size distribution.

The elaboration of mass spectrometric "fingerprints" usable for the identification of bacteria by aerosol mass spectrometry is a key aspect of this study. *Fig. 1* exemplarily depicts an ATOFMS mass spectrum of *Pseudomonas syringae* cell of strain 13b2. The ions representing phosphate, potassium, and nitrogen-containing organic compounds are clearly visible and have been detected by both LDI instruments. However, unidentified peaks remain which have also been observed in ambient aerosols.

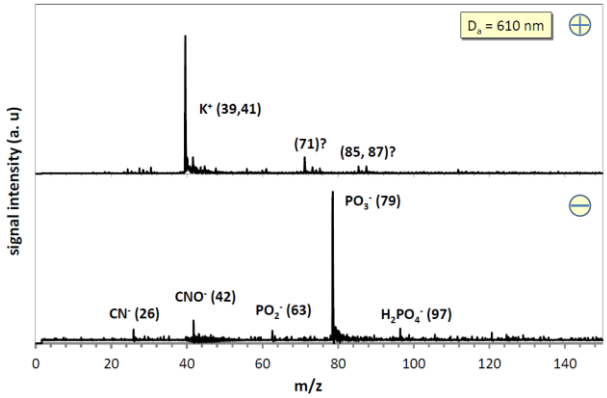

Figure 1. Mass spectrum of *Pseudomonas syringae* bacteria cell recorded by the ATOFMS. The most prominent, identified ion peaks are marked.

Similarities and differences in the ion peaks obtained from all three instruments will be highlighted. The findings are referenced to ambient spectra collected by the identical instruments in the field, and also to spectra referred to as "bioaerosols" in the literature (e.g. Fergenson *et al.*, 2004). The study provides valuable reference spectra for the mass spectrometric community which is of high importance as single particle instruments are widely used for the online, in situ detection and identification of aerosols as well as ice crystal and cloud droplet residuals in field studies.

On-line analysis of organic aerosols with an ion-trap aerosol mass spectrometer

S.J. Gallavardin[1,2], J. Fachinger[1], F. Helleis[1], F. Drewnick[1], and S. Borrmann[1,2]

[1]Particle Chemistry Dept., Max Planck Institute for Chemistry, Mainz, 55128, Germany
[2]Institute for Atmospheric Physics, Johannes-Gutenberg University, Mainz, 55099, Germany
Keywords: Instrument development, organic aerosols, aerosol mass spectrometry
Presenting author email: johannes.fachinger@mpic.de

Organic aerosols in the atmosphere are a complex matter due to the large amount of different compounds. For a better understanding of the evolution of the particle composition and its effect on its environment, a more detailed characterization, in particular of the chemical functionality and/or molecule structures, is necessary (Hallquist et al., 2009).

Compared to time-of-flight mass spectrometers, ion-trap mass spectrometers allow for more detailed chemical analysis due to their unique features: specific ion fragmentations and ion-molecule reactions can be induced to access molecule or ion structural information (Gross, 2011).

We report here on the recent improvements and operation of the Ion-Trap Aerosol Mass Spectrometer (IT-AMS) initially developed by Kürten et al (2007). The IT-AMS is similar to the Aerodyne AMS instrument with the exception of the mass spectrometer module that is replaced by a home-built 3D quadrupole ion-trap mass spectrometer. A home-written software controls the ion-trap mass spectrometer through the definition of series of measurement cycles. Each measurement cycle controls the ion manipulation allowing thereby for specific analyses. By combining successively in time different measurement cycles, one can obtain different structural information related to the different molecules in the aerosol particles.

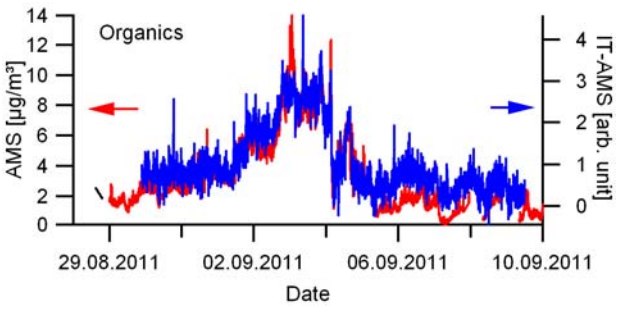

Figure 1. Detection of organics in atmospheric aerosol particles using a standard AMS instrument (left, red) and IT-AMS (right, blue).

Figure 1. shows comparative measurements of IT-AMS with a standard AMS instrument during 10,5 days at the Kleiner Feldberg (Germany) in summer 2011 probing atmospheric aerosols. A good correlation of the temporal evolution of the concentrations of total organics as well as of nitrate and sulphate (not shown here) was observed for both instruments.

In the laboratory, measurement cycles were tested to explore the different features of IT-AMS. As an example, pure aerosol particles of tryptophan and glutathione, considered as markers of primary biological particles, can be distinguished from each other by the fragmentation of one common ion (m/z=130). The used measurement cycles also reveal details of the ion structure and fragmentation pathways (see Figure 2.).

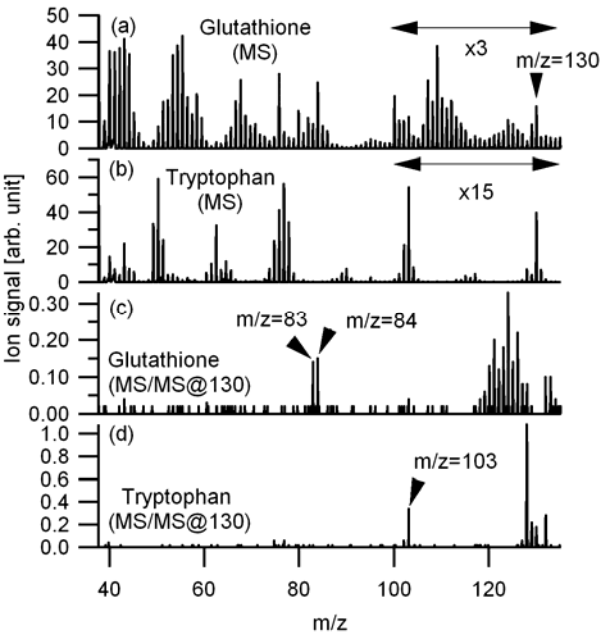

Figure 2. IT-AMS Mass spectra (MS) of glutathione (a) and tryptophan (b). Removal of ions (m/z=40-115) and fragmentation of ions (m/z=130) (MS/MS@130) (c), (d).

Thus, by the choice of appropriate measurement cycles applied to frequently found ions in classic aerosol mass spectrometric analyses with AMS, it is possible to gain on-line more insights into the composition complexity of atmospheric organic aerosols.

Organic particle and gas phase measurements with a new MOVI-CI-TOF-MS

C. Mohr[1], F. Lopez-Hilfiker[1], J. D. Wargo[1], R. L. N. Yatavelli[1,2], and J. A. Thornton[1]

[1]Department of Atmospheric Sciences, University of Washington, Seattle, WA, 98195, USA

Presenting author email: cmohr@u.washington.edu

Organic compounds are ubiquitous in the atmosphere and present in both gas and particle phase. Their evolution in time is determined by emissions, oxidation, deposition, and gas/particle partitioning especially for semi-volatiles (SVOCs). A fundamental understanding of this highly dynamic system thus requires quantitative measurements of organic compounds in both gas and particle phases.

Here we present laboratory and field data from an improved version of the Micro Orifice Volatilization Impactor Chemical Ionization Time-of-Flight Mass Spectrometer (MOVI-CI-ToF-MS, Yatavelli and Thornton, 2010). While particles are impacted on a post for subsequent thermal desorption and analysis using chemical ionization mass spectrometry (CIMS), gases are drawn into the MOVI and analyzed in real time using CIMS. Particle collection/gas phase analysis and temperature-programed desorption for particle phase analysis are alternated ~every 15 min.

The current version of the MOVI incorporates modifications done to (a) minimize the adsorption of gases and thus the loss of semi and low volatility compounds on to the MOVI surfaces, (b) rapidly return the collection post to ambient temperature after a desorption step, and (c) provide a means of robust calibration. Moreover, the instrument continuously switches between positive and negative ion proton transfer chemical ionization, allowing the detection of organic compounds with a variety of functional groups. We demonstrate mass accuracies better than ± 20 ppm and sensitivities in the range of 5 - 15 counts s^{-1} per ppt for gas phase measurements. For particle phase, the detection limit is a few nanomoles per m^3.

The instrument was recently deployed in a month-long field campaign (ClearfLo) in Detling, UK, from January 16 to February 15, 2012. The measurement site is influenced by local emissions from nearby roads and villages, but also by continental air masses or the London plume. Preliminary analysis shows that a high number of organic acids, as well as other compounds such as organonitrates and organosulfates, in both gas and particle phase up to a m/Q of ~500 Th could be detected and quantified (Figure 1). Diurnal patterns of ions with mass-to-charge ratios consistent with levoglucosan, syringic acid (m/Q 197) and tentatively nitrophenols (m/Q 138) indicate the presence and importance of wood smoke in England during cold ambient temperatures (Figure 2). Moreover, the intensity of a number of ions in the thermal desorption steps are well correlated with the organic aerosol time series.

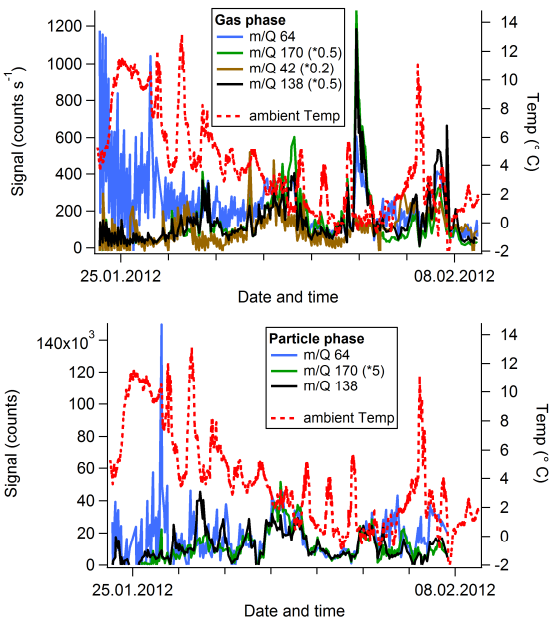

Figure 1. Time series of gas and particle phase species measured in negative mode, as well as ambient temperature.

Overall instrument performance in the field, relative to laboratory characterizations, and initial statistical pattern analysis of the multi-dimensional field data set are also discussed.

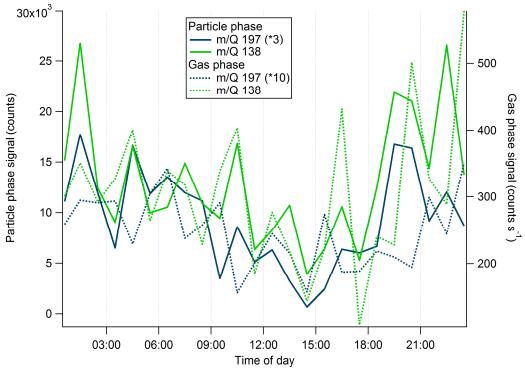

Figure 2. Diurnal pattern of gas and particle phase of m/z 197 (syringic acid) and m/z 138 (nitrophenols), related to biomass burning emissions.

Urban organic aerosols composition measured by ultra-high resolution mass spectrometry

A.G. Rincón[1], A.I. Calvo[2], M. Dietzel[3], M. Kalberer[1]

[1]Department of Chemistry, University of Cambridge, Cambridge, CB2 1EW, UK
[2]Centre for Environmental and Marine Studies, Department of Environment, University of Aveiro, Aveiro, Portugal
[3]Institute of Nano and Microfluidics Center of Smart Interfaces, Technical University Darmstadt, Darmstadt, Germany
Keywords: Water-soluble organic fraction, SOA, urban aerosol, Ultra-high resolution mass spectrometry
Presenting author email: agr36@cam.ac.uk

Organic compounds are major constituents of atmospheric aerosol particles. The understanding of their chemical composition, their properties and reactivity are important for assessing aerosol effects upon both global climate change and human health. Among organic aerosols, secondary organic aerosols (SOA) are predominant especially in summer due to intense photochemical activity.
Here we describe the chemical composition of aerosols with particle diameters <1µm collected on filters at an urban site in Cambridge, UK, during summer 2009 (Rincón *et al*., 2012).

The water-soluble organic fraction of the filters was separated from inorganic ions by a solid phase extraction step and re-dissolved in acetonitrile-water prior to analysis. Ultra-high resolution mass spectrometry (UHRMS) analyses were performed using an LTQ Orbitrap Velos, with an accuracy bellow 2ppm, using an electrospray ionisation source. Mass spectra were measured by direct infusion, in negative and positive polarities and recorded within the range of 50-500m/z. Molecular formulas were assigned to the exact masses of the more than 5000 compounds in a single sample using the Xcalibur™ software. After data processing, visualization schemes, such as van Krevelen diagrams and Kendrick mass defect plots were used for data interpretation.

The identified elemental formulas are classified into six compound categories, including CHO, CHN, CHON, CHOS, CHS, and CHONS compounds. CHONS compounds refer to compounds that contain carbon, hydrogen, oxygen, nitrogen and sulfur. Other compound categories are defined analogously. 80% of the data contains compounds with OS or N heteroatoms; only 20% of the data contains compounds with CHO. The overall average O/C ratios of the all sub-groups are about 0.55 - 0.60 in negative and 0.43 - 0.47 in positive polarity which compares well with other UHRMS studies of urban aerosols, where an average O/C of 0.37 was observed (Roach *et al*., 2011).

Of all N-containing compounds only about 20% can be detected in both polarities emphasizing the need to characterize complex samples like organic aerosols in both modes. Figure 1 shows van Krevelen plots of H/C versus N/C of the CHN subgroup, detected in negative and positive polarity. More CHN compounds are measured in positive mode than in negative mode, which is mainly due to amine functional groups in these compounds. Accordingly, CHN compounds in positive mode have high H/C (>1) and on average a lower N/C than in negative mode. In addition, more CHON components were measured in negative mode especially at N/C > 0.5 and only about 23% of the formulas were detected in both modes, indicating the variety of functional groups in this sub-group.

A large number of highly unsaturated reduced nitrogen-containing compounds were detected, corresponding likely to cyclic amines. Homologous series with mass differences of CH_2 were found, especially pronounced in the CHO sub-group. Both, amines and long-chain aliphatic acids are likely signatures of biomass burning and other primary biological sources.

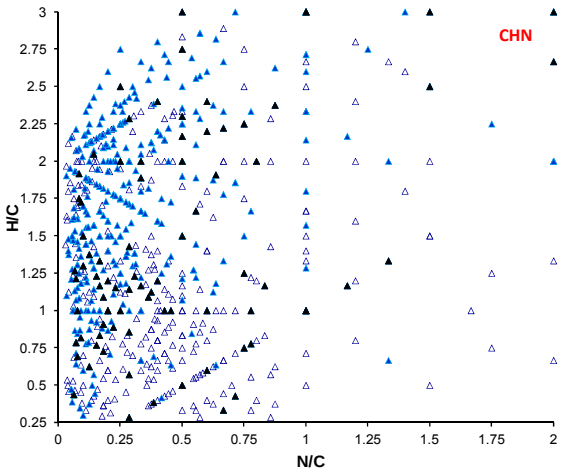

Fig 1. H/C elemental ratio vs. N/C for the CHN sub-group, measured in negative (Δ) and positive (▲) polarity. Black full signs shows compounds measured in both polarities.

Keywords: PM, EC/OC-Carbon analyzer, Photo-ionization mass spectrometry, evolved molecular signature,
Presenting/corresponding author email: ralf.zimmermann@helmholtz-muenchen.de

Carbonaceous material in airborne particulate matter (PM) is of increasing interest due its adverse health effects and its potential influence on the climate. Its analytical ascertainment on a molecular level is still challenging. Hence, analysis of carbonaceous fractions for many studies is often solely carried out by determining sum parameters such as the overall content of organic carbon (OC) and elemental carbon (EC) as well as the total carbon content, TC (sum of OC and EC). The used thermal procedure, however, allows to get additional interesting information: By defining different thermal OC fractions (i.e temperature steps) also information on the refractory properties of the carbonaceous material is obtained. In this context it is particularly interesting to investigate the release and formation behaviors of the molecular species responsible for the different OC and EC fractions. Thus after initial promising results of a pre-study [1] in the current work an EC/OC carbon analyzer (Model DRI 2000) and a homebuilt photo-ionization time-of-flight mass spectrometer (PI-TOFMS) were hyphenated [2] to investigate individual organic compounds especially from the different OC fractions The carbon analyzer enables the stepwise heating of filter samples loaded with PM and provides the sum values of the carbon release (Used steps – "Improve protocol" [2]: OC1 - 120 °C, OC2 - 250°C, OC3 - 450°C OC4 - 550°C). With the on-line coupled PI-TOFMS now in addition the organic compounds which are released during the thermal profile are detectable in real time. This is possible by the soft photo ionization methods (SPI - single photon ionization and REMPI - resonance-enhanced multi photon ionization) which suppress fragmentation upon ionization. The two instruments were coupled by a newly developed interface and characterized with standard substances. The final EC/OC-analyzer - PI-TOFMS instrument then was applied to several types of PM samples, such as ambient aerosol, gasoline/diesel emissions and wood combustion emission. Ambient filter samples e.g. showed a strong impact of wood combustion markers. This was revealed by comparison to the thermal OC signatures of pure cellulose, lignin and wood combustion PM with the ones of ambient air PM. At higher temperatures (450 °C) often a shift to smaller molecules occurs. This is due to the thermal decomposition of larger oligomeric or polymeric molecular structures comparable to lignocelluloses and similar oxygenated humic-like substances. Finally, PM from vehicle exhaust (gasoline and diesel with 10% biodiesel) was analyzed (Fig. 1 and 2). Gasoline PM exhibited large polycyclic aromatic hydrocarbons, whereas diesel PM showed a much higher total organic content in the REMPI measurements. The detected pattern (SPI) revealed a strong influence of the biodiesel content on the nature of the organic PM material.

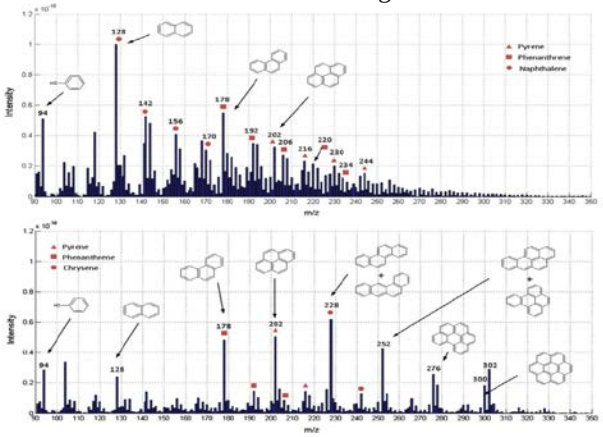

Figure 1. REMPI/TOF-MS spectrum of OC3 (450° C) of diesel (top) and gasoline PM (bottom). REMPI selectively detects aromatic compounds at the chosen ionization wavelength.

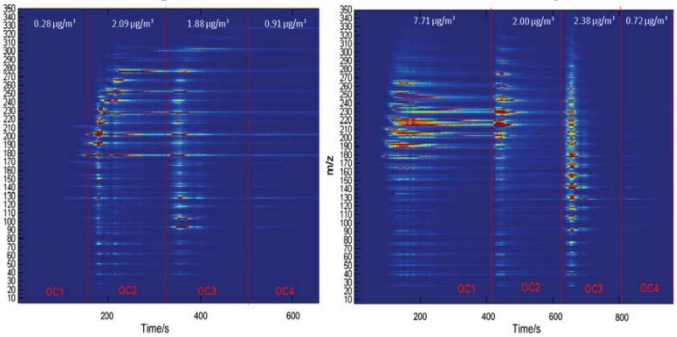

Figure 2. Two-dimensional EC/OC-analyzer - REMPI/TOF-MS signature of filters from car emissions using gasoline (left) and diesel (right). The abscissa reflects the time of the thermo-optical measurements (s), the ordinate shows the molecular masses (m/z).

The health effects of organic fractions in aerosols are currently further investigated in the framework of the Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health, HICE (www.hice-vi.eu).

A long pathlength absorbance photometer for the determination of peroxide content and brown carbon in primary and secondary organic aerosol

J. Dommen[1], P. Mertes[1], S.M. Platt[1], I. El Haddad[1], L. Pfaffenberger[1], A.S.H. Prévôt[1], M. Kalberer[2], and U. Baltensperger[1]

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
[2]Centre for Atmospheric Science, Department of Chemistry, University of Cambridge, United Kingdom
Keywords: peroxide, SOA, light absorption, particle composition.
Presenting author email: josef.dommen@psi.ch

Organic aerosols are chemically still poorly characterized as they are composed of thousands of different organic molecules. These compounds have low vapour pressures and must therefore contain many functional groups, e.g. alcohols, carbonyls, carboxylic acids and peroxides. Of these groups, organic peroxides are the least understood. They are difficult to measure and they have been quantified in only few studies (e.g. Docherty et al., 2005; Surratt et al., 2006). Furthermore it is assumed that they contribute to adverse health effects because of their high reactivity and high oxidation potential.

Not only black carbon but also many organic compounds are light absorbing. The occurrence of such compounds in organic aerosols has been referred to as brown carbon (Andreae and Gelencsér, 2006). Incomplete combustion, especially associated with biomass burning has been shown to produce particulate brown carbon. However, brown carbon formation and its removal by photochemical oxidation is not well understood.

Here we present an instrument for the quantification of peroxides in aerosol particles based on iodometry and long pathlength absorption photometry (Peroxide-LOPAP). Extraction, chemical conversion and subsequent measurement of the aerosol samples is performed in a closed, oxygen-free environment. The limit of detection is 0.1 µM peroxide, which is orders of magnitude lower than previously obtained.

Figure 1 shows the instrument calibration for various hydroperoxides. The method measures quantitatively all peroxides except for very stable compounds like *tert*-butyl hydroperoxide. Thus, with this instrument the total concentration of peroxides in the aerosol is effectively measured.

Since the measurement technique relies on absorption we also measured the light absorbance of other species extracted from the aerosols. Thus, all aerosol samples were divided into two fractions. From one fraction we determined the absorbance due to peroxides after addition of KI, from the second the absorption due to none peroxide species. The following systems were investigated: SOA from ozonolysis and photooxidation of α-pinene, POA and SOA of emissions from wood burning, a diesel car, a two-stroke scooter and cooking.

The highest amount of peroxides with 34% (assuming a molecular weight MW of 300 g/mol) was found in freshly generated SOA from α-pinene ozonolysis, in agreement with measurements of Docherty et al. (2005). Peroxide contents in POA were low while increased levels were observed in the SOA after photo-oxidation of the emission mixtures. Peroxide contents decreased with increasing NO concentration in the photo-oxidation experiments. Generally, a decrease of the peroxide content was observed with aging of the aerosol, indicating a decomposition of peroxides in the particles. Particles from wood combustion showed at 365 nm the highest bulk mass absorption efficiency (0.3-0.5 m^2g^{-1}) followed by diesel, while scooter and cooking emissions exhibited only small mass absorption efficiencies.

Presenting author email: m.v.ghosh@reading.ac.uk

Free radicals control the lifetime of gases important for the Earth's radiative balance (e.g. CH_4), the budget of O_3 in all parts of the atmosphere, as well as the production of acidic species. Understanding the behaviour of free radicals in the atmosphere is of paramount importance for establishing the lifetime and hence spatial scales of pollutant transport. Assessment of the variability of free radical formation from reactions of ozone with terpenes is important for understanding the health effects associated with the particulate matter (Johnson and Marston, 2008). Studies showed that a significant amount of reactive oxygen species is associated with secondary organic aerosol (SOA) formed under laboratory conditions during the reaction of α-pinene with ozone (Pavlovic and Hopke, 2009).

The α-pinene oxidation by ozone has been studied in individually levitated aerosol droplets using an acoustic levitator at 100 kHz encased in a custom-built environmental chamber allowing control of the gas-phase surroundings and relative humidity (Ghosh et al, 2011).

Figure 1: Images of a α-pinene droplet levitated in an ultrasonic trap.

In order to determine the chemical composition of free radical species from the oxidation of levitated α-pinene droplets with ozone by Electron Spin Resonance, a spin trap was employed to stabilize the radicals and increase their lifetimes for characterisation (Ghosh et al, 2008).

The EPR spectra were recorded at ambient temperature on a JEOL FR30EX spectrometer using the following settings: centre field 3360 G, frequency 9.42 GHz, power 4 mW, sweep time 60 s, time constant 0.1 s, modulation frequency 100 kHz and modulation width 1G. The EPR hyperfine coupling constants (due to the interaction of unpaired electron with the nitrogen atom) were extracted from the simulation of the experimental spectra.

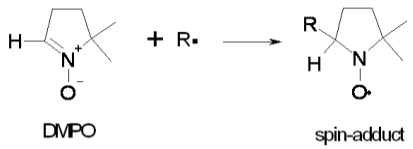

Figure 2. The spin-trapping technique: DMPO (5,5-dimethyl-1-pyrrolidine-N-oxide) spin-trap scavenges a short-lived radical R· by forming a persistent spin-adduct.

Figure 3: Spin adducts spectra from the levitation of α-pinene in Ozone by Spin Trapping Methodology by EPR in DMPO.

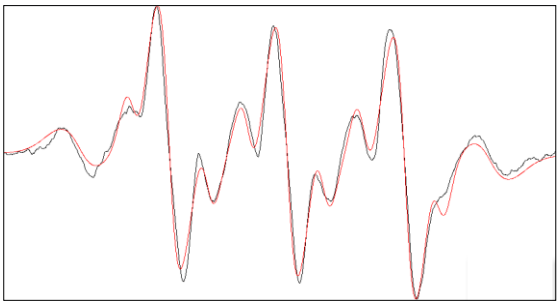

Figure 3 displays the experimental EPR spectrum (in black) together with a computer simulated spectrum (in red). The fitting was achieved with the following simulation parameters based on a mixture of three species: one oxygen-centred radical (5% of the total), with hyperfine couplings a_N=13.54 G and a_H=8.73 G, one carbon centred radical (~20%) with a_N=14.37 G and a_H=19.41 G and a decomposition spin-adduct (~75%) with a_N=13.85 G.

Our study demonstrates that it is possible to analyse free radicals by Electron Spin Resonance formed from the oxidation of α-pinene in a containerless environment with applications to studies of reaction mechanisms in atmospheric science and beyond.

Graphene, a 2-D nanomaterial with unique properties (Zhu et al, 2010) is an attractive optically transparent conductor for optoelectronic applications (Blake et al, 2008). Particularly, graphene thin coatings may be used as saturable absorbers, to develop ultrafast pulsed laser technology (Cho et al, 2011). Recently, Chu et al (2010) electrospray-deposited single walled carbon nanotubes, a close relative of graphene, for use as saturable absorbers in the 1.5 μm region, although they can also be used in the 2 μm emission range (Cho et al, 2009). Electrospray is a liquid atomization method that leads to highly charged, nearly monosized micro- and nano-droplets, which has been applied to create thin films and coatings (Jaworek, 2007; Modesto-Lopez & Biswas, 2010). The small droplet size combined with the low flow rate characteristic of electrospray may be ideal to control the film thickness. In addition, the electrostatic control implies a virtual 100 % deposition efficiency. To our knowledge, however, no reports exist yet on the use of electrospray for depositing graphene films.

Therefore, the purpose of this study is to characterize the deposition patterns of graphene onto flat substrates as a function of electrospray operating parameters and to identify conditions leading to layer-by-layer deposition.

Graphene oxide (GO) was synthesized by oxidizing graphite with potassium chlorate in an acidic medium. GO was filtered and washed several times with HCl and distilled water until reaching a neutral pH of the filtrate. Graphene was then prepared by reduction of GO with iron. The obtained graphene nanosheets were filtered and washed with distilled water and ethanol, and then dried at 100 ºC for over 12 h in vacuum. Figure 1a shows a SEM image of a multi-layered graphene particle. Each layer is formed by hundreds of graphene nanosheets, which cannot be observed by SEM. The nanosheets exfoliate individually when suspended in ethanol, as can be seen by TEM (Figure 1b). Graphene was also characterized by Raman spectroscopy and XRD (Figures 1c and d, respectively).

In the electrospray-deposition experiments, graphene nanosheet powder suspensions were prepared in dimethylformamide (DMF). The suspensions were stable over many hours, allowing for sufficient time to carry out depositions. Electrospray was performed solely in the cone-jet mode. Highly stable spraying was obtained at a liquid flow rate of 1 μL/min and applied voltage of 4.4 kV for suspensions of < 0.5 wt % (relative humidity 39 %, temperature 24 ºC).

Electrosprayed graphene nanosheets were collected onto quartz substrates, and their optical characteristics (including linear and nonlinear transmission, nonlinear response dynamics for saturable absorption, saturation fluences, modulation depths and nonsaturable losses) are studied as a function of electrospray-deposition time and initial suspension concentration.

Single-walled carbon nanotubes (SWCNT) have been widely explored in attempts to take advantage of their outstanding electronic, mechanical and optical properties for many applications, and extensive efforts have been made to develop various fabricating techniques to optimize the growth of SWCNTs. Aerosol chemical vapor deposition (CVD) approach, in particular, has potential for large scale SWCNT growth since it is a continuous process involving both catalyst particle formation and SWCNT growth. Recently, SWCNTs have been reported as excellent saturable absorbers used in solid state and fiber lasers because of their fast recovery time, low saturation intensity, large flexibility and environmental robustness. However, one bottleneck for their widespread applications is the limited control of diameter and chiral angle of the produced SWCNTs, and these physical variations lead to striking changes in their electronic and optical behaviors.

In this work, we report an effective and simple approach to address the above mentioned issue by producing SWCNTs on the surface of iron catalyst nanoparticles formed by decomposition of ferrocene vapor in CO atmosphere in the aerosol CVD reactor. The introduction of the controlled amount of CO_2 is found to be a key factor for the efficient, selective growth of SWCNTs using the aerosol method. Figure 1 shows the absorption spectra of the as-synthesized SWCNT thin film samples grown at different CO_2 concentrations. The intensity of absorption peaks from van Hove transitions of semiconducting and metallic SWCNTs are noticeably pronounced compared to the background absorption, indicating the high purity of the as-synthesized SWCNTs. Moreover, the absorption peaks steadily shift to longer wavelengths from 1450 to 2300 nm as the CO_2 concentration increases from 0.25 to 1.00%. This significant up-shift of absorption peaks implies the increase of SWCNT diameter with the CO_2 concentration. The diameter distributions of SWCNTs calculated based on optical absorption spectra are shown in Figure 1 (Tian *et al.*, 2010). A Gaussian fit shows that the mean diameter of SWCNT samples increases from 1.2 to 1.9 nm with the CO_2 concentration. The diameter distribution mainly ranging from 0.8 to 1.4 nm is obtained for the SWCNT samples synthesized at 0.24 and 0.50% CO_2 concentration. For the SWCNT samples collected at the concentration of 0.75 and 1.00%, the diameter distribution shift to larger diameter range of 1.2~2.0 nm. Increasing the diameter of SWCNTs with CO_2 concentration can be explained by the etching effects of CO_2. When CO_2 is present in the system, the CNT embryos of high curvature can be etched due to the inverse Boudouard reaction, consequently suppressing the growth of small diameter tubes (Tian *et al.*, 2011).

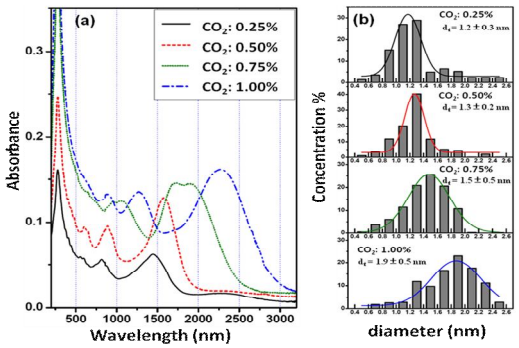

Figure 1. (a) The absorption spectra of SWCNT samples synthesized at 880 °C with different CO_2 concentrations. (b) The evaluated diameter distributions of SWCNT samples with different CO_2 concentrations based on absorption spectra.

This result opens up a route towards the diameter-controlled synthesis of SWCNTs. Using the simple dry-transfer technique, the as-deposited SWCNT films with desirable diameters are stamped onto the highly reflecting Ag-mirrors forming a saturable absorber mirror (SAM). The SAMs with deposited SWCNTs are ready for use without any additional purification and processing steps. Such as-deposited SWCNT thin films with optimized diameters show promising applications as saturable absorbers in mode-locked fiber lasers, due to the adequate control of their absorption properties which ensure the self-starting short-pulse operations. The effect of nanotube diameter distribution on nonlinear absorption characteristics and fiber laser mode-locking behaviour has been studied.

Aerosol-derived antimony doped-tin oxide nanoparticles and studies on the influence of organic and inorganic shells in nanoparticle assemblies on the overall conductance

Transparent conductive oxides are of high interest for transparent electrodes in solar cells or liquid displays and for infrared-reflecting applications. The most common material is indium doped tin oxide showing a high conductivity and transparence. Nevertheless a change to other doped tin or zinc oxides was driven in the last years by the low abundance of indium on earth.[1] Furthermore, the need to overcome the traditional vacuum deposition methods for more cost efficient and moreover even flexible devices, led to intensive investigation on nanoparticle film processing.

Good film forming behavior in nanoparticle deposition methods, as spin coating or dip coating, is based on highly stabilized dispersions, where normally surfactant molecules are added or a functionalization of the particles is necessary. The introduction of such impurities in the films, which cannot always be removed by heat post-treatment (flexible polymer substrates: temperature sensitive) mostly leads to an decrease in conductivity in the overall nanoparticle assembly.[2]

We therefore present the high temperature, aerosol synthesis of antimony doped tin oxide nanoparticles and a systematic study on the influence of organic and inorganic shells on the overall conductivity of assembled nanoparticles.[3] Flame spray synthesis was used as scalable and cost efficient process to produce high purity antimony doped tin oxide with a highly controlled dopant content.[4] The as-prepared particles were coated with three different organic surfactants using common dispersing processes. For comparison to well-known insulating shell thickness, additionally particles with in-situ coating of SiO_2 were produced.[5]

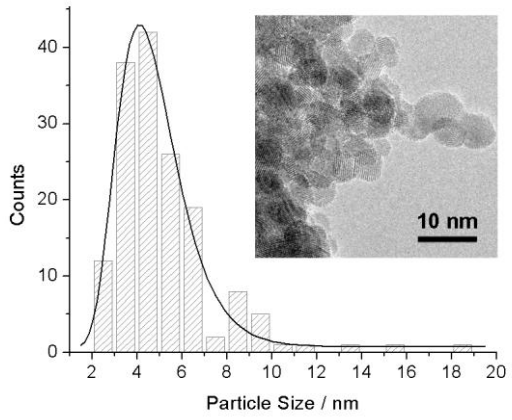

Figure 1. Antimony doped tin oxide nanoparticles produced by high temperature, aerosol flame spray synthesis.

The electron transport through the nanocomposites was tested for both organic and inorganic shell materials by measuring the electrical resistivity of pressed pills. Pure conducting nanoparticles, thin organic shells as well as thin, probably only partially coated SiO_2 shells showed a clear decrease in resistivity under pressure load due to irreversible compaction of the powder. However, thick polymer shells showed a relaxation of the resistivity when the pressure was decreased. For insulating SiO_2 shells of similar thickness the same reversible behavior in resistivity was observed and we could therefore describe this effect by electron tunneling through the insulating shell. The compression of the shell led to a decrease in thickness and therefore a higher electron tunneling probability.[6]

These findings on the influence of impurities such as surfactants or processing aids on the electron transport in assembled nanoparticle systems are important for improving the production of low cost, high performance electronics.

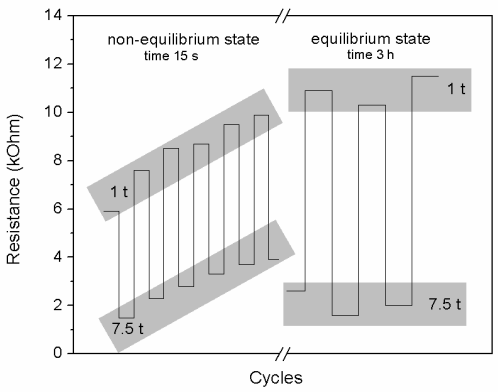

Figure 2. Reversible resistivity of polymer coated antimony doped tin oxide nanoparticle due to electron tunnelling probability changes under pressure cycles.

Introduction

Platinum on metal oxide support is a widely used catalyst in chemical synthesis and environmental technology. The dependency of activity and selectivity on surface structure and modification of catalysts is a research topic of growing interest. Continuous chemical vapour synthesis (CVS) of gas-borne support particles combined with chemical vapour deposition (CVD) of noble metal dots gives ordered, defined nanocatalysts with high surface area. Previous investigations show narrowly distributed, highly dispersed palladium nanoparticles with median sizes between 3 and 9 nm on SiO_2 (figure 1) produced by the CVS/CVD process at atmospheric pressure (Binder *et al.*, 2010). In this study Pt nanoparticles are deposited on spherical SiO_2 substrates by metal organic chemical vapour deposition (MOCVD) using commercial and newly synthesized precursors. The surface chemistry of the support particles has a great influence on the Pt deposition. It is proposed that the Pt precursor interacts with the surface hydroxyl group (OH) of SiO_2 and decomposes to form Pt on the surface (Xue *et al.*, 1992). Afterwards autocatalysis takes place on local Pt clusters and catalyses nucleation and deposition. Thereby platinum acts as a hydrogenation catalyst on the surface during the deposition mechanism (Kumar *et al.*, 1989). We propose that the precursor formulation is the decisive factor for controlled and highly dispersed Pt dot concentration on the support.

Experimental

For support particle production alkoxide tetra-ethylorthosilicate ($Si(OC_2H_5)_4$,TEOS) is evaporated at 60 °C and mixed with oxygen and nitrogen. Subsequently spherical SiO_2 nanoparticles with mean particle size of about 80 nm are generated by homogeneous nucleation, followed by sintering at 1500 °C. Commercially available Methylcyclopentadienyl-(trimethyl)Platinum(IV) ($MeCpPtMe_3$) or three synthesized organometallic precursors are sublimated at 100 °C. Directly in the aerosol, Pt is deposited on SiO_2 support particle surface in CVD reactor at 380 °C and atmospheric pressure. Afterwards nanoparticles are characterized by SMPS measurement and TEM images.

Results and discussion

According to TEM images (figure 2) the difference between Pt particles deposited on SiO_2 using the commercial precursor $MeCpPtMe_3$ and using newly synthesized precursors are significant. In contrast to the particles produced by the commercial precursor, the Pt dots are homogeneously dispersed with narrow size distributions between 2 and 4 nm. Our observations show that the suitable stability of the new precursors under vaporization and the adequate decomposition under CVD conditions play an important role in the synthesis of these well-structured Pt catalysts.

Different hybrid and single-phase nanoparticles by aerosol-photopolymerization

Polymeric hybrid nanomaterials containing inorganic nanoparticles find a variety of applications in optical, magnetic and electronic components as, for example, UV-protecting transparent polymers and magneto-optical storage elements. Depending on the inorganic and organic materials, the polymer matrix could serve as the low-cost printing agent onto a surface for the inorganic content to fulfill its function within such multifunctional nanocomposites (Althues *et al*, 2007). Such nanomaterials are also used in nanomedicine. In drug delivery, for instance, they can be used as carrier vehicles (Shi *et al*, 2010).

Different methods are available to produce nanoscale polymer particles or polymeric hybrid structures. Among wet methods, the mini-emulsion polymerization is a widely used technique. Based on particle generation methods in aerosols, Esen and Schweiger (1996) and Gao *et al* (2007) performed photopolymerization for the generation of spherical microscale polymer particles. These authors used multiacrylate mixtures as monomer solutions and finally obtained low-concentrated particles in aerosols. In our work, we demonstrate the aerosol-photopolymerization not only for the production of concentrated and spherical nanoscale polymer particles, but also for hybrid particles. There are many advantages of photoinitiated polymerization in aerosols compared to other methods. The polymerization reactions in each single monomer droplet can be started instantaneously due to photoinitiation via UV irradiation. Furthermore, the initiation rate can be adjusted by the photoinitiator concentration in monomer solution and by UV photon flux. In comparison to wet methods, there is no need of surfactant addition in the aerosol process, which results in higher product purity. Additionally, photochemistry allows a continuous experimental set-up.

Main components of the set-up are an aerosol generator and an in-house constructed flow-through photoreactor. The aerosol generator, which is an atomizer, produces nitrogen-carried submicron monomer droplets from the monomer solution containing at least one monomer type and photoinitiator. Additives like cross-linker or inorganic nanoparticles can also be added into the monomer solution. The produced droplet aerosol is passed through the photoreactor, where polymeric particles are formed from nanoscale droplets by UV-initiated free radical polymerization. Irradiation in the photoreactor starts the polymerization reactions in each single monomer droplet, which in turn leads to the formation of solid polymers. For characterization, the produced particles in the aerosol leaving the photoreactor may be collected on a filter membrane, on a TEM grid, or transferred into a liquid phase.

The resulting particles were characterized by Fourier Transform Infrared Spectrometry with an attenuated total reflection unit (FTIR-ATR), Scanning Mobility Particle Sizer (SMPS), Transmission Electron Microscopy (TEM), Scanning Electron Microscopy (SEM), and Gel Permeation Chromatography (GPC). In addition, simulation has been performed to support the experimental results and to illustrate the power of photoinitiated polymerization for homopolymer and organic-inorganic hybrid nanostructure synthesis.

Figure 1 shows on the left side a SEM picture of on purpose agglomerated single-phase spherical nanopolymers. On the right side, a TEM picture of a hybrid nanoparticle can be seen. In this type of hybrid nanoparticles, where the inorganic nanoparticles are distributed in the polymer matrix, the concentration of the inorganic phase can be varied broadly ranging from 0.5 to 20 mass percent.

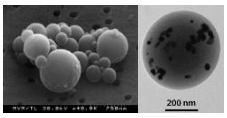

Figure 1. On left: spherical single-phase particles; on right: a spherical hybrid particle composed of organic and inorganic phases.

Other types of hybrid nanoparticles are generated as well and will be demonstrated.

Continuous, electrostatic controlled synthesis of organic-inorganic composite particles

S. Sigmund[1], E. Akgün[2], J. Meyer[1], M. Wörner[2], W. Gerlinger[3] and G. Kasper[1]

[1]Institute of Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology, 76131 Karlsruhe, Germany

Presenting author email: stephanie.sigmund@kit.edu

An electrostatic controlled process will be described to generate organic-inorganic composite particles, consisting of an inorganic core, and a polymeric shell. Depending on the respective application, either a porous or a closed shell is desired.

Mostly, a polymeric shell serves as protection for core particles. This protection can keep the core particle from changing its chemical conditions, for example from oxidizing. A polymeric shell can ensure defined spacing between the core particles. Other applications of organic-inorganic composite materials can be found in medicine. A modified organic shell is applied for specific transport of the core material into cells, where it is used either for diagnostics, or therapy. But there are other applications as well. The shell affords the printability of every desired core material on a surface, which can serve as a low cost manufacturing method of semi-conductor technology. Therefore a polymeric shell turns the core particle into a versatile applicable and processable product while preserving its characteristics.

The coating process which we use is an electrostatic controlled process. The core material is charged, while the coating material is charged with inverse polarity. The attractive forces between negative and positive charges cause an increase in coagulation rate, compared to diffusive coagulation, which has been described by Zebel (1959). Additionally, repulsive forces between unipolar charges decrease coagulation rate of two coating particles, or two core particles, respectively. This effect of selective coagulation, controlled by surface charges is capitalized for the generation of composite particles. The method of charge supported agglomeration has been used before (Maisels et al. 2000) to generate particle doublets, but not to generate a core-shell structure. The charge controlled coating process is a purely physical process and thus independent of the core and the coating material. The coating thickness is conditioned by the amount of polymer material. The charges on the core particles surface locate themselves homogeneously due to repulsive forces and this leads to homogeneous allocation of the polymer material onto the core particle. The generation of composite particles in liquid phase has been investigated by Nabih et al. (2011) but a liquid phase process cannot provide the product pureness, process control and short time scales an integrated gas phase process does.

For our experiments a model system of SiO_2 core particles and polystyrene coating particles is used. The spherical, monodisperse core particles are 250 nm in size. An aqueous suspension of core particles is atomized and the water is removed by a diffusion-dryer. Afterwards the core particles are charged by a corona charger. Every core particle carries several ten positive elementary charges after leaving the charging system. The polymer particles, used to form a porous shell around the core particle, are also suspended in water and dispersed into air. These spherical polystyrene particles of 34 nm in diameter get charged negatively by passing a second corona charging system. Subsequently, charged core particles and charged coating particles are mixed and passed through a variable residence time volume ensuring selective coagulation. The attachment of negative polymer particles to the positive silica surface leads to equalization of positive charges. While using a mobility scan via SMPS for monitoring the number of positive elementary charges per core particle, one can follow the coating process progress. After the completion of surface coating several analyses were done. Samples were taken for control of coating thickness and structure via electron microscopy. Results from offline analysis were compared to those from online coating thickness measurements by SMPS.

Also presented will be a modified process to generate a continuous polymer shell of variable thickness around a core particle. This process cannot be described yet due to patent law reasons.

Presenting author email: peter@snu.ac.kr

We report a novel type of MgO nanoparticles that we named “geometrical” smoke which appeared to be a room-temperature ultraviolet nanophosphor.

Unlike usual MgO nanocubes that are generated during a Mg metal particle self-burning in air “geometrical” smoke is characterised by an abundance of pure spherical and terraced nanoparticles yet preserving the perfect cubic lattice of MgO. The generation of “geometrical” smoke follows the violent burning of Mg powder assisted by oxy-hydrogen flame Yang *et al* (2010) or by applying a cw CO2 laser to the self burning Mg particle. The dramatic intensification of the combustion process leads to switching to another nanoparticle growth mechanism leading not only to spherical shapes of MgO nanoparticles but also to creation of new types of structural defects in “geometrical” smoke.

These novel di-vacancy defects named P-centers may appear in the perfect cubic MgO structure when a whole MgO molecule is omitted. The P-center looks formally as a close pair of other well-known defects F (oxygen vacancy) and V (Mg vacancy) centers both of which are optically active in MgO Gibson *et al* (1994). We performed cathodoluminescence (CL) measurements and interpreted two strongly correlated bands (at ultraviolet (UV) 260 nm and at 490 nm) shown in Fig. 1 as the optical response from the P-center. For ordinary MgO smoke the cathodoluminescence revealed only the band from F^+ centers at 420 nm depicted in Fig. 2.

Finding room temperature strong UV in pure MgO looks unusual as far as all UV bands found above 5 eV and at low temperatures previously were due to impurities like Al, Si etc. Kalder *et al* (1976). Yet in our case we found no correlation with the impurity levels as far as the same low level of impurities existed in both UV and non-UV emitting samples.

We also checked the robustness of the P-centers by treating the powder with immersing in water, with hydrogen plasma and outgassing at high temperatures only to find out that the UV activity remained intact.

As far as such a well-distinguished UV CL makes it possible to indicate the “violent” history of the nanoparticle generation we foresee possible applications of the reported phenomenon in geosciences, planetology and astrophysics. Other application for nanooptics are possible as well.

Presenting author email: muelhopt@kit.edu

Background:

QNano is a European Union-funded infrastructure for nanomaterial safety testing. This four year project which has begun in February 2011 comprises 27 top European analytical and experimental facilities in nanotechnology, medicine and natural sciences. It aims to create an integrated hub to support Europe's nanosafety research community. It also covers research themes about nanoparticle production and characterization. In WP 5 one aspect is to define the sources for batch-to-batch-variability of nanoparticles within one production route.

Material and Methods:

Particle production:

The only variable is the amount of aqueous ammonia present in the system which was used to determine resultant particle size. To a defined amount of aqueous ammonia (28%) in a polypropylene container was added EtOH (99.9%) to a volume of 50 ml and stirred at 25^{0}C (for SilNP007 and SilNP009) or 55^{0}C (for SilNP008 and SilNP010) and 600 r.p.m on a plate stirrer. To this rapidly stirring solution was then added Tetraethylorthosilicate (TEOS) (1670 µl) in one aliquot. The solution was then sealed under N_2 and stirred for a further 20 hours at 25^{0}C. The resulting nanoparticle suspension was divided in fractions and centrifuged down at 14,000 rpm for 20 minutes with the pellet then resuspended in fresh ethanol aided by bath sonication. This washing procedure was repeated twice more with ethanol followed by 3 pure water washes and a final resuspension in pure water to a concentration of 10 mg/ml.

Size Measurements

The silica nanoparticles were size characterized by different methods: in suspension by dynamic light scattering with a Malvern Zetasizer Nano ZS and for comparison it was aerosolized by electrospray (Model 3480, TSI, USA) and measured with SMPS (Model 3934, TSI, USA) in the range of 7 – 350 nm.

Results:

The analysis shows a very similar behaviour but depending on method and suspension medium there is a difference in number mean size of about 10 nm. The batches SilNP007 and SilNP009 show a modal value at about 43 nm by DLS (Table 1) but 50 and 53 nm in the SMPS measurements in aerosol phase (Figure 1). The batches SilNP008 and SilNP010 were determined to be 20 nm in liquid suspension and 33 nm in the gas phase.

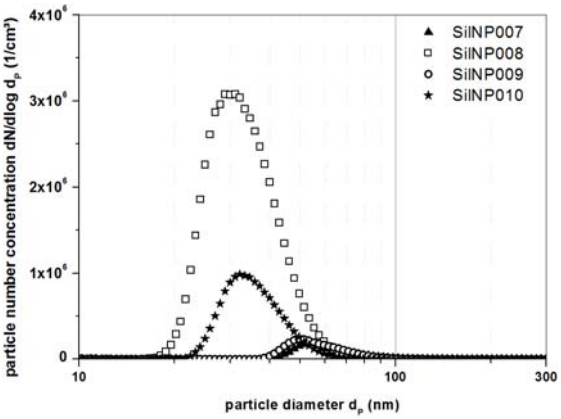

Figure 1. SMPS measurements of the 4 batches SilNP007 – SilNP010 of Stöber synthesized silica suspended in air by electrospray.

Table 1. Comparison between different methods of size measurements. DLS: number mean in nm. SMPS: Modal diameter of number size distribution in nm.

	DLS	SMPS
SilNP007	43	53
SilNP008	20	33
SilNP009	44	50
SilNP010	21	33

Ion Beam Analysis (IBA) techniques are very suitable for non-destructive characterization of atmospheric particulate matter. The most used for this purpose is Particle Induced X-ray Emission (PIXE) thanks to its ability to detect a wide range of elements (Z>10) simultaneously with higher sensitivity than other IBA techniques. Nevertheless, the determination of light elements content, as C, N, O and H, is of crucial interest, as these elements constitute a big amount of the aerosol composition. These elements are not detectable by PIXE because of the self-absorption of their characteristic X-rays in the sample itself and in the detector window. A method has been developed to measure light elements in aerosol particulate matter collected on Teflon (CF_2) filters by Elastic Backscattering Analysis (EBS) and Particle Elastic Scattering Techniques (PESA) with proton beams (Chiari, 2004, Chiari, 2005). Quantitative results have been obtained for these light elements with very satisfactory accuracies for C, and some less for O and especially for N.

In this work, Nuclear Reaction Analysis (NRA) has been used as an alternative IBA technique for N determination in aerosol samples collected on Teflon, namely exploiting the reactions $^{14}N(d,\alpha_0)^{12}C$ and $^{14}N(d,\alpha_1)^{12}C$. The high Q-values of these reactions avoid the interferences between the reaction products and the backscattered beam particles. NRA measurements have been performed at the 3 MV Pelletron accelerator of the CNA in Seville on a set of PM10 and PM2.5 samples with beams of deuterium of 1.9 MeV energy and a detection angle θ = 150º, which corresponded to the optimal measurement conditions. As can be seen in Figure 1, the signal peak from the $^{14}N(d,\alpha_0)^{12}C$ reaction appears in a background-free region of the spectrum thus allowing Nitrogen determination without interferences from filter or other aerosol components. Absolute N concentrations were obtained by normalization to thin reference standards containing known areal density of Nitrogen, with an overall uncertainty of about 4-8%. Typical minimum detection limit (MDL) for N is 0.1 μg/cm^2, corresponding to 0.02 μg/m^3 considering a 47 mm diameter Teflon filter and sampling for 24 hours at 2.3 m^3/h (EN12341 European standard).

The samples have been analysed also by EBS at the 3 MV Tandetron accelerator of the LABEC laboratory of INFN in Florence, using proton beams of 3.6 MeV energy and a scattering angle of 150°. The total N content obtained by the different IBA techniques is comparable, nevertheless EBS provides about 20% more Nitrogen concentration than NRA.

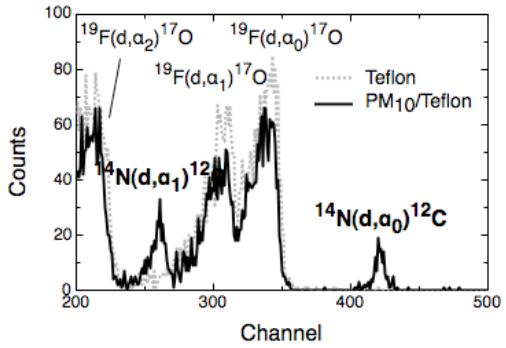

Figure 1. Comparison of NRA spectra of blank and loaded (PM10) Teflon filters obtained with 1.9 MeV deuterons.

Ion Chromatography measurements have been performed on a portion of the same samples for the determination of ammonium (NH_4^+) and nitrates (NO_3^-). Then the organic component of Nitrogen can be obtained from the total N concentrations measured by NRA as the amount in excess of "ammonium N" and "nitrate N", being in our situation negligible the contribution from nitrites. In PM10 samples "organic N" resulted about 40% of total Nitrogen, while this fraction decreased to about 25% for PM2.5 samples.

This work has been supported by INFN (NUMEN project) and by the Spanish Ministry of Education and Science (MEC).

Presenting author email: patrik.nilsson@design.lth.se

The production of materials containing engineered nanoparticles (ENPs) is a rapidly growing industry and emissions of such particles can occur any time during the materials lifetime.

The aim with this work was to utilize and to explore the potential of the Aerodyne Laser Vaporizer Aerosol Mass Spectrometer (LV-AMS) as a tool to investigate and characterize exposure levels of metal ENPs. In contrast to the regular AMS technique, that uses a heated plate (600 ^{o}C) for vaporization of the sampled particles, the LV-AMS has an Nd-YAG laser (λ = 1064 nm) installed in the vaporization zone (Onasch, 2012). This vaporisation technique is selective for absorbing particles, e.g. black carbon and metals. Vaporized molecules are then ionised using electron ionization (70 eV) and detected in a high resolution time of flight mass spectrometer.

Two methods for production of metal ENPs were used in a clean room laboratory, a spark discharge generator (SDG) and a high temperature furnace (HT). For particle size selection a tandem-DMA set-up was used with intermediary sintering furnace. The LV-AMS was used in parallel with an electrometer and a CPC to measure directly on the particles formed by the generators. One type of particles was generated at a time and the generated metals were Au, Ag, Pd, PdAg, FeO and CuO.

Emission measurements were performed in the ambient air during the cleaning of the generators. The sampling point for the LV-AMS and a photometer sensor (Dusttrak, TSI Inc.) was located a few centimeters away from the expected emission zone.

The vacuum aerodynamic diameter (d_{va}), given by the AMS, can together with the mobility diameter (d_m) be used to calculate effective densities as:

$$\rho_{eff} = \frac{d_{va}}{d_m}\rho_o \qquad (1)$$

Information on particle effective density is crucial when particle mass is to be determined from number concentrations. Often, for instance during dose estimations in exposure studies, a unit density has to be assumed which may induce significant errors. For Au particles the effective densities from the LV-AMS could be compared to values obtained with a DMA-Aerosol Particle Mass Analyzer (DMA-APM).

It was deduced that all the generated metals, except CuO, could be vaporized by the laser and detected in the mass spectrometer. The calculated mass based relative ionization efficiency (Onasch, 2012) were similar (0.01-0.02) for all detected compounds.

In figure 1 LV-AMS and Dusttrak times series, obtained during the cleaning process of the generator setup, are presented. Only the Au (m/z 197) and one Fe (m/z 56) isotope signal is shown. Each detected metal showed a unique time series.

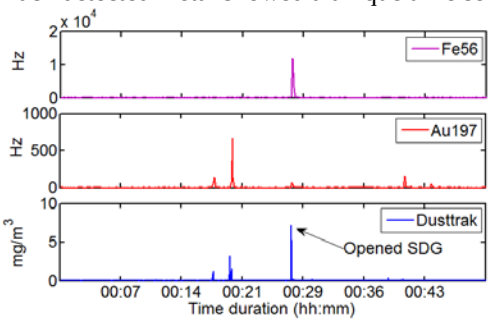

Figure 1. Time series of Au and Fe signal and Dusttrak during cleaning of the generator setup

The effective densities for Au agglomerates, determined by DMA-LVAMS, showed the same trend as those determined with DMA-APM, with slightly lower values from the DMA-LVAMS.

Table 1. Effective densities for Au agglomerates

d_m (nm)	DMA-LVAMS (g/cm^3)	DMA-APM (g/cm^3)
60	1.8	2.4
100	1.3	1.5

The LV-AMS is a promising tool for highly time-resolved studies of airborne exposures to engineered metal nanoparticles.

Keywords: aerosol size distribution, epiphaniometer, surface area, spark source
gini@ipta.demokritos.gr

It has been generally accepted that the physical properties of engineered nanoparticles can be important with respect to the industrial usage of these particles, the potential hazardous health effects when inhaled and their fate when they are released in the environment. The objective of this work was to demonstrate results of a novel technique regarding size and surface area characterization of generated nanoparticles by spark generation.

Nanoparticles synthesis by spark discharge is based on the evaporation of the electrode material used to produce the spark, and the subsequent cooling of the vapor stream that initiates nucleation of the vapors to clusters and primary nanoparticles. Further coagulation of the primary nanoparticles can lead to particles of versatile size and shape. In this study Carbon nanoparticles (CNps) were generated by a Novel Spark Generator operating under a controlled spark mode providing modulated pulses of chosen frequency between the two graphite electrodes.

The characterization of the generated nanoparticles was performed by Scanning Mobility Particle Sizer spectrometry (SMPS). The surface area of the generated particles was measured in parallel by the SMPS described above and the Cascade Epiphaniometer (CEPI) (Gini et al., 2010) which measures the surface area for different size fractions. Further information on the shape and structure was also obtained by low voltage scanning electron microscopy (SEM).

The cascade epiphaniometer was thoroughly calibrated against mono- and poly-disperse aerosols of known properties. The results show that SMPS and CEPI size distributions in the case of spherical or almost spherical particles are in reasonable accord. The average root mean square deviation of the total surface area measured with the CEPI from the theoretically estimated total surface area was about 15%.

In fig.1a, the calculated surface area of the generated CNps from SMPS data assuming equivalent spheres of measured mobility diameter (d_m) is depicted. Another approach for idealized loose agglomerates was also adopted for calculating aggregate surface area from SMPS data, estimating the number of the primary particles that compose the aggregate of a given mobility diameter (Lall et al., 2004). The primary particles were spheres with a typical diameter between 18nm and 20nm, which was estimated from SEM micrographs. In fig.1b, the surface area size distribution from CEPI is shown. The size distribution of CEPI is a function of aerodynamic diameter (d_a) whereas the distribution from SMPS is a function of mobility diameter.

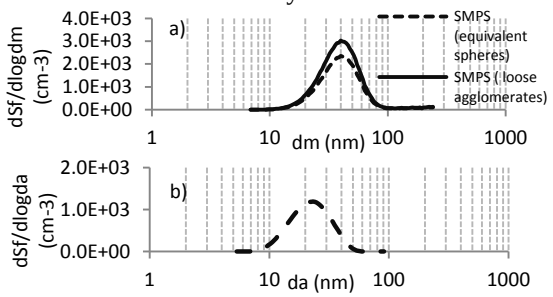

Fig.1. Surface area size distribution of CNps estimated from SMPS data (a) and measured with CEPI (b).

The results of the comparison between the calculated and the measured surface area demonstrate the importance of surface area measurements for non-spherical nanoparticles, since the calculated total surface area showed an overestimation, by a factor of 2, in relation to the measured one. This discrepancy cannot be explained by the uncertainty of the measurement. Fig.2. shows the estimated and the measured surface area as a function of the mobility diameter after accounting for the relationship between the particle mobility diameter and its aerodynamic diameter. The best fit value for the shape factor was 2.42.

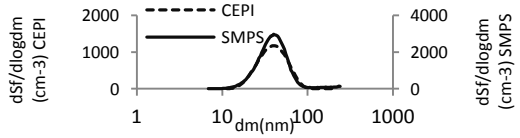

Fig.2. 'Fuchs' surface area distribution of CNps calculated from SMPS data and measured with the CEPI.

TwinPAS – a photoacoustic instrument for the parallel, time-resolved analysis of soot and NO_2 in exhaust gas

C. Haisch and R. Niessner

Chair for Analytical Chemistry, Technische Universität München, Marchioninistr. 17, 81377, Munich, Germany

Keywords: photoacoustic, NO_2, soot, Diesel exhaust.
Presenting author email: Christoph.Haisch@ch.tum.de

Photoacoustic (PA) spectroscopy earned its merits in aerosol analysis on many occasions. In automotive industry, a PA-based instrument is routinely to monitor the mass concentration of soot in exhaust gas. An extension of our PA soot sensor, which had been the basis of the commercial soot sensor, allows for parallel detection of NO_2 and soot.

The PA effect is the conversion of absorbed optical energy to thermal energy, which results in thermal expansion. This effect is well suitable for aerosol analysis, as it allows for an artefact-free absorption analysis in the presence of light scattering particles. The direct correlation between excitation light intensity, optical absorption, and the resulting PA signal makes it a very sensitive tool with a dynamic concentration range of several orders of magnitude and time resolution in the range of seconds.

Beyond soot, NO_2 is one of the major hazardous engine emissions. Parallel quantification of these two components is particularly relevant due to their anticyclical behaviour in modern exhaust aftertreatment systems. Up to now, there is no routine instrument allowing for the parallel detection of both compounds. Current instrumentation for NO_2 analysis in exhaust gas requires for the filtration of the sample gas before the sampling cell in order to avoid contamination by the soot. Adsorption and chemical reactions of the NO_2 on the soot loaded filter surface can inflict artefacts, particularly in the case of transient analyses.

Consequently, the new TwinPAS system allows for a parallel detection of both components without filtration. The core components of the system are two PA cells, one for soot detection and one for the quantification of NO_2. While soot is detected at a laser wavelength of 806 nm, NO_2 is monitored at 532 nm. Both wavelengths are generated by a single semiconductor laser source with an emission wavelength of 806 nm. The 532 nm radiation is generated by a set of non-linear optical crystals, thus making the system compact and limiting the costs.

For exhaust gas monitoring, heating of the whole sampling and analysis system is desirable in order to prevent condensation in the system. A special PA cell design has been developed, which is heated to 80 °C, while the sensitive microphones are kept at a temperature of 45 °C. To achieve high signal stability for a wide range of gas conditions, a low-Q acoustical resonator was designed which is a combination of a longitudinal and a Helmholtz-type resonator. The data recording rate is 5 Hz; however, the time resolution (10/90 rise and fall times) are in the range of a second. In order to increase temporal resolution, a special design of the gas flow system is required. On the one hand, high flow rates result in high gas exchange rates as required for high temporal resolution, on the other hand, high-velocity gas flows may generate significant flow noise, which is picked up by the PA microphone and thus limits the signal to noise ratio.

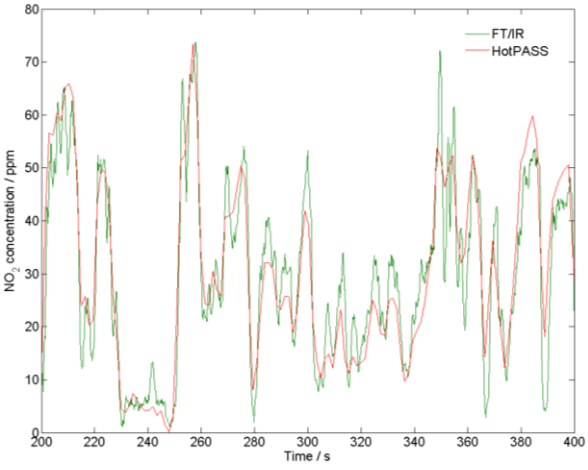

Figure 1.: NO_2 emissions of a typical driving cycle analysed by a FT/IR spectrometer and the TwinPAS system.

In the current configuration, the system features detection limits of 0.6 ppm for NO_2 and 1.2 µg m^3 for soot, determined by the common $6s_B$ criterion and on a 0.2 s time basis. A typical transient measurement is presented in Fig. 1, where the TwinPAS results are compared to the NO_2 concentrations determined by FT/IR. Further results, highlighting the key features of the new system will be presented. Future developments will be devoted to the extension to further gas components and to an improved tolerance to sample gas pressure and temperature fluctuations.

Investigation of Fast Scanning SMPS Measurements: 16s and Below

K. Erickson, F. Quant, J. Farnsworth and R. Caldow

TSI Incorporated, Shoreview, MN, 55126, USA
Keywords: SMPS, CPC, Particle Size
Presenting author email: kerickson@tsi.com

The concept introduced by Wang and Flagan (1990) of scanning the voltage in an electrical mobility based sizing instrument (SMPS) resulted in a dramatic improvement in the time resolution of the technique. Practically, moving from a voltage stepping approach to a scanning approach also increases size resolution above a minimum scan time. However, as would be expected, at some point shortening the voltage scan time will result in reduced resolution compared to the ideal resolution of the instrument defined by the DMA transfer function.

The reduced resolution is thought to be primarily a function of the response time of the CPC and the non-ideal flow laminarity between the DMA and the CPC. Now, two decades after Wang and Flagan's original work, CPCs are available which have significantly faster response times and higher sample flow rates, opening the door to faster SMPS size measurements. Tubing lengths between the DMA and CPC have also been substantially reduced. We have investigated SMPS sizing scans at 16 seconds and below using a TDMA technique. CPCs used had varying response times and sample flow rates and are detailed in Table 1.

Table 1. CPCs used in fast scanning study.

Feature	3788 N-WCPC	3787 GP-WCPC	3776 UCPC
Sample Flow (LPM)	0.3	0.6	0.05
Sheath Flow (LPM)	0.3	N/A	0.25
Time Constant τ_s (s)	0.043	0.13	0.069
Working Fluid	H_2O	H_2O	C_4H_9OH

Russell et al 1995 investigated resolution limitations to fast scanning and determined that the transfer function widened with increasing time constant (τ_s) and decreasing scan time (τ_r).

Table 2. Theoretical lower limit for scan time. τ_s/τ_r ratio >0.1 corresponds with decreased resolution.

Scan Time (s)	3788 τ_s/τ_r	3787 τ_s/τ_r	3776 τ_s/τ_r
1	0.297	0.896	0.476
2	0.145	0.440	0.233
3	0.098	0.297	0.157
5	0.059	0.178	0.094
7	0.042	0.128	0.068
10	0.029	0.088	0.047
30	0.010	0.030	0.016

The CPC response time to a step function change in concentration can be described by an exponential function. The time constant (τ_s) is the denominator of the natural logarithm exponent. The exponential voltage ramp used in scanning mobility measurements can be described with a time constant of (τ_r). It was noted that if the ratio of τ_s to τ_r was less than 0.1, that the rise of the transfer function of the scanning system was nearly as sharp as the ideal transfer function of the DMA. Table 2 details the τ_s/τ_r ratios for the scan times and CPC used in this study.

The effect of scan time on SMPS resolution was measured for a variety of scan times using monodisperse and polydisperse aerosol. Experimental conditions and results will be discussed.

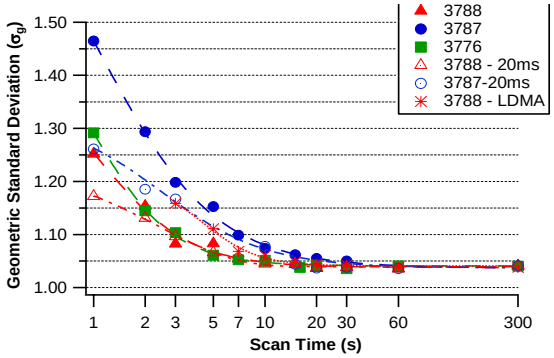

Figure 1. Geometric standard deviation (σ_g) of the size distribution of DMA classified aerosol measured using a variety of scan times. As scan time decreases, the monodisperse peak widens.

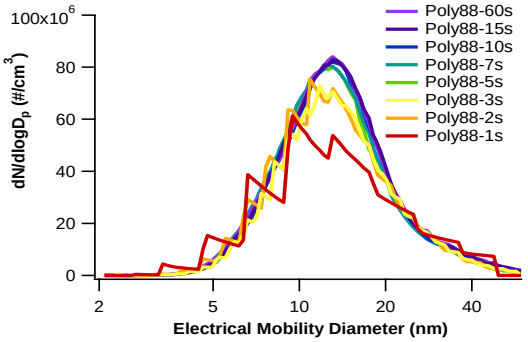

Figure 2. Polydisperse silver aerosol taken using a 3788 N-WCPC. As shown, little difference is seen in polydisperse size distributions as a function of scan time. Below 3 seconds, data reporting rate became a limiting factor even though a 20ms data reporting rate was used.

New portable device for high time resolved measurements of particle size distributions

Hans Grimm[1], Daniel Huhn[1], M. Pesch[1], M. Richter[1] and Friedhelm Schneider[1]

[1]Grimm Aerosol Technik GmbH & Co. KG, 83404 Ainring, Germany
Keywords: aerosol instruments, Nano particles, particle size distributions, work place measurements
Presenting author email: mp@grimm-aerosol.com

Measurements of particle size distributions for Nano particles and particles in the µ-meter size range generally requires a combination of separate devices as SMPS and optical particle counters (OPC) or aerodynamic particle sizers (APS). The company GRIMM developed in the frame of the EU founded Project NANODEVICE a new compact and portable (pre)-prototype that consists of an optical and electrical sensor in one device. It allows a wide range of particle size detection between approx. 10 nm and 20 µm in over 30 size channels with a time resolution of only 1 minute for one complete scan. Thus very short-lived as well as highly time-varying particle sources can be examined. Figure 1: shows the new prototype.

Figure 1: New prototype for particle size distributions

The measured values of the two sensors are combined internally by special electronics and firmware, such that the user receives measurements, which do not differ from the output of a single sensor in the nature and structure. The calculation of the derived measurands as particle surfaces and particle volumes is done online and the output as data telegram is send via the interfaces Bluetooth or RS232. A special control software was developed, which allows full operation with a small Netbook. Figure 2 shows a typical measurement example.

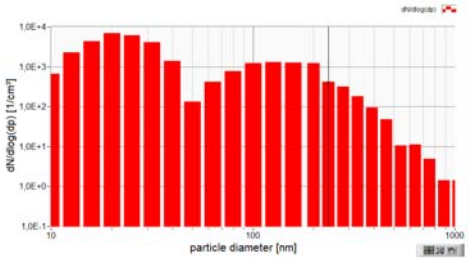

Figure 2: Measurement example

The optical module is a newly designed particle spectrometer, which detects each individual particle and classifies its size accordingly (single particle counting). A powerful laser diode is used as light source. An internal monitor diode monitors the power of the laser diode and keeps it constant. A pin diode generates the detection signal, which turned out to be the best compromise between reliability and performance. The number of particles is determined by the number of stray light pulses per period, the particle size determines the amplitude of the scattered light. These measurements require a precisely controlled flow rate which is determined continuously via aperture and pressure sensors.

The electrical module consists of three main components, the unipolar corona charger, a precipitation electrode and a Faraday Cup Electrometer (FCE). Once the aerosol particles (each single particle) are counted by the optical sensor and classified, they pass a short tube connected directly to the electrical sensor. Here all Nanoparticles can be detected reliably. Initially the particles are charged unipolar (negatively) in the electric sensor with a negative corona charge. Then the particles enter a collecting electrode, where they are separated according to their electrical mobility. A portion of the aerosol stream passes through the collecting electrode and is recorded in the Faraday Cup Electrometer (FCE). Based on the current measured at the FCE, the volume flow, the geometry of the sensor and the charge efficiency of the particles, the size of the particles can be determined. The electrical sensor offers the possibility to determine the number of particles in each size distribution of particles similar to the optical sensor: A change of the electrode voltage in 10 steps classifies the particle size between 10 nm to approximately 300 nm in 10 classes.

When measuring particles, humidity plays an important role. On the one hand, increased air humidity leads to a swelling of particles, which alters their diameter, on the other hand charges of particles change with air humidity. In addition, the determination of currents with an FCE is very sensitive to moisture and cause changes in the offset. To ensure reliable operation at varying humidity levels and to permit very high humidity (up to 90%), an internal drying cycle was designed. The FCE is continuously purged with dry air, dried by dint of a cartridge filled with silica gel.

The calibration and validation is based on parallel SMPS measurements with latex particles of different sizes.

Experimental aerosol characterization for the evaluation of source term from RDE's (Radiological Dispersion Events)

F.G. Di Lemma[1, 2], J.Y. Colle[2], H. Thiele[2] and R.J.M. Konings[1, 2]

In the recent years, following the 9/11 terrorist attack in the U.S., an increased focus has been posed on the threat of malicious attacks involving radioactive materials. In view of this, evaluation of the source term related to RDE's and especially to the detonation of "dirty bombs" has become relevant. The descriptions of the aerosols formed during these events (both in dimension and chemical composition) are the input for modelling studies to "quantify respirable hazards, the associated radiological risk assessments and vulnerability assessments" (Molecke *et al.* (2006)). Dedicated experiments in this field could also reduce the uncertainties on the source terms applied in software codes (e.g. HOTSPOT), which assess the extension of the contaminated area after a radioactive fallout.

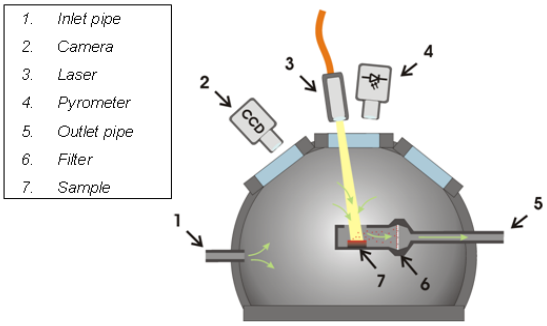

Figure 1. A scheme of the experimental set-up.

A new experimental set-up was created for these purposes. The laser heating pulse technique was applied for the first time to simulate RDE's. Different samples which could simulate widely used radioactive material are tested, in their no-radioactive form (CsCl, Co, ZrO_2 and ZrO_2 with simulated fission products). ZrO_2 was selected as a ceramic material to simulate UO_2. Samples were heated through a focused Nd-YAG laser beam. The laser can be controlled in a very flexible way, applying pulse from ms to minutes and power from 0 W to several kW, thus producing a broad variety of thermal transients. The sample surface temperature was measured by a 650 nm pyrometer. The set-up offers also the possibility to test different environments, and in our tests atmospheric conditions were established in order to assess the interaction between the aerosols and a real environment. The aerosols formed are collected by means of filters, to which they are transported by air flow created by a vacuum pump and pressurized air inlet. The filter are subsequently analysed by SEM and EDX.

From the first tests two types of aerosols were generally collected: spherical individual particles with a diameter >1 μm and "string" structures formed by particles in the range of 50-300 nm. The micrometer sized particles may be related to the ejection of liquid particles by mechanical process due to boiling. These spherical particles usually were present in a small fraction (0.1-1% of the covered filter surface). The nanometre sized particles instead may have formed by condensation processes from the vapour (Friedlander (2000)). These particles formed cluster structures, which could have been produced by agglomeration during the transport phase to the filter. Of particular interest were the doped ZrO_2 samples; the EDX analysis of the aerosols showed that low volatile elements (as Ba, Zr) were present in the bigger particles, while high volatile elements (Cs and I) were enriched in smaller aerosols. Through these last results on ZrO_2 the hypothesis on aerosol formation could be confirmed. Finally SEM analyses suggested that particles are mostly formed in the inhalable fraction (<10 μm), with potential health risk.

A relation between the thermo-physical properties of the samples and the aerosols is investigated. Experimental results suggest that the vapour pressure, surface tension and viscosity may be important parameters; these will be further studied with a wider class of materials.

Session WG01S3O. Remote Sensing of Aerosol Properties

Aerosol vertical distribution and its variability over Sweden during nighttime: A view from the CALIOP-CALIPSO and AIRS instruments

M.A. Thomas[1], A. Devasthale[1] and M. Kahnert[1,2]

[1]Swedish Meteorological and Hydrological Institute, Research Department, Norrköping, SE-60176, Sweden

Keywords: Atmospheric aerosols, Satellites, Vertical distribution
Presenting author email: manu.thomas@smhi.se

An accurate knowledge of aerosol properties is a key to understand its direct and indirect radiative effects. Especially the vertical distribution of aerosols determines the degree with which it would interact with clouds, influence air quality and the atmospheric heating profiles, among others. Most of the passive satellite imagers have difficulties in retrieving accurate aerosol properties over Sweden due to large solar zenith angles during most part of the year, snow and ice covered surfaces etc. CALIPSO offers a viable alternative to overcome this difficulty. It also has a distinct advantage of providing vertical structure and nighttime observations [1]. Furthermore, the orbital track of CALIPSO is aligned very well with the semi-major axis of Sweden's elongated topography during nighttime (Fig. 1), thus making it extremely appealing for generating statistics of aerosol properties. Here, we use 5 years of Aerosol 5km Layer product from CALIPSO and investigate statistics of aerosol properties. We further investigate the role of temperature inversions in influencing vertical distribution of aerosols.

For the present study we use the standard CALIPSO 5km Aerosol Layer Product (Version 3.01) [1], specifically the aerosol retrievals of aerosol layer base and top heights, and optical depth at the 532nm wavelength. A rigorous quality control is applied while selecting the data for analysis. For example, if a feature is classified as aerosol and the classification quality flag is set to "high", only then are the results used for the analysis. The aerosols are further categorized into six different types, based on their integrated attenuated backscatter and volume depolarization ratio along with ancillary information on surface type and altitude [2]. The six aerosol types analyzed are "clean continental", "polluted continental", "dust", "polluted dust", "clean marine", and "smoke".

The data used in the present study cover the period from June 2006 through May 2011 and is analyzed for four seasons separately, winter (December, January, and February; DJF), spring (March, April, and May; MAM), summer (June, July, and August; JJA), and autumn (September, October, and November; SON).

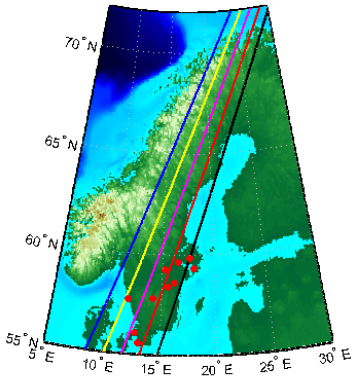

Fig. 1: CALIPSO track over Sweden during nighttime. The red dots show top 10 populated cities.

We investigate the seasonality of:

1) The vertical distribution of aerosols along five selected curtains over Sweden shown in Fig. 1.
2) Aerosol layer optical thickness.
3) Number of aerosol layers present.
4) Relative distribution of aerosol types.
5) Aerosol verticality with respect to temperature inversions derived from AIRS [3,4].

Between June 2006 and September 2009, an instrumented light aircraft (the NOAA Airborne Aerosol Observatory, AAO) measured over 400 vertical profiles of aerosol and trace gas properties over eastern and central Illinois. The primary objectives of this program were to 1) measure the *in situ* aerosol properties and determine their vertical and temporal variability and 2) compare these aircraft measurements with concurrent surface and satellite measurements. The satellite comparisons were accomplished by coordination of aircraft activities with A-Train satellite overflights. The satellite sensors require "air truth" *in situ* measurements to identify and constrain systematic errors in the retrievals of aerosol physical properties. Improvements in these algorithms will improve the quality of height dependent information from CALIPSO and other satellites that measure vertical aerosol profiles.

Aircraft profiles were conducted near the NOAA/ESRL surface aerosol monitoring station near Bondville, Illinois, with each profile location within 10 km of an A-Train satellite track. Of the 401 research profiles, 63 were conducted during an overpass of the CALIPSO satellite. Of these 63 profiles, CALIPSO was able to retrieve extinction in the nearest 35-km path of the satellite track for 28 cases. The aircraft sampled at 10 levels at each profile location, starting at an altitude of ~4.6 km above sea level (asl) and finishing at ~0.5 km asl. About half of the levels were conducted in the free troposphere (10 minute legs) while the remainder were flown in the boundary layer (5 minute legs). Flight times were chosen so that the aircraft was sampling in the boundary layer when the satellite passed overhead.

The primary aerosol optical property measurements made on the aircraft were the aerosol light scattering coefficient (σ_{sp}), the aerosol hemispheric backscattering coefficient (σ_{bsp}), and the aerosol light absorption coefficient (σ_{ap}). Each of these was made at three visible wavelengths. Measurements of the light scattering coefficient in the mid-visible at elevated relative humidity were made for determination of the aerosol hygroscopic growth factor. The primary measurements permitted calculation of the aerosol light extinction coefficient (σ_{ep}) at ambient conditions at 532 nm at each level, for direct comparison with the CALIPSO lidar extinction retrieval. Other optical properties calculated were the single scattering albedo, scattering and absorption Ångström exponents, hemispheric backscatter fraction, submicron scattering ratio, and aerosol radiative forcing efficiency.

Figure 1 shows the statistical comparison of all 28 collocated *in situ* (AAO) and satellite-derived (CALIPSO) extinction profiles. The comparisons suggest that CALIPSO tends to overestimate extinction in the boundary layer and underestimate it at higher altitudes. The overestimation of extinction at lower altitudes appears to be related to problems associated with cloud screening. Our *in situ* aerosol data suggest extinction thresholds for the likelihood of aerosol layers being detected by the CALIPSO sensor. In this study, 71% of the aerosol layers CALIPSO did not detect had aerosol extinction values <20 Mm^{-1}, and 95% of the undetected layers were <50 Mm^{-1}. These statistical data offer guidance as to the likelihood of CALIPSO's ability to measure aerosol extinction at various locations around the globe.

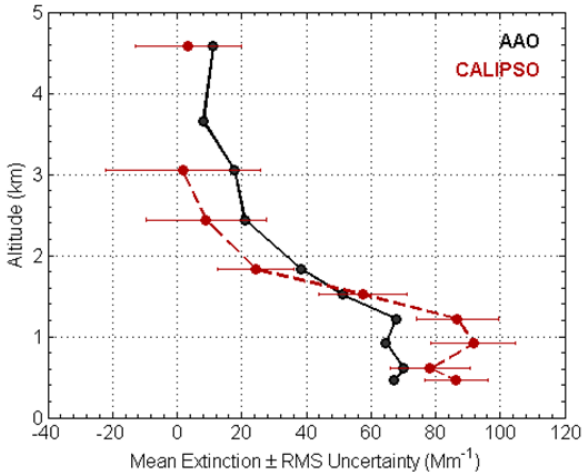

Figure 1. Median in situ and satellite-derived extinction profiles.

It is well known that aerosol particle effects play an important role in the radiative balance of the Earth-Atmosphere system. According to the forth assessment of the IPCC (Forster et al., 2007) there are still uncertainties in the role of atmospheric aerosols on climate change predictions. In this sense, one of the main objectives of the European project ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) is to improve the observations of the vertical aerosol distribution. Particularly, working package WP2 intends to define new aerosol parameters to improve its study, as the aerosol depolarization ratio.

CLIMARENO campaign was developed during June 2011 with the main objective of studying the Saharan dust impact on the Earth radiative forcing (J. Andrey et al., 2012; Guerrero-Rascado et al., 2012, submitted to this conference). Particularly, two flights were performed under non-dust (14th June) and dust (27th June) conditions over Granada (37.2ºN, 3.6ºW, 680 m a.s.l.) where ground-based instrumentations were deployed.

Two lidar systems were operating during CLIMARENO campaign. The multiwavelength Raman lidar (Raymetrics S.A.) is a system with detection of elastic signals at 1064, 355 and 532 nm (in parallel and perpendicular components) and three Raman signals at 607, 408 and 387 nm. The scanning Raman lidar (Raymetrics S.A.) allows for detecting elastic signals at 355 (in parallel and perpendicular components) and one Raman signal at 387 nm. The synergic use of both lidar allows dual aerosol depolarization ratio study. Column-integrated characterization of the atmospheric aerosol has been done by means of a sun-photometer CE-318-4 included in the AERONET network. Additionally, surface measurements have been obtained at the Granada station by means of an integrating nephelometer (TSI3563), a Multiangle Absorption Particle, (MAAP) and an Aerosol Particle Sizer (APS).

In this work, the aerosol optical properties obtained from ground based active and passive remote sensing and in-situ instrumentation are analyzed and compared with height-resolved information retrieved from airborne instrumentation. On 14th June fine and coarse modes present similar contributions (Fig.1 Top) and a lofted aerosol layer was detected around 5 km asl with backscattered-related Angström Exponent, $å_{\beta}$(355/532nm) around 1.7 Fig. 1(bottom). According to HYSPLIT backward trajectories analyses (http://wwww.arl.noaa.gov/ready/hysplit4.html) and MODIS Fire (http://firefly.geog.umd.edu/firemap/), this layer was a smoke layer originated in North America. On 27th June, coarse particle mode predominance (Fig.1 Top) and low $å_{\beta}$ (0.3, averaging range 2-4.5 km asl), (Fig.1 Bottom), showed up the dust conditions.

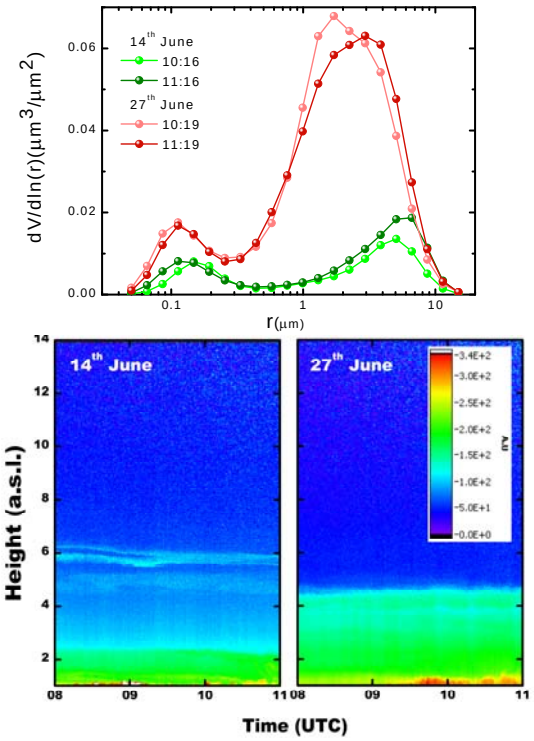

Figure 1. Top: Aerosol volume size distributions obtained during non-dust (green) and dust (red) events Bottom: temporal evolution of the range corrected signal

Tropospheric aerosols remote sensing with a sensitive and accurate UV-VIS polarization Lidar

G. David[1], B. Thomas[1], A. Miffre[1] and P. Rairoux[1]

[1]Laboratoire de Spectrométrie Ionique et Moléculaire, CNRS UMR 5579, Université Lyon 1, Villeurbanne, 69622, France

Keywords: tropospheric aerosols, polarization, optical properties: remote sensing.

Presenting author email: gdavid@lasim.univ-lyon1.fr

Tropospheric aerosol is a very complex mixture of particles having different sizes, shapes and chemical composition. In this paper, to study the tropospheric aerosols morphology, we built, optimized and used an UV-VIS polarization Lidar to remotely measure the tropospheric aerosols backscattering and polarization properties, under real atmospheric conditions of temperature and humidity. Our 2λ-polarization detector has been designed to detect very small changes in the tropospheric aerosols morphology, corresponding to a measured detection limit of 0.6 % for the aerosol depolarization ratios δ_a, comparable to the molecular depolarization. Hence, to our knowledge for the first time, the non-sphericity of tropospheric aerosols is addressed in the UV spectral range with a calibrated time-altitude map (while UV-molecular scattering is strong). Very small aerosols depolarization ratios are hence measured, enhancing the non-sphericity of these aerosols, which is new (David et al., 2012).

Our new and home-built 2λ-polarization Lidar detects tropospheric backscattered photons as a function of their wavelength (λ = 355, 532 nm) and their polarization ($\boldsymbol{\pi}$ = {//, ⊥} with respect to the laser linear polarization). UV-light has been chosen to increase our sensitivity to aerosols in the fine particle mode (Mishchenko et al., 2002), while VIS-light is more sensitive to coarse particles. Monitoring δ_a-values in the percent range requires sensitive and accurate polarization measurements. Hence, we carefully analyzed any possible system bias affecting δ_a: imperfect laser linear polarization, presence of possible polarization cross-talks, role of the dichroic beamsplitter used for the λ-separation, misalignment between the laser and the polarization axes. We hence specified each optical component separately, on a laboratory test-bench to achieve the best possible sensitivity and accuracy in the UV and the VIS. The measured polarization cross-talks were found to be fully negligible (below 10^{-7}). Moreover, by introducing controlled amounts of polarization cross-talks (Alvarez et al., 2006), we calibrated the 2λ-polarization Lidar experiment with better than 2% accuracy. Range averaging and high frequency noise filtering lead to a 75 m-altitude resolution.

Figure 1 displays the measured parallel and perpendicular tropospheric aerosols backscattering coefficient ($\beta_{a,//}$, $\beta_{a,\perp}$) and the aerosols depolarization ratio δ_a, in the form of UV, VIS time-altitude maps. To our knowledge, such a calibrated time-altitude map is new in the UV. The achieved sensitivity and accuracy allows distinguishing different layers having different polarization backscattering properties and revealing the presence of small non-spherical tropospheric aerosols.

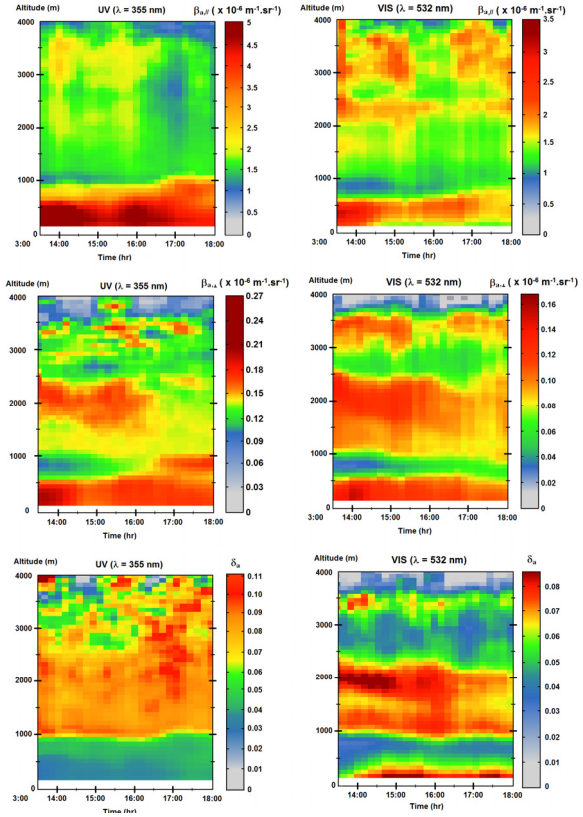

Figure 1. UV, VIS ($\beta_{a,//}$, $\beta_{a,\perp}$, δ_a) time-altitude maps for tropospheric aerosols on October 18th 2011 at Lyon.

The different behavior UV / VIS can be interpreted by considering the higher scattering efficiency of fine particles in the UV. Hence, fine and coarse particles are addressed in the PBL (where a smog episode is observed) and in the free troposphere (where expected sea-salt particles are observed). The presentation will explicit the achieved sensitivity and accuracy of our home-built 2λ-polarization Lidar and further detail the optical properties of tropospheric aerosols, derived from the above time-altitude maps. The methodology associated to this work is currently under review in Appl. Phys B (David et al., 2012).

Study on the influence of different error sources on sky radiance measurements and inversion-derived aerosol products in the frame of AERONET

The remote sensing of the atmospheric aerosol is a well-established technique that is currently used for routine monitoring of this atmospheric component, both ground-based and from satellite. The AERONET program, initiated in the 90's, is the most extended network and the data provided are currently used by a wide community for aerosol characterization, satellite and model validation and synergetic use with other instrumentation (lidar, in-situ, etc.). However there are still open questions and inconsistencies in the modeling of the aerosol optical properties. For example, there are known limitations in the inversion of sky radiances, especially related to the large uncertainty of the retrieved products from almucantar scans at low solar zenith angles (SZA) or at low aerosol optical thickness conditions. Another topic of especial interest is the analysis of desert dust, which is by far the most problematic aerosol type regarding the adequate modeling of optical properties. Within AERONET, sky radiances are acquired in two geometries: almucantar and principal plane. Principal plane inversions were provided together with the almucantar inversion products at the beginning of the AERONET version 2 direct Sun and inversion algorithm, released in 2006. However the principal plane retrievals were later removed from the AERONET database, keeping only almucantar retrievals considered more stable and reliable, although only at large solar zenith angles. Two problems arise from this situation: first, the monitoring of inversion-derived properties such as size distribution, refractive index and single scattering albedo, which are necessary for the evaluation of the aerosol, cannot be retrieved in the middle of the day. Second, there is a need to find out the reason for the inconsistency between principal plane and almucantar retrievals.

We have investigated to what extent the discrepancies can be a consequence of the measurement procedure. In particular, three systematic errors in the radiance observations were analyzed in order to quantify the effects on the inversion-derived aerosol properties: calibration, pointing accuracy and finite field of view. The aim of this work is to determine how each of the analyzed errors affects the aerosol retrievals in both geometries and try to provide criteria for quality assurance and product error estimations. For this purpose, sky radiances were simulated with the forward module of the Dubovik's algorithm using several aerosol types (desert dust, oceanic, urban and biomass burning), described by the volume size distribution and the complex refractive index. Then the systematic errors were induced and we applied the inversion module to the erroneous radiances in order to compare the retrieved aerosol properties with the original ones.

The results of the analysis show that only the pointing error can cause these discrepancies, since it affects more the principal plane than almucantar (less affected at least from the typical pointing errors considered: 0.2° y 0.4°).

On the other hand, self-consistency test demonstrated that, even for simulated measurements without error, aerosol retrievals at low SZA are distorted due to the lack of information of scattering angles larger than 2·SZA in the almucantar measurements. And what's more, the insertion of the calibration errors presents more influence on the retrievals at low SZA, therefore they can amplify the differences between retrievals at low and large SZA.

Finally we want to remark that most of the investigated errors are more relevant for the desert dust aerosol type: the coarse mode has the worst behaviour in the self-consistency test; the least sensitive to the inversion procedure; and the most affected by calibration errors. These facts, together with the particle non-sphericity, can explain why this aerosol type presents the largest complications in the retrieval of properties from sky radiances.

Carbonaceous material constitutes a major fraction of atmospheric aerosol, and is considered a significant parameter for global climatic change and for public health. Therefore, several studies have focused worldwide on the estimation of aerosol organic carbon (OC) and elemental (EC) or black carbon (BC) composition.

This study provides a first long term comparison of the estimated AERONET (AErosol RObotic NETwork) (Arola *et al* 2011) OC and BC concentrations with in-situ measurements in the southern Europe, in order to validate the particulate matter OC/BC composition from remote sensing techniques.

Multiyear surface PM_1 measurements performed on Crete Island and $PM_{2.5}$ performed on Athens, Greece, were compared to ground-based remote sensing measurements (AERONET FORTH-Crete and Athens-NOA station).

The quality assured (level 2.0) FORTH-Crete and Athens-NOA Aeronet data, were processed for columnar mass concentration of absorbing organic carbon and OC/BC ratio using the innovative retrieval procedures developed by Arola et al (2011). On Crete aerosol PM_1 fractions were collected from 2004 to 2011 at Finokalia station (35°32'N, 25°67'N; http://finokalia.chemistry.uoc.gr) and were analysed for OC and EC concentration according to the analytical procedure described by Theodosi et al 2010; while, PM2.5 were collected from 2008 to 2011 at Demokritos urban background station in Athens (GAW-DEM, 2007), by a Semi-Continuous OCEC Field Instrument (Sunset Laboratory Inc.).

The monthly mean seasonality of OC/BC ratio and the yearly seasonality of EC or BC concentration for Finokalia and for AERONET data is presented in Fig.1a, and 1b, respectively. The whole period average OC/EC ratio from in situ measurements was 12.26 compared to AERONET columnar OC/BC ratio found of 0.97. The difference could be attributed to that in our AERONET approach not all OC species are estimated as "organic carbon" but only those species that cause enhanced absorption at the shortest wavelengths.

The comparisons between AERONET data and in situ measurements suggested that for the majority of the study (sampling period 2004-2011) OC/BC ratio presented similar monthly seasonality while, the same similarity was observed concerning the yearly and monthly seasonality of OC and EC concentrations (not shown). The ground based measurements of OC/BC ratio and in situ OC/EC ratio were well correlated (R^2 0.33).

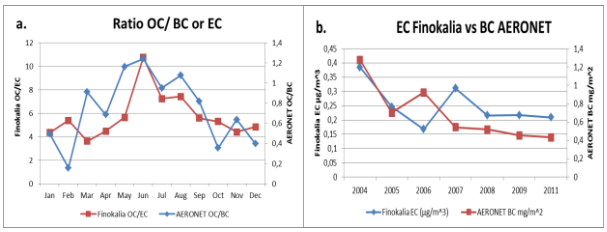

Figure 1 a. Monthly mean value of OC/EC or BC ratio and b. Yearly mean values of EC or BC concentration, for PM_1 collected fraction at Finokalia and for AERONET data, from 2004 to 2011.

All the aforementioned data indicate that for most of our sampling period, remote sensing data from AERONET could provide a reasonable estimation of the OC and BC seasonality at the ground level. We plan to extend this comparison to additional data from other southern European locations.

Satellite remote sensing with nadir scanning radiometer provides quantitative measurements of spectral Aerosol Optical Depth (AOD) from local to global scales (Kaufman et al., 2002). Monitoring and understanding the behavior of the atmospheric aerosols on local scales over complex urban terrain like Hong Kong requires aerosol retrieval algorithms that support high spatial resolution (Wong et al., 2010; Nichol et al., 2008). In the current study, a Real Time Fine Spatial Resolution (RTFSR) algorithm is developed to retrieve the AOD using MODerate resolution Imaging Spectroradiometer (MODIS) Level-2 Swath data (MOD02HKM) of 500 m spatial resolution over the complex and bright surfaces of Hong Kong. This study employs a novel approach to high-resolution AOD retrieval because it does not rely on an empirical AOD lookup table generated using a Radiation Transfer Model (RTM). Instead, AOD is retrieved on real-time basis by applying RTM's equations directly on the MODIS data.

The RTFSR algorithm is evaluated with AOT from the PolyU AERONET station in Hong Kong. Comparison between RTFSR AOD at 3x3 spatial region and AERONET AOT at $\pm$ 30 min of MODIS overpass times in November and December 2007 is shown in Table 1. The RTFSR AOD algorithm also successfully detected biomass burning over mainland China on 30th November 2007 that was also detected by the MODIS Web Fire Mapper but was not detected by the MOD04-V05 Level-2 Aerosol Product at 10 km spatial resolution (Figure 1).

Table 1. Comparison of RTFSR AOD with AERONET AOT over Hong Kong

Session WG02S4O. Marine and Carbonaceous Aerosol

New Findings on Submicron Sea Salt Source Flux

J. Ovadnevaite, D. Ceburnis, H. Berresheim and C. O'Dowd

School of Physics and Centre for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland Galway, University Road, Galway, Ireland

Keywords: sea salt, sea spray source function, marine aerosol, HR-ToF-AMS.
Presenting author email: jurgita.ovadnevaite@nuigalway.ie

Sea spray aerosol is a significant component of the aerosol population in the marine environment, and given that 70% of the Earth's surface is oceanic, sea spray contributes significantly to the global aerosol budget (Vignati et al., 2010). In order to better understand and quantify these effects, detailed information on the chemical composition, along with size distribution and abundance, is required.

The high-time resolution sea salt measurement by a High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS) enabled the quantification of sea salt mass in both increasing and decreasing wind speed regimes up to 26 m s^{-1}. A mass flux source function was also derived and found to have a power-law wind speed dependency with an exponent of 3.1 for increasing winds and 2.3 for decreasing winds. Whereas, submicron aerosol particles are expected to be uniformly mixed in the marine boundary layer, an effective sea spray aerosol production flux was estimated from the sea spray concentration divided by a filling time and multiplied by the marine boundary layer height.

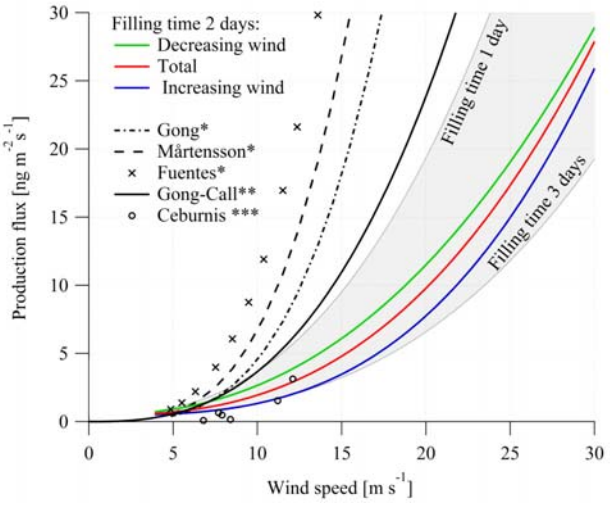

Figure 1. Production flux dependence on the wind speed. Color lines represent the flux derivations from the AMS sea salt measurements at different wind speed regimes. Grey area represents the flux variability due to the different time of filling. Black lines illustrates fluxes derived from the parameterizations by Gong (2003), Mårtensson et al. (2003) , Callaghan et al. (2008), Ceburnis et al. (2008) and Fuentes et al. (2010).
*number flux presented in the original work was recalculated to the mass flux; **includes differential whitecap - to - aerosol productivity derived by Gong (2003), ***fluxes calculated from the data presented.

A comparison with already existing source functions derived from the whitecap method is presented in Figure 1. It suggests that previous schemes based on the Monahan whitecap - wind speed approach significantly over-estimate the submicron mass flux. There could be several reasons for that: one is the whitecap area - to - wind speed parameterization and another is the parameterization of differential whitecap - to - aerosol productivity. The former parameterization has recently improved by applying a digital image processing of sea-state photographs and removing the subjectivity in determining the intensity threshold. Replacing the Monahan component of the source flux with the more recent Callaghan et al. (2008) whitecap – wind speed relationship brings the Gong (2003) source function closer to the ones presented in this study; however, the comparison also points to an over-estimation of the differential whitecap - aerosol productivity component of the source flux function.

Carbon is one of the main constituents of atmospheric aerosol. The study of carbonaceous aerosol is important because of its adverse effects on health, air quality, visibility, and Earth's radiation balance. In this context, the development of analytical and modelling techniques aiming at the identification of natural and anthropogenic contributions gains great importance.

^{14}C measurement on total carbon (TC) is a good tool for fossil/non fossil sources separation (Hildemann et al., 1994). However, wood burning has to be considered mainly of anthropogenic origin at mid-latitudes. Therefore, ^{14}C measurements on TC do not allow the complete natural/anthropogenic contributions separation.

^{14}C measurements on organic and elemental carbon (OC and EC, respectively) allow a distinction between the wood/biomass burning and the biogenic source, provided that the OC/EC emission ratio for wood/biomass burning is known. This model is limited by the difficulty in the assessment of the secondary contribution from wood/biomass burning (Szidat et al., 2009), as the OC/EC emission ratio measured at the source cannot correctly account for secondary aerosol formation. Moreover, ^{14}C measurements for the fraction of modern carbon (f_m) determination must be carried out on each carbon fraction after a suitable isolation. At the state of art EC and OC are operationally defined. Therefore, a key point of ^{14}C measurements on carbon fractions is the thermal separation of OC and EC.

This work aimed at gaining information on the effects of different thermal treatments on ^{14}C measurements of organic (OC) and elemental (EC) carbon fractions in the atmospheric aerosol. Improvements to the traditional approaches for the determination of the f_m(OC) and f_m(EC) are proposed and tested using a devoted sample preparation line (Calzolai et al., 2011).

f_m(EC) determination is usually carried out after EC isolation using a single oxygen combustion step. In this work, we show that the most refractory OC fraction cannot be efficiently removed by the oxygen treatment alone without significantly affecting the EC recovery. Therefore, we propose to use a Helium combustion step at high temperature in addition to the oxygen treatment. Our tests demonstrate that the addition of a high temperature He step (optimised temperature setting: 750 °C) to the oxygen treatment (375°C, 40 min) is effective in removing the refractory OC.

The direct determination of f_m(OC) can be difficult because of possible OC pyrolysis, which can be reduced by water soluble components removal. Therefore, here we propose to determine f_m(OC) measuring either the fraction of modern carbon of TC and EC or the fraction of modern carbon of water soluble (f_m(WSOC)) and water insoluble (f_m(WINSOC)) organic carbon. Tests on the equivalence of the approaches have shown good agreement.

Our tests were carried out on PM10 samples collected in a heavily polluted urban area (Milan, Italy) during wintertime. f_m(OC), f_m(EC), and f_m(TC) values obtained in our tests were then used to attempt a preliminary source apportionment using ^{14}C measurements (Figure 1).

The wood burning primary contribution to OC was evaluated from both ^{14}C and levoglucosan using tailored emission factors (Piazzalunga et al., 2011). A good agreement between the approaches was found and wood burning primary contribution accounted for about 18% of OC in Milan during wintertime. Secondary OC from biomass burning and the contribution from other urban sources were tentatively identified following literature approaches, with the aim of evaluating the biogenic contribution to OC, which was estimated to be about 18%.

In order to fill in the gap of observation in the Mediterranean basin and to obtain more information about sources of air pollutants and atmospheric dynamical and chemical mechanisms, the Joint Research Centre of the European Commission (JRC, EC) has started a long-term monitoring program over the Mediterranean Sea in collaboration with the cruise line Costa Crociere. In this framework, in a joint experiment with the Department of Physics of the University of Genoa, an intensive PM2.5 sampling campaign was organized in summer 2011, on a cruise ship following a regular route in the Western Mediterranean with continuous measurements of BC, NO_x, CO, SO_2 and O_3 by the monitoring station, placed in a cabin of the top deck of the ship.

During this campaign the route of the ship was Civitavecchia-Savona-Barcelona-Palma de Mallorca-Malta (Valletta)-Palermo-Civitavecchia (see Figure 1).

From July 18 to 25, August 15 to 22, and September 12 to 19, 2011, PM samples were collected on Quartz and Teflon filters (47mm diameter, flow rate 2.3 m^3/h) using in parallel two Sven Leckel Ingenieurburo sequential samplers, placed on the top of the cabin where the monitoring station itself was located. The samplers were switched on after the departure from each harbor and stopped before the arrival in the next port. Each leg was then divided in periods of about 5 hours with one filter for each sampler collected per period, thus resulting in a variable number of filters per leg and in a total of about 100 filters for all the sampling campaigns during summer 2011. Information about meteorological parameters (wind speed and direction, temperature, humidity) was available with 10 min intervals from the meteorological station of the ship, together with information about the ship position, speed and sailing direction.

Samples were analyzed with different techniques: Energy Dispersive X-Ray Fluorescence at the Department of Physics of Genoa (Ariola et al, 2006); Ion Chromatography (Chow and Watson, 1999) at Department of Chemistry of University of Milan; Thermo-optical analysis (Birch and Cary, 1996) at the JRC laboratory. Ion Beam Analysis measurements of the Teflon filters sampled during the week of September 2011, using simultaneously PIXE, EBS and PESA techniques (Chiari, 2005), were performed at the 3 MV Tandetron accelerator of the LABEC laboratory of INFN in Florence.

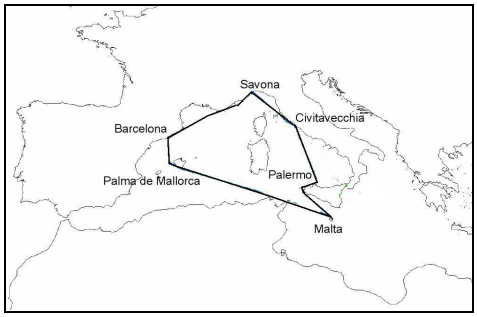

Figure 1. Route of the ship during the sampling campaigns in the summer 2011.

Positive Matrix Factorization, PMF (Paatero et al, 1994), was used to identify and characterize the major PM2.5 sources along the ship route. Particular attention was given to the evidence of emissions from heavy fuel oil combustion by ships, known to be an important source of secondary sulphate aerosol. The biogenic contribution to sulphate concentration along the route was estimated from the measurement of the MSA (methanesulfonic acid) concentrations.

This work has been partially supported by INFN (NUMEN project) and by Costa Crociere.

Organic Carbon detection in crude-oil plant emissions in South Italy

M. Calvello[2], F. Esposito[1] , G. Pavese[2], M. Lovallo[3], L. Mangiamele[3]

Presenting author email: calvello@imaa.cnr.it

The possibility to evaluate Organic Carbon (OC) presence in carbonaceous aerosol by a 7-wavelenghts Aethalometer has been tested in a site with intensive extraction activities of crude oil in South Italy (Agri Valley, 40.33°N, 15.92° E, 582 m a.s.l).

In the measurements site a crude oil pre-treatment plant is present and the area is characterized by continuous and controlled smokes emissions.

In-situ measurements of Black Carbon (BC) content have been continuously carried out by a Magee AE31 aethalometer (7 wavelenghts from 370 to 950 nm) from January to April 2011 . Usually, when dealing with aethalometer data, the difference between BC computed at 370 nm and BC computed at 800 nm is used to detect the presence of organic compounds (Hansen, 2005). For all data collected in Agri Valley a prevailing 370-UV component was found indicating the presence of organic compounds among carbonaceous absorbing particles. An example is shown in Figure 1.

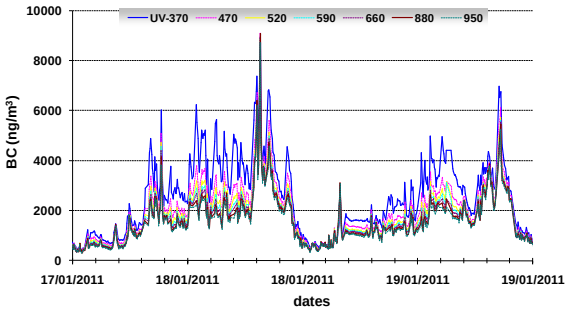

Figure 1. Temporal variation of BC content in Agri Valley near the oil plant as estimated at the 7 wavelenghts for the period January 17th-19th 2011.

These results have been compared to those obtained after three years (2008-09-10) of BC content measurements carried out in a rural site (Tito Scalo) always in South Italy where no particular BC emission sources are present a part from vehicular traffic. In this case a prevailing 370-UV component of BC has never been detected (Calvello *et al*., 2010, Pavese et al. Submitted).

Going back to data collected in Agri Valley, in Figure 2 the time dependence of the difference between 370-UV component and 880-BC component as estimated by Magee Aethalometer is reported together whit that of benzene concentration as measured by ARPAB (Basilicata region environmental protection agency).

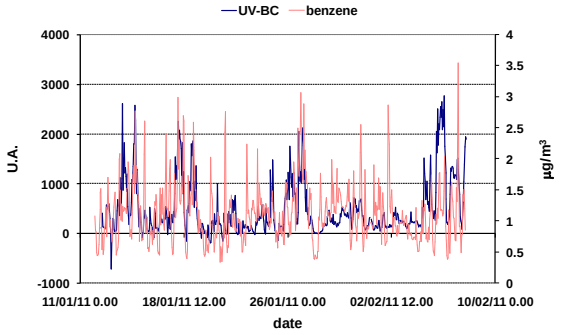

Figure 2. Time dependence of the difference between 370-UV component and 880-BC as estimated by Magee Aethalometer and of benzene concentration as measured by ARPAB.

As it is possible to see, a good agreement is found showing the goodness of Aethalometer data to qualitatevely determine OC presence.

It must be pointed out, anyway, that the attenuation at 370 nm as measured by the Aethalometer cannot give a quantitative estimate of OC content. Moreover, if Brown Carbon (BrC) is one of the particulate component, the standard Magee algorithm, based on the hypotesis of a mass absorption coefficient inversely proportional to the wavelength, can give wrong information on OC detection. Thus a novel algorithm has been tested on Agri valley BC content data to improve the standard Magee algorithm. This new algorithm is able to verify the carbonaceous particles spectral absorption behavior thus distinguishing between BC and BrC and to better detect OC component (Esposito *et al.*, 2012).

The Seasonal Cycle of Sea Spray Emissions: Long term Eddy Covariance Aerosol Flux measurements from Östergarnsholm, Baltic Sea (57°27`N ,18°59` E)

E. Douglas Nilsson[1] and Monica E. Mårtensson[2]

[1]Department of Applied Environmental Science, Stockholm University, S-10691 Stockholm, Sweden
[2]Department of Earth Sciences, Uppsala University, S-752 36 Uppsala, Sweden
Keywords: Sea spray, eddy covariance, aerosol fluxes, marine aerosol
Presenting author email: douglas.nilsson@itm.su.se

On the island Östergarnsholm (57°27`N ,18°59` E) in the Baltic Sea we have measured turbulent fluxes of aerosols, CO_2, H_2O, heat and momentum using Eddy Covariance (EC). The measurements were conducted from a tower at the southern tip of the island, with an asymmetric ultrasonic anemometer (Gill HS-50) and a CO_2+H_2O sensor (LICOR 7500) and aerosol air inlets at ~12m above sea level, see Figure 1. The aerosol was counted with an Optical Particle Counter (OPC) (Grimm 1.109), with 15 size bins from 0.25-2.5 μm Diameter (D), and a Condensational Particle Counter (CPC) (TSI 3772), for particles >10 nm D. Fluxes were de-trended, rotated, and corrected for tube effects etc., and calculated over 30 minutes periods. Power were provided by solar panels and a wind power generator. More than a decade of research on CO_2 air-sea-exchange, has characterized the site as representing open sea conditions within a wide wind sector to the south-east and south.

Figure 1. To the left, the new Stockholm University aerosol flux tower, to the right, mast with CO_2 fluxes at several levels operated by Uppsala University.

So far all existing in situ flux measurements are limited to short campaigns of at the most a few months (e.g. Nilsson et al., 2001, 2007; Geever et al., 2005). The strongest driving physical parameter, the wind speed, usually experience seasonal variations. For example, in the North-Atlantic we expect stronger wind in winter than in summer. Strong seasonal cycles in the organic fraction of the sea spray has been found on both southern and northern hemisphere and attributed to the seasonal cycle in marine biology (Yoon et al., 2007; Sciare et al., 2009). The current project was therefore initiated in order to provide the first long term direct measurements of sea spray emissions. This should allow us to determine the importance of seasonal changes in physical parameters (wind, water temperature etc.) and marine biology, and to better judge the effect of climate driven changes in these parameters.

Preliminary evaluation of the data suggest that the magnitude of the sea spray emissions exceed that which can be explained by sea salt only, which leaves room for a substantial organic sea spray fraction, see Figure 2. There is evidently, as expected, as strong wind dependency, and several severe storms during the winter season have resulted in record levels of sea spray emissions. At the time of the EAC2012 we will have more than a year of data, and we will be able to present the first ever full seasonal cycle in sea spray emissions based on direct emission measurements.

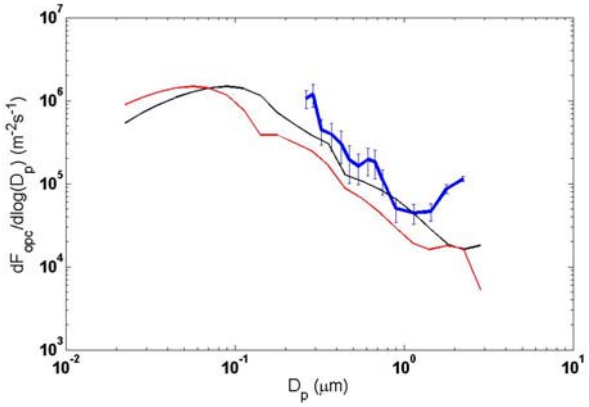

Figure 2. Winter season median aerosol emission fluxes in the OPC size range (blue curve) with the 25-75 percentile, compared to the Mårtensson et al. (2003) sea salt source parameterisation (black curve), corrected for the lower salinity of the Baltic Sea (red curve).

This work was supported by the Swedish Research Council for the Environment (FORMAS).

The Sum of carbonaceous particles (total carbon, TC) is a major fraction of the fine aerosol and affects climate and human health. TC is classified into the sub-fractions elemental carbon (EC) and organic carbon (OC). EC originates only from fossil fuel combustion and biomass burning. OC can be emitted directly as primary organic aerosol (POA) from biogenic emissions, wood burning and fossil fuel combustion or can be formed in-situ in the atmosphere (secondary organic aerosol, SOA) (Szidat et al. 2006). Radiocarbon (^{14}C) analysis is a direct and quantitative tool for distinguishing fossil and non-fossil sources, since ^{14}C in fossil fuels is completely depleted whereas other sources have a contemporary ^{14}C level.

Previous ^{14}C analyses have been performed on aerosol filter samples with a sampling time ≥6h, hindering clear and time-resolved assessment of the sources and processes emitting TC. This study presents unprecedented ^{14}C measurements performed on high time resolution (3-4h) PM_1 filter samples collected during the CalNex-LA 2010 campaign at the California Institute of Technology in Pasadena located about 20 km northeast of downtown Los Angeles (LA). Separation of OC and TC was carried out using the THEODORE system (Szidat et al. 2004) and a Sunset EC/OC analyzer. The resulting CO_2 was cryo-trapped and sealed in glass ampoules for ^{14}C measurements, performed with the mini radiocarbon dating system MICADAS (Ruff et al. 2007).

Results for several days show a consistent and distinct diurnal cycle with a fossil peak for TC and OC (Fig.1, top panel) in the early afternoon after the plume of the western LA basin is transported to Pasadena with the sea breeze. The non-fossil fractions of TC and OC (Fig. 1, bottom panel) show no daily cycles and stay constant throughout all days. The EC concentrations are low (max. 1.0 µg/m^3) and show only weak daily cycles. Likewise, the traffic related factor HOA (hydrogen like organic aerosol) (see Fig. 1, bottom panel) calculated with positive matrix factorisation (PMF) from aerosol mass spectrometry (AMS) data and measurements of benzene, a tracer for anthropogenic POA, show also only a weak diurnal variation.

In contrast, the semi-volatile oxygenated organic aerosol (SV-OOA) found by PMF shows a strong diurnal cycle with a peak in the afternoon and correlates well with the fossil OC for all days (r^2 = 0.74 ± 0.1 on average). In addition, acetaldehyde, a tracer for photochemical processing, shows a clear daily cycle with a peak around the same time as SV-OOA, and non-fossil OC and TC. These results indicate that the increase of fossil OC and TC in the early afternoon is mainly attributed to fossil SOA formed from anthropogenic precursor gases in the LA plume, suggesting that anthropogenic emissions can substantially influence the SOA formation in urban areas, especially in megacities.

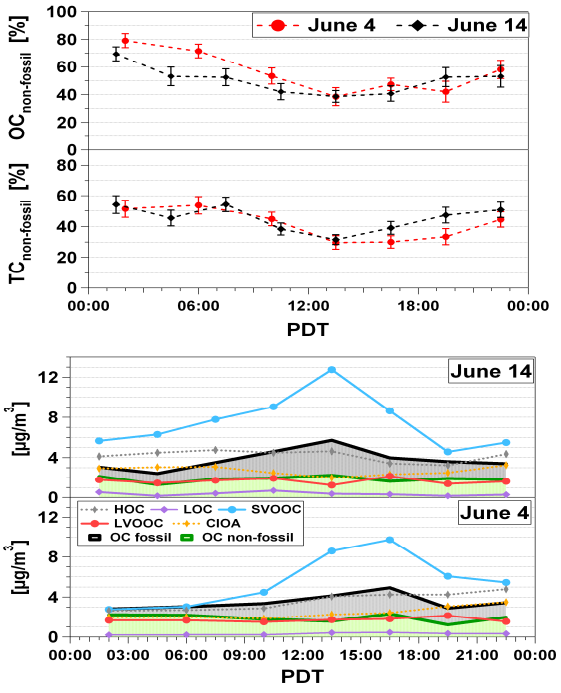

Figure 1. Diurnal cycle of non-fossil OC and TC (top) and comparison with PMF factors (bottom).

A new sea-salt module implemented within the NMMB/BSC Chemical Transport Model

M. Spada[1], O. Jorba[1], C. Pérez[2], Z.I. Janjic[3] and J.M. Baldasano[1,4]

Keywords: Sea salt, Aerosol modelling.
Presenting author email: michele.spada@bsc.es

A new sectional module for the forecasting of sea-salt aerosol has been implemented within the NMMB/BSC Chemical Transport Model (NMMB/BSC-CTM) (Pérez *et al*, 2011; Jorba *et al*, 2011), currently under development at the Barcelona Supercomputing Center. While most of the global aerosol models are not capable to reproduce meso-β or smaller scale phenomena, NMMB/BSC-CTM can simulate from global to regional scales, with a fully on-line coupling of atmospheric physics and aerosol processes.

The major uncertainities in sea-salt modeling at global scale are related to the comparison with observations: in effect, surface measurements could be affected by surf-zone production and it is difficult to separate the sea-salt contribution from measured total aerosol optical depths. Moreover, since the short lifetime of large sea-salt articles, comparisons between models and measurements may be very sensitive to the model resolution, especially when complex terrains and/or land-ocean interfaces occurr. Thus, the NMMB/BSC-CTM capability to downscale may be very useful.

The sea-salt module uses 8 bins in the dry radius interval $[0.1 - 15]\mu$m to properly describe mass concentrations and optical depth. Ultrafine particles are not considered. A sub-bin lognormal approach is assumed to calculate the optical properties of the particles. Different open-ocean emission schemes are implemented, accounting both for bubble-bursting and spume production, such as the combined Monahan *et al* (1986)/Smith *et al* (1993) (M86/SM93) and Gong (2003) (G03). SST-dependent emissions of sea-salt bubbles have been also implemented by merging with the scheme of Martensson *et al* (2003) (MA03/M86/SM93). The water uptake is taken into account by using prescribed growth factors for different relative humidity values. The parameterizations of the aerosol processes affected by the water-uptake (i.e. sedimentation, dry deposition, wet deposition, etc.) have been extended to wet particles from those implemented in the dust module (Pérez et al, 2011).

We describe the new module and we present its results vs observations, climatologies, and spatial patterns from different datasets, e.g. the University of Miami Network, the AERONET Sunphotometers Network, cruise measurements, and satellite data. Global simulations of the year 2006 have been performed at different resolutions (ranging from 2 x 2.8 to 0.333 x 0.469 degrees). The coarse part of the optical depth has also been taken into consideration in order to avoid the influence of other fine particles, such as sulfate. The dust contribution to the optical depth is provided from the dust module of NMMB/BSC-CTM. Evaluation and influence of horizontal resolution are discussed, also by the performing of regional simulations. Figure 1 shows the resulting surface concentration at Bermuda for different emission schemes.

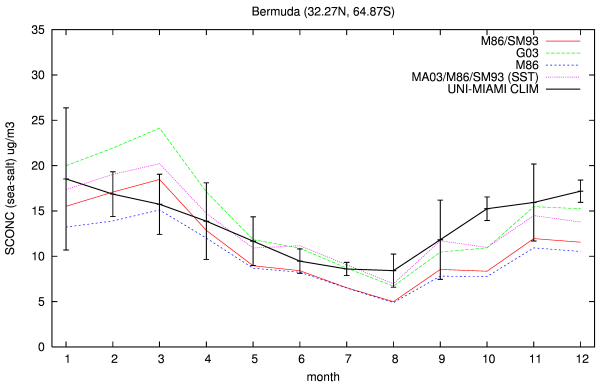

Figure 1: Sea-salt surface concentration: modeled monthly means of year 2006 vs UNI-MIAMI network climatology (means+stdevs) at Bermuda. Model res.=1x1.4

Keywords: aerosol, HULIS, size distribution, chemical properties
Author email: kissgy@almos.uni-pannon.hu

Humic-like substances (HULIS) constitute a considerable fraction (often the majority) of the water-soluble organic matter present in atmospheric aerosol. Consequently, this complex organic mixture significantly influences the physical and chemical properties of the aerosol particles as well as their biological effects. Several studies have dealt with the sources and characterisation of humic-like substances leading to considerable knowledge on their potential formation mechanism, elemental composition, molecular weight range, spectroscopic features, higroscopicity, CCN ability, etc. However, information on the size distribution of HULIS is very limited (Peng et al., 2010) although knowledge of this feature provides important information on possible sources and formation mechanisms in the atmosphere.

In this work humic-like substances isolated from aerosol particles of different size ranges were characterized. Aerosol samples were collected in the 0.0625-16 μm size range with an 8-stage Berner impactor at a rural site (K-puszta) in Hungary, an urban site (Zagreb) and a coastal site (Martinska) in Croatia. Humic-like substances were isolated from the aqueous extracts of each stage and their carbon content was determined by TOC analysis. The UV absorbance and fluorescence properties as well as the mass spectra of the constituents of the aqueous extracts and those of the isolated HULIS were studied. Approximately 90% of fluorescing compounds (EX=235nm/EM=410nm) were found in the 0.0625-1 μm size range which indicated that humic-like substances occurred in the fine fraction. This was confirmed by the results of carbon analysis and mass spectrometric investigations: the mass spectrum of the organic matter isolated from the particles in the 0.0625-1 μm size range resembled that of humic-like substances while the mass spectrum of the low amount of organic matter isolated from bigger particles differed significantly. Specific UV and fluorescent properties indicated that the chemical composition of particles within the 0.0625-1 μm size range is diverse. In order to confirm this finding the isolated humic-like substances were analyzed by ultra high resolution mass spectrometry (FT-ICR-MS). Elemental composition (obtained from FT-ICR-MS), UV absorbance and fluorescent properties of HULIS isolated from aerosol particles of different sizes will be shown for aerosol samples collected at different sites.

Observations of monoterpene organosulfates in wintertime aerosols

A.M.K. Hansen, K. Kristensen, F. Cozzi, A. Zare, M.F. Lauridsen and M. Glasius

Department of Chemistry, University of Aarhus, Langelandsgade 140, DK-8000 Aarhus C, Denmark
Keywords: Biogenic Secondary Organic Aerosols, Monoterpene Oxidation Products, Chemical Analysis
Presenting author email: glasius@chem.au.dk

Organosulfate derivatives of isoprene and monoterpenes, as well as their oxidation products, have been identified in both laboratory and field studies where they are formed through heterogeneous reactions involving sulphur compounds (e.g. Surratt *et al*., 2008), primarily emitted to the atmosphere from anthropogenic sources. Organosulfates of biogenic oxidation products thus provide a coupling between air pollution and formation of low-volatility secondary organic aerosols (SOA), contributing to anthropogenically enhanced biogenic SOA (ABSOA) as suggested in recent studies (e.g. Hoyle et al., 2011).

Particles ($PM_{2.5}$) were collected using a high-volume sampler at an urban background site in Aarhus, Denmark in January 2011. After extraction, the samples were analysed by HPLC coupled through an electrospray inlet to a quadrupole time-of-flight mass spectrometer (qTOF-MS) (Kristensen, Glasius, 2011). Organosulfates and nitrooxy organosulfates were identified from their characteristic MS-fragments (HSO_4^-, SO_3^- and HNO_3) and the isotopic patterns of sulphur and nitrogen and quantified using a standard.

Molecular formula, MW	Suggested molecular structure	Suggested precursors
$C_{10}H_{18}O_5S$, 250		α-pinene, β-pinene
$C_{10}H_{16}O_7S$, 280		α-pinene β-pinene
$C_{10}H_{17}NO_7S$, 295		α-pinene β-pinene
$C_9H_{15}NO_8S$, 297		Limonene
$C_{10}H_{17}NO_{10}S$, 343	Unknown	α-pinene, α-terpinene

Table 1. Organosulfates identified in $PM_{2.5}$ samples collected during winter (January 2011)

Organosulfates of α -pinene and β -pinene were identified in the samples together with nitrooxy organosulfates of monoterpenes (see examples in Table 1). All of these compounds have previously been observed in aerosol samples from Denmark during spring and summer (Kristensen and Glasius, 2011), as well as Norway, Sweden and Finland during summer (Yttri *et al*., 2011), but not during winter.

Concentrations of most of the classical monoterpene oxidation products were generally much lower than during springtime, while some, such as terpenylic acid, where observed at comparable levels.

The ground was snow-covered during the study period, so local, as well as regional, emissions of monoterpenes are expected to be minimal.

The results thus point towards regional-scale processes affecting formation of ABSOA during winter, in accordance with the study by Frossard *et al*. (2011) in the Arctic. This will be further investigated by use of air mass back-trajectories and modelling of monoterpene emissions in source regions.

We thank the VILLUM Foundation and the Nordic Top-level Research Initiative (CRAICC) for funding of this work.

Simultaneous study of gas and particulate products formed from limonene oxidation: smog chamber and citrus fruit field measurements

L. Chiappini[1], S. Rossignol[1], C. Rio[1], S. Fable[1], G. Grignion[2], J.L. Savelli[2]

[1]Institut National de l'Environnement Industriel et des Risques (INERIS), 60 550 Verneuil-en-Halatte, France
[2] Qualit'Air Corse, Lieu-dit Lergie RN 200, 20250 Corte, France
Keywords: SOA, gas-particle partitioning, nucleation event
Presenting author email: laura.chiappini@ineris.fr

Limonene is a significant contributor to monoterpenes emissions that accounts for around 11 % of global VOCs emissions (Guenther 1995). Its two double bonds enhance its reactivity making it display a higher SOA yield (around two times,Griffin 1999) compared to mono-unsaturated monoterpenes, such as α- and β-pinene, more emitted at a global scale (Geron 2000). Limonene can therefore be considered as a significant contributor to SOA.

To accurately evaluate secondary organic aerosol climate and health impacts from limonene oxidation, and provide models with data obtained under real atmospheric conditions, the evaluation of gas/particle partitioning behaviour of secondary organic matter semi-volatile fraction and the associated multiphase chemistry is needed.

To that purpose, smog chamber experiments and field measurement campaign to be provided with partitioning coefficients obtained under real conditions, have been combined.

In order to describe multiphase chemistry involved in SOAs formation and to take into account gas/particles partitioning phenomena, a new analytical approach has been employed (Rossignol 2012). Both gas and particulate phases are simultaneously collected, respectively on sorbent tubes and filters, and molecular composition is investigated using PFBHA and MTBSTFA derivatization prior to thermal-desorption coupled with gas chromatography and mass spectrometry (TD-GC-MS) analysis.

For each experiment, chemical data are coupled with ozone and limonene concentrations evolution monitoring and physics characterisation of formed particles: mass, size and number distribution evolution.

Simulation chamber experiments

Simulation chamber experiments were performed at the EUPHORE European chamber (Figure 1, Valencia, Spain) under close to reality conditions: ozone and limonene concentrations around 80 ppb, seeds introductions and humidity ratio close to 50 %. In mean 75 µg of SOAs are formed.

Chemical characterisation of both gas and particulate phases allowed identification of limonene ozonolysis tracers, such as limononaldehyde or limonaketone, and evaluation of gas/particles partitioning of these species for a better understanding of physico-chemical mechanisms and processes involved in the limonene SOAs formation.

Figure 1: EUPHORE European atmospheric simulation chamber (left) and the INRA citrus fruits field (right)

Field campaign

A field campaign was performed in the French National Institute for Agricultural Research (INRA) citrus fruits filed in Northern Corsica during a week in June 2011.

Episodic $PM_{2.5}$ number concentration increases could be observed when limonene concentrations were rising during the day, and have been tentatively attributed to SOA formation from limonene oxidation.

Indeed, among the thirty compounds which have been positively or tentatively identified in gas and/or particle phases, some can be specifically attributed to limonene ozonolysis such as ketolimonene, Limononaldehyde and ketonorlimonic acid. These limonene oxidation specific tracers, have been quantified and for those identified in both gas and particulate phases, an experimental partitioning coefficient is proposed.

This study provides an insight into particulate and gaseous phase secondary products formation from limonene ozonolysis .

Keywords: aerosol characterization, biomass burning, HPLC-MS, PM10, SOA (Secondary Organic Aerosol)

Presenting author email: irena.grgic@ki.si

In the last decade, it was demonstrated that organic aerosol (OA) represents a significant fraction of ambient aerosol, and further a substantial portion of it is secondary organic aerosol (SOA) (Hallquist *et al.*, 2009). However, there are still large uncertainties in evaluation of their role in the chemistry and physics of the atmosphere.

Biomass burning (BB) emits huge amounts of organic aerosols in the atmosphere (Laskin *et al.*, 2009). Many different compounds can be present in BB aerosol (Simoneit, 2002). Some of these compounds are very specific to biomass burning; hence, they can be used as markers, e.g., levoglucosan for primary BBA (Fine *et al.*, 2002). An important class of compounds of SOA are nitrocatechols known as very strong absorbers of UV and Vis light. Very recently, methyl-nitrocatechols were proposed as suitable tracers for highly oxidized secondary BBA (Iinuma *et al.*, 2010).

The objective of the present study was to characterize nitrocatechols and related compounds in ambient aerosols using liquid chromatography/negative ion electrospray ionization mass spectrometry [LC/(-)ESI-MS]. A new method for the separation and identification of these compounds has just been developed (Kitanovski *et al.*, 2012), and further validated for quantitative analysis.

For this purpose, an HPLC system (Agilent 1100) coupled with a linear ion trap (4000 QTRAP, Applied Biosystems/MDS Sciex) was used. The separation of nitrocatechol and related nitro-aromatic compounds was achieved using an Atlantis T3 column. PM10 samples were collected on quartz fiber filters at an urban background location in Ljubljana, Slovenia. The deposits on the filters were extracted with methanol in an ultrasonic bath. The extracts were evaporated to dryness and dissolved in methanol/water with ammonium formate buffer pH 3 prior to LC/MS^2 analysis.

Several nitro-aromatic compounds were detected in the wintertime PM10 (Figure 1). The most intense peaks were found for 4-nitrocatechol and the methyl-nitrocatechols. In comparison with the summertime PM10 samples (August 2010), the concentration of these compounds was found to be 100 – 500 times higher; for example, for 4-nitrocatechol the winter concentrations were in the range of 20-135 ng/m^3. Furthermore, the targeted nitro-aromatic compounds were well correlated with levoglucosan, but less with the organic carbon (OC) levels.

These measurements, for the first time, give information about the real concentrations of the nitro-aromatics in ambient aerosols, and without doubt support the proposed role for 4-nitrocatechol and methyl-nitrocatechols as tracers for BB SOA.

Presenting author email: imad.el-haddad@psi.ch

Long before the industrial evolution and the era of fossil fuels, high concentrations of aerosol particles were alluded to in heavily populated areas, including ancient Rome and medieval London. Recent radiocarbon measurements (^{14}C) conducted in modern megacities came as a surprise: carbonaceous aerosol (mainly Organic Aerosol, OA), itself a predominant fraction of particulate matter (PM), remains overwhelmingly non-fossil despite extensive fossil fuel combustion. Such particles are directly emitted (Primary OA, POA) or formed in-situ in the atmosphere (Secondary OA, SOA) via photochemical reactions of volatile organic compounds (VOCs). Urban levels of non-fossil OA exceed several folds the levels measured in pristine environments strongly impacted by biogenic emissions, suggesting a contribution from unidentified anthropogenic non-fossil sources to urban OA.

Positive Matrix Factorization (PMF) techniques applied to ambient aerosol mass spectrometer (AMS, Aerodyne) data identified primary cooking emissions (COA) as one of the main sources of primary non-fossil OA in major cities like London (Allan et al., 2010), New York (Sun et al., 2011) and Beijing (Huang et al., 2010). Cooking processes can also be associated with VOCs that can act as SOA precursors, explaining potentially in part the high levels of oxygenated OA (OOA) identified by the AMS in urban areas. However, at present, the chemical nature of these VOCs and their secondary aerosol production potential (SAPP) remain virtually unknown.

The approach adopted here is multi-dimensional, involving ambient measurements of the COA contribution in European megacities, as well as laboratory quantification of PM and VOC emission factors from the main primary COA emitting processes and their SAPP. Primary emissions from deep-fat frying, vegetable boiling, vegetable frying and meat cooking were analysed under controlled conditions after ~100 times dilution for different oils, meats and vegetables. A high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) and a high resolution proton transfer time-of-flight mass spectrometer (PTR-ToF-MS) were used to quantify OA and VOC emissions, respectively. SOA production potential of the different emissions was quantified by introducing them into the new PSI mobile smog chamber where they were photochemically aged.

Our AMS measurements in Paris (Jan. 2010) and Barcelona (Mar. 2009) showed that cooking emissions constitute a predominant source of urban OA. In the case of Barcelona for example (Mohr et al., 2012), primary cooking emissions contributed, on average, 17% to total OA and 28% to total non-fossil OA (Fig.1a). Laboratory measurements of primary emissions suggest that the COA factor identified in ambient atmospheric aerosols is mostly related to fat release from frying with vegetable oils or grilling fatty-meats (Fig.1b). In contrast, vegetable cooking (boiling and frying) was associated with significant VOC emissions. Emission factors and SAPP from all these processes and their potential contribution to non-fossil carbon in urban areas will be discussed.

The Nitrogen, Aerosol Composition, and Halogens on a Tall Tower (NACHTT) field campaign was carried out at Erie (40.0500°N, 105.0039°W), CO between February 17 and March 14, 2011. An Aerodyne Compact Time-of-Flight Aerosol Mass Spectrometer (C-ToF-AMS, henceforth it will be called AMS) was deployed to measure the non-refractory PM_1 (NR-PM_1) composition. The AMS was installed in a moving carriage, obtaining vertical profiles along a 300 m tall tower during the study period. Complementary data such as meteorological parameters (wind speed and direction, temperature, and RH), nitrogen oxides, ozone, and aerosol size distributions were simultaneously determined on this carriage. To our knowledge, this study is unique since it represents for the first time the vertical profile of NR-PM_1 composition determined by the AMS during wintertime in a suburban environment.

Ten-second-resolved measurements of the AMS data were analysed and the average total mass concentration was 4.64±5.71 μg/m^3. The average contributions of nitrate, organics, sulphate, ammonium, and chloride to the total NR-PM_1 mass were 35, 26, 20, 17, and 1 %, respectively.

Average vertical profiles of NR-PM_1 during day (07:00-18:00 local time) - and night (20:00-05:00 local time) are depicted in Figure 1. It is clear from Figure 1 that aerosol concentrations were low above 120 m while higher values were observed from the surface up to 120 m. Based on the temperature and NR-PM_1 mass profiles, we evaluated data for two layers: Layer I ranges from the ground up to 40 m and Layer II ranges from 40 to 120 m. Wind sector analysis was performed to find the immediate sources affecting the chemical composition of NR-PM_1 in Layer I. Forty-eight-hour HYSPLIT backward trajectories were calculated to use as input for cluster

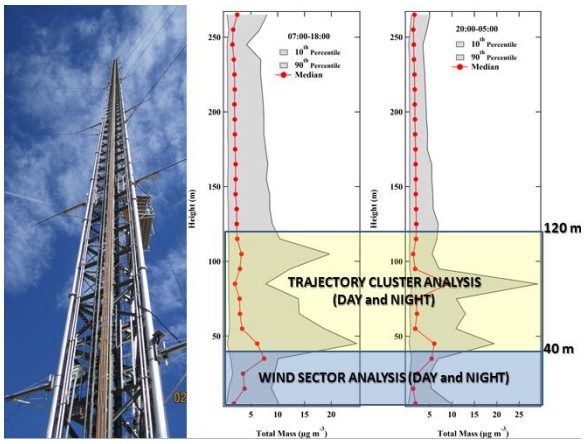

Figure 1: Average vertical profiles of total mass during day (left) and night (right) along the tower

analysis to find the long range transported sources influencing the data collected in Layer II. In addition, variations in the mass distributions of AMS measured parameters for each layer were investigated in this study. Positive Matrix Factorization (PMF) was applied to the organic aerosol (OA) data to characterize contributions of different types of OA. PMF identified three factors: (1) OOA-I (Oxygenated Organic Aerosol, a surrogate for secondary and highly aged OA), (2) OOA-II, and (3) HOA (Hydrocarbon-like Organic Aerosol). OOA-I and OOA-II represent the low-volatility and semi volatile components of OA, respectively, based on the contribution of m/z 43 and 44. HOA represents primary organic aerosol from combustion sources. Average contribution of OOA-I, OOA-II and HOA to total organic mass was 52, 32, and 16 %, respectively. Correlations between the PMF factors, air mass types, and inorganic aerosol components were evaluated.

Composition and formation of organic aerosol particles in the Amazon

We applied scanning transmission X-ray microscopy with near edge X-ray absorption fine structure (STXM-NEXAFS) analysis to investigate the morphology and chemical composition of aerosol samples from a pristine tropical environment, the Amazon Basin. The samples were collected in the Amazonian rainforest during the rainy season and can be regarded as a natural background aerosol (Martin et al. 2010; Pöschl et al. 2010). The samples were found to be dominated by secondary organic aerosol (SOA) particles in the fine and primary biological aerosol particles (PBAP) in the coarse mode. Lab-generated SOA-samples from isoprene and terpene oxidation as well as pure organic compounds from spray-drying of aqueous solution were measured as reference samples. The aim of this study was to investigate the microphysical and chemical properties of a tropical background aerosol in the submicron size range and its internal mixing state.

The lab-generated SOA and pure organic compounds occurred as spherical and mostly homogenous droplet-like particles, whereas the Amazonian SOA particles comprised a mixture of homogeneous droplets and droplets having internal structures due to atmospheric aging. In spite of the similar morphological appearance, the Amazon samples showed considerable differences in elemental and functional group composition. According to their NEXAFS spectra, three chemically distinct types of organic material were found and could be assigned to the following three categories: (1) particles with a pronounced carboxylic acid (COOH) peak similar to those of laboratory-generated SOA particles from terpene oxidation; (2) particles with a strong hydroxy (C-OH) signal similar to pure carbohydrate particles; and (3) particles with spectra resembling a mixture of the first two classes.

In addition to the dominant organic component, the NEXAFS spectra revealed clearly resolved potassium (K) signals for all analyzed particles. During the rainy season and in the absence of anthropogenic influence, active biota is regarded to be the major potassium source (Artaxo and Hansson 1995; Andreae and Crutzen 1997). In addition a strong size dependence of the K mass fraction in the SOA particles has been found, with highest K content in small particles. We suggest that K-rich biogenic salts act as a template for condensational growth by low-volatility organic compounds from atmospheric isoprene and terpene oxidation. The presence of K-rich salts in SOA particles has been confirmed by scanning electron microscopy (SEM) and secondary ion mass spectrometry (NanoSIMS) techniques. Seeding of SOA particles by biogenic salts may explain the absence of new particle formation events in pristine boundary layer air over the Amazonian rainforest.

Several epidemiological studies have shown adverse health effects of ambient particulate matter (PM). Many epidemiological studies on effects of air pollutants use data from a central measurement station as a surrogate for exposure. However, exposure assessment studies have demonstrated that individual personal exposure to PM is poorly correlated with ambient concentrations. Here we report data from a pilot study investigating personal exposure to ambient PM in differently characterised outdoor micro environments.

Measurements were performed in May 2011 in Augsburg, Germany. Exposure data were collected by a researcher equipped with personal monitors and a sampler walking along roads with high traffic volume (traffic) or walking in residential areas with little traffic (residential). Particle number concentration (PNC) in the size range of 10 nm – 1 µm was measured with a Condensation Particle Counter (Model 3007, TSI). Black carbon (BC) was measured by an Aethalometer (microAeth® Model AE51, Magee Scientific), $PM_{2.5}$ mass was determined with a personal aerosol monitor (Model DataRAM pDR-1500, Thermo). $PM_{2.5}$ samples (PEM-10-2.5, MSP) were collected on pre-fired quartz fibre filters at a flow of 10 l min^{-1} (Leland Legacy Pump, SKC). Average sampling times were 60 minutes. Samples were analysed by IDTD-GC-TOFMS (Orasche et al., 2011). Results were compared with the stationary monitors for PNC, BC and $PM_{2.5}$, operated at a central aerosol measurement station located at an urban background site (Cyrys et al., 2006).

High correlations were found for variables measured at the fixed site and the personal monitors, but the personal monitors generally showed the higher values. On average 1.5 fold higher $PM_{2.5}$ mass was found in personal samples (traffic 1.5, residential 1.4). PNC on average showed 2.1 higher values (traffic 2.7, residential 1.2) in the personal measurements. Walking near roads with dense traffic resulted in 4.3 fold higher BC values compared to the fixed background site. In the residential area the increase in BC levels compared to the fixed background site was similar to the increase in PNC (1.3 fold).

Differences of the personal monitoring results from the differently characterised sampling areas were less pronounced. $PM_{2.5}$ mass showed no significant differences whereas PNC and BC showed much higher values in the traffic area. About three times higher BC concentrations were found near the busy street compared to the residential area.

The differences in concentration of organic compounds were less pronounced than BC and PNC. The highest differences were found for hopanes, which are discussed as molecular markers for traffic emissions. On average, 1.9 fold higher values were found in the highly traffic-influenced area. Compounds coming from different sources showed lesser differences. The polycyclic aromatic hydrocarbons showed varying differences ranging from almost equal average concentrations (bezofluoranthenes, crysene) to about 2 fold higher values (bezo[ghi]perylene) in the traffic area. Compounds which have a more uniform emission within the city area, like levoglucosan which is discussed as marker for biomass (in this case wood) combustion, did not show significant differences amongst the investigated areas.

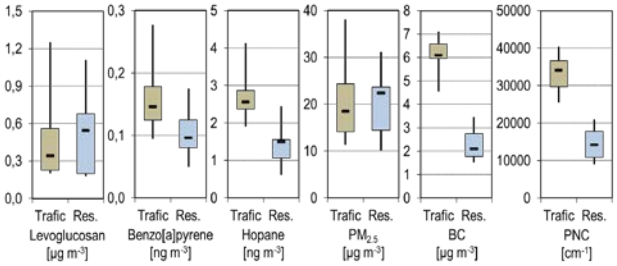

Figure 1. Box plots of concentrations of selected variables determined from personal monitoring near highly traffic influenced roads (Traffic) and in residential areas with little traffic (Res.)

This pilot study clearly indicates the variability in personal exposure to ambient PM and its constituents or source contributions when walking in a city.

The Health effects of organic compounds in aerosols are currently investigated in the framework of the Virtual Helmholtz Institute HICE (www.hice-vi.eu)

The eastward transport of aerosols exported from mainland Asia strongly influences air quality in the Japanese archipelago. The bulk of the inhalable particulate matter (PM_{10}) in these intrusions comprises either natural, desert-derived minerals or anthropogenic pollutants, in various states of mixing. In this context we analyse PM_{10} collected in Kumamoto, SW Japan, during contrasting types of aerosol intrusions involving different PM mixtures. In addition to analysing the daily chemistry of PM_{10} using 24-hour filter samples, an elemental characterization of PM was performed by a Streaker sampler collecting hourly aerosol samples in two size ranges (0.1-2.5µm and 2.5-10µm) that were then analyzed by Particle Induced X-Ray Emission (PIXE).

Whereas the chemistry of the natural mineral component is characterised by "crustal" elements (Si, Al, Fe, Mg, K, Li, P, Sc, V, Rb, Sr, Zr, Th, lanthanoids), the anthropogenic component is rich in secondary inorganic compounds and more toxic metallic elements (NH_4^+, SO_4^{2-}, As, Pb, Cd, Cu, Zn, Sn, Bi, Sb, and Ge). Some desert-dust (*Kosa*) intrusions are more calcareous than others, implicating geologically different source areas, and contain enhanced levels of NO_3^-, probably as supermicron $Ca(NO_3)_2$ particles produced by chemical reaction between NOx pollutants and carbonate during atmospheric transport. The overall trace element chemistry of aerosol intrusions into Kumamoto shows low V/Rb, low NO_3^-/SO_4^{2-}, enhanced As levels, and unfractionated La/Ce values, which are all consistent with anthropogenic sources including coal emissions rather than those derived from the refining and combustion of oil fractionates.

On Figure 1 we introduce a ternary AsCeLax2 diagram to illustrate the As-enrichment in our samples. The Kumamoto samples, displaying no lanthanoid fractionation, lie on a mixing line between the Izaña (located in the free troposphere, Canary Islands) and Wuhan samples (up to 70ngAs/m^3 attributed to a mixture of metallurgical and coal emissions), with the most crustal compositions corresponding to the arrival of dust waves. The most anthropogenically contaminated Kumamoto samples plot close to the As apex. For comparison, we also plot the natural composition of coal compared with its different constituents separated into different densities. The lightest coal fraction, mostly silicate mineral matter, plots close to crustal compositions (UCC). In contrast, the heaviest coal fraction, representing the volatile material released during combustion and thus including the bulk of the heavy metal content as sulphides, plots adjacent to the As apex. For comparison we also add PM_{10} samples contaminated by La during FCC oil refining, and by Ce in ceramic industrial emissions.

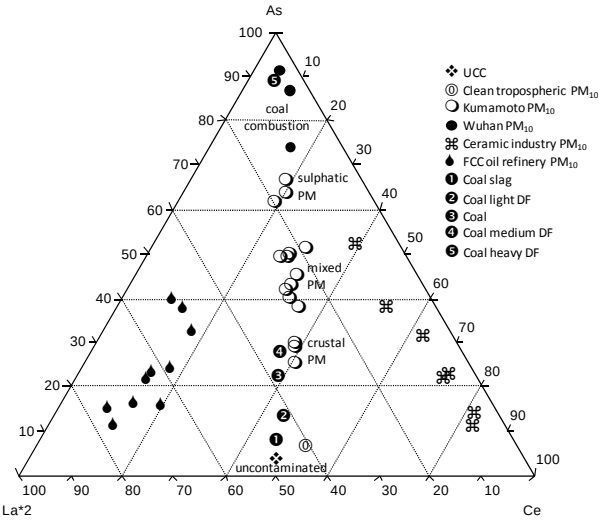

Figure 1. Ternary diagram depicting the mixing line between uncontaminated crustal compositions (UCC) and urban PM contaminated by coal/industrial emissions in Wuhan, China.

Our data clearly demonstrate the great chemical differences between the natural and anthropogenic aerosol components arriving in Japan from China. It is unlikely that the inhalation of coarse silicate mineral dust during a *Kosa* event has the same chronic health impact as a persistent haze of finely respirable sulphatic aerosol containing enhanced amounts of toxic metals. Finally, as we can also see in many other studies of ambient aerosol chemistry, the Kumamoto dataset highlights the limitations associated with legal air quality standards based only on PM mass rather than chemical composition.

Size-segregated Characterization of PM_{10} in German low lands (EMEP site Melpitz) using a five-stage Impactor: A six year study

G. Spindler, A. Grüner, Y. Iinuma, K. Müller, S. Scheinhardt, H. Herrmann

Leibniz-Institut für Troposphärenforschung e.V., Permoserstrasse 15, 04318 Leipzig, Germany

Presenting author email: spindler@tropos.de

Particle sampling took place at the IfT-research station and EMEP-site Melpitz (12°56' E, 51°32' N, 86 m asl.). This site is located about 50 km northeast of Leipzig and 120 km west from the Polish border in a rural region in the German low-lands (EMEP, 2007). Particle samples were collected on ring–like aluminium foils using a BERNER impactor (van Pinxteren *et al.*, 2009) for five size classes (stages 1-5: aerodynamic cut-off diameters 0.05-0.14-0.42-1.2-3.5-10 µm, duration 24 hours, sampled air volume 108 m³). Sampling was planned following the weather forecast. Days without precipitation and with a continuous airflow from either the West or the East were preferred. Air-mass origin was rechecked after sampling based on 96-h backward trajectories (NOAA-Hysplit-Model). Between June 2004 and September 2009, 169 daily samples were taken (8.9 % of the total number of days). The sorting criteria were (i) the distinction between winter (W, November to April) and summer (S, May to October) and (ii) a distinction between air mass inflow from a sector West (W, 210° - 320°) and from sector East (E, 35° - 140°). Four categories (WW, WE, SW and SE) with 48, 18, 42 and 29 days were established. For every sampling day and all stages the mass concentrations of gravimetric mass (weighing of equilibrated aluminium foils before and after sampling), the water soluble ions (cations: ion chromatography, anions: capillary electrophoresis), the organic (OC) and elemental carbon (EC) (two-step thermographic method VDI 2465 part 2) and the PAH and n-alkanes (CPP-GC-MS, Curie point 510°C) were determined. The water content was calculated using the extended Aerosol Thermodynamics Model (E-AIM). OC was converted to organic matter (OM) using different conversion factors (1.4 for stage 1, 1.7 for stage 2 and 2 for stages 3-5).

The lowest mean particle mass concentrations have been found for SW and the highest for WE with relative mass concentration distributions (stages 1-5) of 5.9, 28.2, 36.5, 18.0, and 11.4% and 3.5, 22.7, 52.6, 16.7, and 4.5%, respectively. The mean mass closure for water soluble ions, water, OM and EC accounts for 81 to 99% in summer and 60-81 % in winter (depending on the stage). The fractions of nitrate are relatively high for WW; in contrast, sulphate is high for WE. The estimated mean concentrations of secondary organic carbon (SOA) (Castro *et al.*, 1999) on stage 3 for WW, WE, SW and SE are 0.32, 1.25, 0.27 and 0.58 µgm^{-3}, respectively. The highest difference in the percentages of SOA in OC was found between winter (WW 55%, WE 59%) and summer (SW and SE 74%), indicating photochemical processes. The mean Carbon Preference Indices (CPI) are the highest for SE (stage 4: 7.57 and stage 5: 9.82), resulting from plant wax abrasion in the surrounding forests. The mean PAH concentration for WE on stage 3 is 9.7 ngm^{-3} which is more than 4 times higher than for WW. PAHs account for about 610 and 310 ppm of the particle mass concentration for WE and WW, respectively. This indicates long range transport from emissions of domestic heating and other combustion processes (Figure 1) especially for WE.

These results are in agreement with former findings of higher fractions of sulphate, organic and black carbon during air mass transport from E (especially in winter) in particles of different size ranges at the Melpitz site (Spindler *et al.*, 2010).

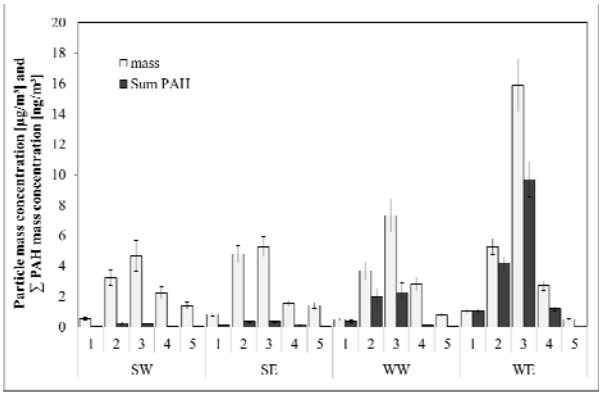

Figure 1. Sum of individual PAH and particle mass concentration for stages 1 to 5 of the BERNER-impactor in Melpitz. Means for the four categories WW, WE, SW and SE.

In urban areas, ultrafine particles and PM1 are of great concern because can deeply enter the respiratory system strongly affecting human health.

Hot-spot pollution areas are peculiar sites where source emissions and meteorological conditions foster particulate matter accumulation and very high aerosol concentrations are often registered. The Po Valley is one of the main hot-spot pollution areas in Europe, especially during wintertime. Despite the high levels of PM registered in the area, little knowledge on PM1 and ultrafine particles composition and sources is available, apart from a couple of studies carried out by our group in 2002 and 2004 in the same area.

This work aimed at a detailed physical and chemical characterisation of PM1 and ultrafine particles and at singling out major sources contributing to the high concentrations observed in the urban area. A critical comparison to the results obtained during the previous PM1 campaigns will be also shown.

PM1 was sampled at an urban background station in Milan, Italy, during winter 2011-2012. Parallel PM1 sampling was carried out twice a day (07-16, 19-04) on PTFE and quartz fibre filters using two low-volume samplers for a total of about 300 samples. Mass concentration was determined by the gravimetric technique and all the PM1 samples were chemically characterised for elements, inorganic ions, levoglucosan, EC/OC and water soluble organic compounds. BC determination was also carried out on both PTFE and quartz fibre filters by a polar photometer (Vecchi et al., 2010; Vecchi et al., 2012). Moreover, BC concentrations in PM1 were monitored with a 5 minute resolution by a MAAP.

The ultrafine fraction was characterised for number size distribution by an optical particle counter (range 0.25-32 μm in 31 size bins) and a differential mobility particle scanner (8-700 nm in 31 size bins). Moreover, parallel samplings using multistage cascade impactors (Dekati-SDI and nanoMOUDI) were collected on different substrates (polycarbonate membranes and quartz fibre filters) to gain information on the size-segregated chemical composition (elements, ions, and carbonaceous components). It is noteworthy that the detailed characterisation of size-segregated PM required the optimisation of the analytical techniques because of the small quantities of material to analyse and of the peculiarities of the PM deposits.

Ancillary information on atmospheric dispersion conditions was available by ^{222}Rn measurements and the main meteorological parameters (temperature, pressure, RH, solar radiation, wind speed and direction) were also monitored at the sampling site.

PM1 data will be used to resolve the main sources in the area using Positive Matrix Factorization. This is important to develop suitable and efficient abatement strategies in an area heavily affected by high PM levels.

Results obtained for size-segregated samples will be analysed using the MICRON inversion model aiming at the identification of the size-distribution modes for the different chemical components. These modes can track different formation processes adding useful information to the results obtained by PMF on the PM1 samples.

Factors influencing levels and composition of PM in the Barcelona's city subway system

Querol X.[1], Moreno T.[1], Karanasiou A.[1], Reche C.[1], Alastuey A.[1], Viana M.[1], Font O.[1], Gil J.[1], de Miguel E.[2], Capdevila M.[2]

[1.]Institute of Environmental assessment and Water Research, IDAEA, CSIC, C/ Jordi Girona 18-24, 08034 Barcelona, Spain

Keywords: PM, metro system, air quality, train, indoor, exposure
Presenting author email: xavier.querol@idae.csic.es

An assessment of indoor air quality and passenger exposure in the Barcelona metro focusing on PM levels and their metal contents is presented.

Summer and winter measurement campaigns are carried out in platforms and trains to measure levels of PM10, PM2.5 and PM1. Furthermore, sampling of PM10 and PM2.5 and subsequent analysis of around 40 major and trace components is carried out. The impact of a new and advanced ventilation system, as well as of the platform screen door systems (automated systems consisting of closed rail track and platforms) on indoor air quality are evaluated, to determine whether these systems reduce passenger exposure to PM when compared with conventional systems (open tracks and platforms). To this end measurements were carried out in July 2011 and February-March 2012.

Results show summer PM levels inside the trains amongst the lowest reported for worldwide metro systems (11-32 µPM2.5/m3). This is most probably due to the air conditioning system working in all carriages of the Barcelona metro during the whole year. On the platforms, levels were considerably higher, reaching mean levels of 59 and 88 µgPM2.5/m3 in the new (L9) and old (L3) lines, respectively. PM10 data are also reported in the present study, but comparison with other metro systems is more difficult due to the scarcity of data compared with PM2.5.

The elements with the highest enrichment are those associated with wheel or brake abrasion products (Ba, Fe, Cu, Mn, Cr, Sb, As, Mo, Co, Sr, among others). Laminar hematite (Fe2O3) was the dominant particle type, being mainly originated by mechanical abrasion of the rail track and wheels.

Regarding passenger exposure to PM inside the metro system, the contribution of commuting by metro was estimated to account for around 10% of the daily exposure. Finally, we conclude that the implementation of platform screen door systems results in reductions of both PM levels and metal concentrations, but in addition an advanced optimized ventilation system gave even a much higher efficiency in reducing PM exposure to metro commuters. Combining these two features PM exposure levels in the platforms may be reduced down by a factor of 7 with respect the old subway lines in Barcelona. Thus, full summer ventilation set up implemented from 13th July at S-L9 produces a high air renovation rate, but also higher convective dynamics may cause the resuspension of dust. The ventilation system is very complex and with the data available is not possible to identify the specific features causing the large differences in PM levels measured. In any case, during the first 8 days of measurements, without this summer ventilation set up being fully implemented, the reduction of ambient PM with respect to the conventional L3 line reached a factor of 7.2, but also of 4.2 with respect to the full summer ventilation operation settings at the same S-L9.

Subsequent tests carried out in February 2012 yield similar results concerning the influence of the ventilation system.

The different composition of brake pads of the braking systems of the new lines is responsible for much higher levels (by factors from 5 to 200) of specific metals, such as Ba, As, Sr, Mo, Cu, among others, in the conventional line 3. Low metal specifications for brake pads would reduce considerably exposure to metals of commuters.

The chemical speciation of PM allowed identifying 3 major sources of particles in the metros system: a) Brake wear; b) Outdoor air introduced into the metro; c) Metal wear.

The mineralogical characterization by means of SEM and XRD permitted to identify the presence of laminar hematite (Fe2O3) as the dominant particle, being mainly originated by mechanical abrasion of the rail track and wheels.

Outside urban areas, oxidized organic aerosols (OOA) dominate composition of organic atmospheric particulate matter. In the frame of the EC project EUCAARI and of the Italian project SUPERSITO, the submicron aerosol chemical composition in rural background site of S. Pietro Capofiume, Po Valley, Italy, was characterized by means of proton-Nuclear Magnetic Resonance (^{1}H-NMR) spectroscopy and Aerosol Mass Spectroscopy (AMS) used in parallel with aim of organic aerosol characterization and source apportionment.

The experiments were conducted in 3 different intensive campaigns in different seasons: spring 2008, summer 2009 and fall 2011, representative of very different atmospheric conditions and active sources contributions. Sets of PM_1 filter samples for each of these 3 IOPs were analysed by **^{1}H-NMR spectroscopy** and the resulting collection of spectra was processed using a suite of **Factor Analysis** techniques (Positive Matrix Factorization or PMF, Non-negative Matrix Factorization or NMF, Multivariate Curve Resolution or MCR) aiming to identify recurrent spectral profiles. The contributions of the identified factors to total NMR-detected organics with the help of additional chromatographic measurements of organic and inorganic ions were used to trace the temporal variations of the various organic aerosol types at the sampling location and to identify different prevalent sources. The analysis was applied to water-soluble organic aerosols (WSOA), which is a proxy for OOA.

The comparison of NMR results with those of Positive Matrix Factorization (**PMF**) applied to parallel **HR-Tof-AMS** datasets showed that the NMR factors broadly match with chemical classes already identified by AMS.

On the basis of their spectral profiles and their correlation with organic or inorganic tracers, the identified factors can be characterized as follows: (a) wood burning products, with clear signatures from aromatic phenolic compounds and polyols and showing a good correlation with levoglucosan; (b) one or more WSOA factors showing spectra having less distinguishing features but reflecting a high functionalization degree, similar to those of Humic-Like substances (HULIS); (c) semi-volatile WSOA associated to low-molecular weight alkyl-amines and correlated with nitrate, probably linked with biogenic sources from anaerobic processes and agriculture activity; (d) minor contribution from WSOA associated to Methanesulphonic Acid (MSA), with probable marine origin; (e) compounds bearing oxygenated linear aliphatic structures.

Biomass burning products were clearly major constituents of WSOA in spring and fall seasons. Levoglucosan/OC ratios suggest that more than one factor is needed to account for the whole BB fraction. The best match between total biomass burning fraction of OC estimated from AMS and NMR is found when including an oxygenated fraction of possible secondary origin together with the primary component. Overall, the biomass burning fraction reached 40% of total water-soluble organic carbon during the spring and fall campaigns.

During the summer campaign, the wood burning factor could not be found, whereas the alkyl-amines were still present and the "HULIS" factors increased their contributions (about 60-70% of total WSOC). The latter were clearly enriched in daytime and were present in both polluted and more background conditions indicating that they are mainly associated to low-volatility organic compounds (i.e., AMS OOA1-type) forming from photochemical activity and accumulating in regional pollution.

Another factor which was found to occur in summertime was that of aliphatic compounds, possibly originating from photochemical degradation of unsaturated fatty acids and also linked to a AMS factor with a strong peak at m/z 55, reminding the "cooking organic aerosols" (COA) detected at the site mainly during night time. Concomitant ATOFMS measurements also revealed a unique particle type internally mixed with nitrate and OOA.

Therefore factor analysis applied to NMR atmospheric datasets complement AMS in lumping the complex oxidized organic mixtures into chemical classes characterized by specific sources or ageing states.

Towards an identification of sources of HUmic LIke Substances (HULIS) by statistical analysis

J. Guilhermet[1], C. Piot[1], J. Vessaire[1], C. Baduel[1], J.-L. Jaffrezo[1] and D. Voisin[1]

[1]UJF-Grenoble 1 / CNRS, LGGE UMR 5183, Grenoble, F-38041, France

Presenting author email: guilhermet@lgge.obs.ujf-grenoble.fr

Chemical composition of aerosol can be described with three fractions: inorganic, elementary carbon (also called black carbon) and organic carbon (OC). The radiative effects of inorganic aerosol composed of sulfate, sea salt or mineral dust, and black carbon begin to be reasonably well-known and are now included in several climate models (Carslaw *et al.*, 2010). Conversely, composition and effects on the climate of the Particulate Organic Matter (POM) is still largely unknown.

Until recently, studies of POM failed to assign more than half of the organic carbon measured globally to individual organic compounds (Turpin *et al.*, 2000), suggesting that a significant fraction of OC may be present as oligomeric or polymeric matter. These substances, commonly named HULIS (Humic Like Substances) are oligomeric material with strong polar, poly-acidic, and chromophoric properties. Potential origins of HULIS in the atmosphere are primary sources (e.g. biomass burning) for the winter season and secondary sources for the summer (Baduel *et al.*, 2010). HULIS may strongly affect the radiative properties of aerosol by absorbing light and might have a significant impact on the radiative budget of aerosol (Dinar *et al.*, 2008). Despite their potential impact on climate and the physical and chemical properties of aerosol, HULIS are still poorly documented in terms of concentration, temporal evolution and sources.

Source apportionment of aerosols can be achieved by using statistical analysis like Principal Component Analysis (PCA) or multivariate statistical models such as Positive Matrix Factorization (PMF) both commonly applied to the main chemical components of aerosols or to detailed organic speciation (Viana *et al.*, 2008). In this work, these statistical tools are used with HULIS concentrations and physical characterization, in order to explore their sources.

In a first step, PCA and PMF analysis are applied on the chemical characterization of aerosols for a large database obtained in different environment (urban or rural) and seasons (winter and summer). These chemical data include the main components, organic tracers of sources like levoglucosan (biomass burning tracer), together with HULIS concentrations. In second step, physical characterization of HULIS (UV absorbance at several wavelengths) is also integrated in statistical analysis. Specific absorbance and ratios of particular wavelengths give indications on the chemical structure (aromatic and/or aliphatic) of HULIS (Fig.1) and can also be considered as indicator of the origin of HULIS (Baduel *et al.*, 2010).

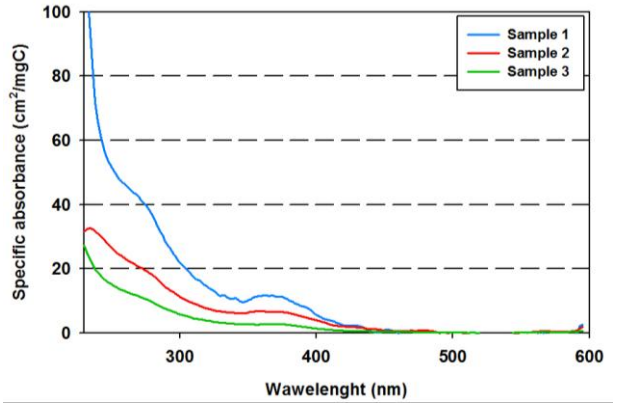

Figure 1. Specific absorbance for three different HULIS ice core samples.

The first results of the statistical analysis indicate very large changes in the associations between the various chemical indicators and HULIS, depending upon the season and location. For exemple, changes in the aromaticity of the HULIS are linked with the levoglucosan content, a good indication of the impact of biomass burming emissions on this type of complex organic matter.

In the presentation, results obtained for the complete set of statistical analyses on data of chemical composition and physical characteristics of HULIS in the different environments and seasons will be detailed and discussed. A comparison between PCA and PMF results will also be presented.

The authors would like to acknowledge the support of several funding agencies, including ADEME, LCSQA, Région Rhône Alpes, for the funding of programs that allowed the construction of this data base.

In the production of consumer goods and building materials the use of nanomaterial as additives becomes more and more common. High-tech applications like printed electronics and solar-cells as well as daily life products like toothpaste and cosmetics are enhances by addition of e.g. TiO_2, ZnO, carbon spheres or tubes, and silver particles. Especially in the production environment, where large amounts of nanomaterial is handled and substantial exposure is possible, monitoring of the air quality is an important issue in respect to further use of this technology. In the production industry, a demand for personal monitors to assess the exposure of workers towards these particles undoubtedly exists (Tsai et al, 2011). Unlike a conventional particle counter, such a device must be small and lightweight, and the sensor and the electronics must be simple enough to allow a mass production at low costs.

Simple collection of the particles on filters or impactors offers an affordable solution to this, but requires complex laboratory analysis and can cannot provide timely warning in case of increased concentrations in the surrounding environment.

A MEMS (micro-electromechanical system) based approach was proposed to weigh extremely small particles (Hajjam 2010). This concept was developed further to design a particle detector for use in personal monitors. A joint project (NANOEXPO) examines the possibility of use thermally excited cantilevers as sensors for ultrafine particles. The project aims towards developing a small personal dosimeter-like sampler that collects and weighs ultrafine particles over a work shift.

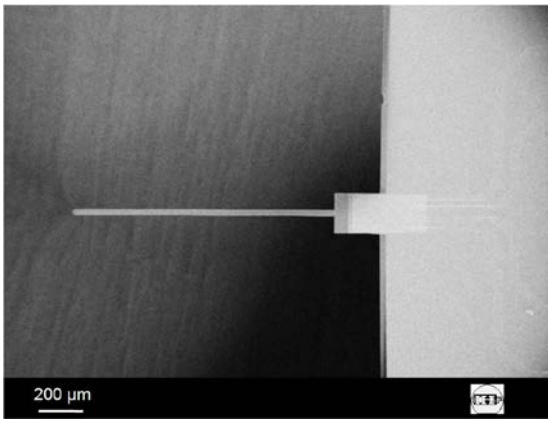

Figure 1. The cantilever sensor.

A slender geometry (Figure 1) allows for a very sensitive detection of particles impacting on the cantilever. After manufacturing the first prototypes of the sensor, and providing proof-of-principle measurements, work is on-going to further improve the sensitivity of the microbalance, to integrate part of the excitation and sensing electronics, and to construct a sampler case with defined flow field around the sensing cantilever.

The following section highlights a number of achievements of the project at the current state.

Results

Cantilevers of different sizes and geometries were tested in regard to their particle collection and sensing efficiencies. Current experiments are carried out with silicon-based cantilever-type resonators with fully integrated Wheatstone bridge piezo-resistors for signal read out.

To test the microbalances, test aerosols were generated in a 1 m³ environmental test chamber by nebulizing a suspension of e.g. carbon nanoparticles (< 30 nm) in water/butanol using a constant output atomizer (TSI 3076), followed by a dryer. Particle number concentration and size distribution is controlled by a fast mobility particle sizer (FMPS, TSI 3091). To improve the collection efficiency, the sensor was mounted on a nanometer aerosol sampler (TSI 3089) – at later stages, the collection voltage will be supplied by the sampler electronics.

Using the second resonant mode, a mass sensitivity of 32.7 Hz/ng was found. Detection limits of less than 1 ng can be achieved with current prototypes under climatic standard conditions and normal pressure.

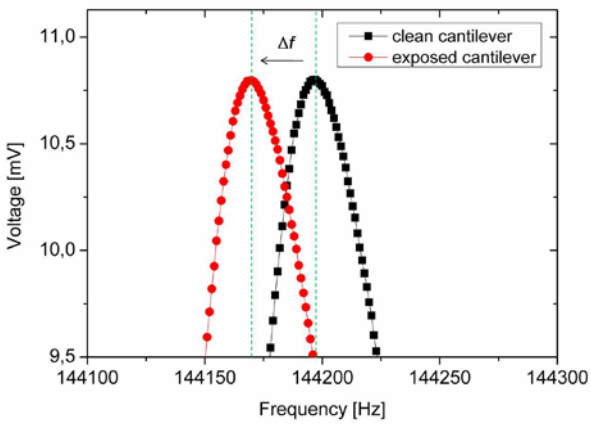

Figure 2. Frequency shift measured with a prototype cantilever (black line: clean cantilever; red line: exposed to carbon aerosol (5000 #/cm³) for 15 min.

Particles were collected predominantly at the tip and along the edges of the cantilever (Figure 3). An improved design of the field around the cantilever will be used to increase the sampling efficiency and to focus the particles deposition to the tip of the cantilever.

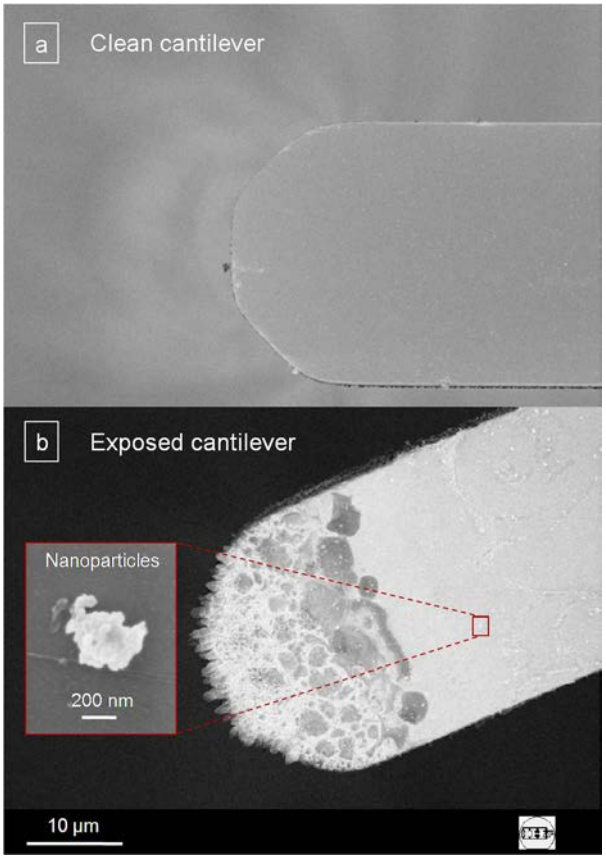

Figure 3. Cantilever tip (a) before and (b) after exposure to airborne carbon particles.

In a next step possible climatic interferences on particle sensing were studied: Temperature and relative humidity were expected to impact on the performance of the sensor. Variation of pressure, temperature and relative humidity during operation of the sensor revealed a minor cross sensitivity: Temperature changes of 2 K, pressure changes of 20 kPa, and relative humidity changes of 10 % during the measurement cycle would lead to an uncertainty of 15% with the current prototypes (Wasisto et al., 2012). Slower climatic changes that extend over several measurement cycles are less critical. Considering a measurement cycle time of only 15 to 30 min, the cross sensitivity is not critical for the workplace environment.

Currently, a sensor case with integrated fan is designed and tested. The main development targets are an optimized air supply to the sensor and a defined electrical field to improve particle collection (Figure 4).

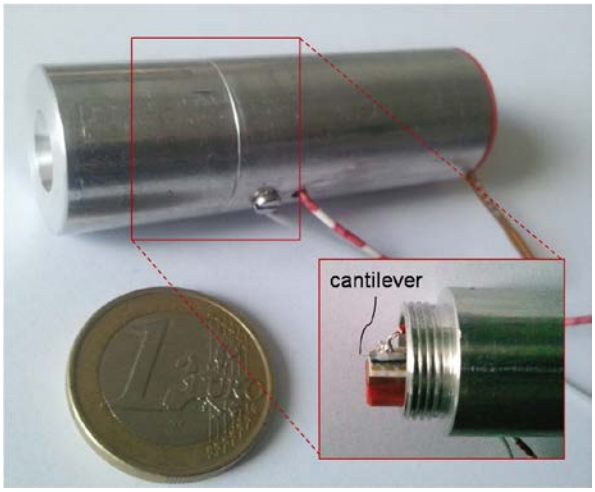

Figure 4. The sensor case with integrated fan.

Conclusion

At the current development stage the microbalance-detector prototypes show a mass-sensitivity sufficient to allow for 15-minute measurement cycles if the (preferred) second resonant mode is used for sensing. A mass resolution below 1 ng can be reached under typical indoor conditions, and the cross-sensitivity in regard to environmental changes is in an acceptable range. Evaluation the performance of the sensor towards a selection of industrially relevant nanoparticles (TiO_2, Silver, Carbon, SiO_2, PTFE) is still on-going, and a number of integration steps have to be finished before the sensor/sampler can be tested under more realistic conditions.

Physical defect formation in few layer graphene-like carbon on aerosol-made metal nanoparticles

Magnetic nanoparticles are used in a multitude of research areas. Comparably high and readily available specific surfaces combined with the ease of separation (Grass 2007) due to very high saturation magnetizations make aerosol-derived carbon-metal nanomagnets promising candidates as precious metal extraction agents (Rossier 2009) and in magnetic chemistry where a reagent is linked to a nanomagnet (Schaetz 2010). Furthermore, the feasibility as cleaning agents of complex liquids such as blood has been demonstrated (Herrmann 2010). The chemical stability in conjunction with a high saturation magnetization is a decisive parameter for a broad range of practicability.

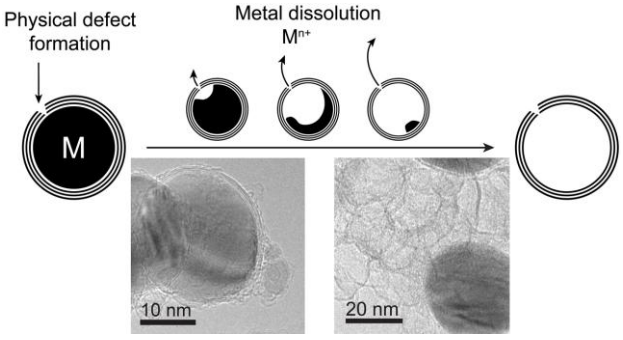

Figure 1. Physical defect formation on a metal-carbon nanoparticle leads to fast release of core-material into the surrounding solution. The prevalent mechanism results in empty graphene-like carbon-nanoshells with possibly one specific shell defect in the size of a few carbon atoms.

A systematical examination of the chemical stability of cobalt metal nanomagnets with a graphene-like carbon coating was used to study the otherwise rather elusive formation of nanometer sized physical defects in few layer graphene as a result of acid treatments (Schumacher 2012). The release of metal into the solutions over time offered a simple tool to monitor the progress of particle degradation and therefore to determine the prevalent mechanism of physical defect formation. The suggested mechanistic insight was further confirmed by the covalent chemical functionalization of the particle surface with chemically inert aryl species, which leads to an additional thickening of the shells. The possibility to prepare well-defined shells or containers combined with the new findings may provide attractive tools to material sciences.

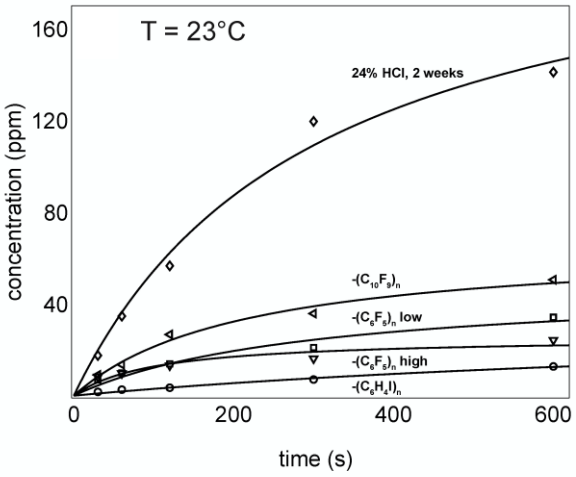

Figure 2. Metal release rates into acidic solutions at pH = 2 as a simple tool to observe the physical defect formation rate. Compared to non-functionalized particles (washed in 24% HCl, 2 weeks) the physical defect formation rate shows a strong dependence on the carbon-shell thickening when inert chemical aryl species (pentaflurobenzene, nonafluorobiphenyl and iodobenzene) are attached to the graphene-like surface by the use of aqueous diazotation.

Measurement of the velocity of nanoparticles in a molecular beam of a particle mass spectrometer

W. Baumann, H. Mätzing, J. Seibold, M. Hauser, H.-R. Paur and H. Seifert

Institute of Technical Chemistry (ITC), Karlsruhe Institute of Technology (KIT)

Presenting author email: w.baumann@kit.edu

The size distributions of primary nanoparticles synthesized in plasmas (Paur, 2005) or flames (Mätzing, 2012) were measured using a particle mass spectrometer (PMS), which was developed for low and atmospheric pressure applications. The size range of the spectrometer is from 1 to 25 nm and for number concentrations between 10^9 and 10^{13} cm^{-3}. The microwave plasma burns under low pressure conditions in the range between 10 to 150 mbar. The maximum process pressure depends on the carrier gas. Silica nanoparticles were generated in a microwave plasma discharge, using Silane as precursor. Further, the microwave plasma with Argon and Helium as carrier gas with a flow rate of 4 slpm and 50 ppm Silane were operated.

The particles were sampled without prior dilution, 40-140 ms behind the plasma region with a molecular beam technique of a two-stage nozzle arrangement. With this sampling technique the inlet stream is rapidly quenched and, in particular, all particle–gas interactions are minimized which allows the measurement of particles with high concentration. A high fraction of the nanoparticles are charged in the microwave plasma, therefore, it is not necessary to ionise particles in the spectrometer. The charged particles are deflected according to the m/z ratio by an electric field in the spectrometer. The deflection voltage (U) is proportional to the ratio of the kinetic energy of the particles and the number of charges ($U \sim ½\ m\ v^2/z$). For positively and negatively charged particles Faraday cups are located symmetrically left and right of the centre line at the end of the detection chamber with defined deflection angle. By varying the deflection voltage, particles of different energy-to-charge ratio are collected at Faraday cups. The current detected at the Faraday cup is proportional to the incoming number of particles times their total charge, which is measured with a highly sensitive amplifier. The raw data give the energy distribution and can be converted with knowledge of the particle velocity and the material density. Primary particles from flames and plasmas are usually singly charged with a narrow particle size distribution.

The advantage of PMS is the simultaneous measurement of the signal intensity and the flight time of the particle with a lock-in amplifier. The PMS works with an electrostatic chopper technique to get a chopped particle beam and the deflected particle beam hits the Faraday cups periodically with a known frequency. The lock-in amplifier measures the flight time difference between triggering of the capacitor voltage and the detection of the particle signal at the Faraday cup as a phase shift. The phase shift grows proportional with the frequency of the particle beam modulation and to get a good resolution for the simultaneous measurement of the phase shift and the signal intensity, the particle beam is chopped with a frequency in the range of 1 kHz.

In this study, we report about our investigations of measuring the velocity of nanoparticles in the molecular beam of the PMS. The particle size of the silica nanoparticles generated in the microwave plasma discharge depends on the pressure in the plasma zone and the precursor concentration. Figure 1 shows the velocity and mean particle diameter of SiO_2 nanoparticles in the molecular beam of the PMS as function of the pressure with Argon and Helium as carrier gas. Our investigations show that the particle velocity depends mainly on the pressure (p_o) in front of the inlet nozzle. SiO_2 nanoparticles synthesised in microwave plasma with 4 nm, operated at 25 mbar have particle velocity of 400 m s^{-1} with Argon, whereas 650 m s^{-1} with Helium. With Argon as carrier gas the particle velocity and the particle diameter increases nearly linear with the pressure. With Helium as carrier gas the particle velocity was higher than with Argon and nearly independent from the particle diameter.

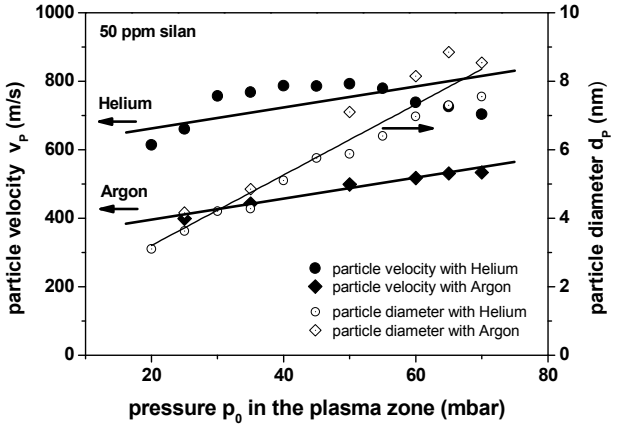

Figure 1. Particle velocity and particle diameter as function of the pressure (p_0)

There are many possibilities for generating aerosols containing particles between 5 and 100 nm at production rates around 1 g/hr. Characteristic for these processes it is that the particles are polydisperse due to Brownian motion, leading to a theoretic lower limit for the geometric standard deviation around 1.45. Thus, size fractionation is needed for applications requiring a narrower distribution than given by this theoretical limit.

The scalability of the particle-size selection technique based on Differential Mobility Analyzer (DMA) was demonstrated before (Hontañón and Kruis, 2008 and 2009) for aerosol and sheath flow rates as large as 0.1 and 1 m^3min^{-1}, respectively. In this work we describe a pilot plant (BigMAG - Big Monodisperse Aerosol Generator) for high-yield delivery of size-selected nanoparticles. Basically the facility consists of a plasma reactor for the generation of bipolarly charged nanoparticles up to 100 nm, a novel DMA of parallel plate electrodes (MegaDMA) developed by RAMEM, a particle collector, recirculation lines with cooling units for the aerosol flow (up to 1 m^3min^{-1}) and sheath flow (up to 10 m^3min^{-1}) and precision laminar flow elements (LFE) for monitoring the flow rates (figure 1).

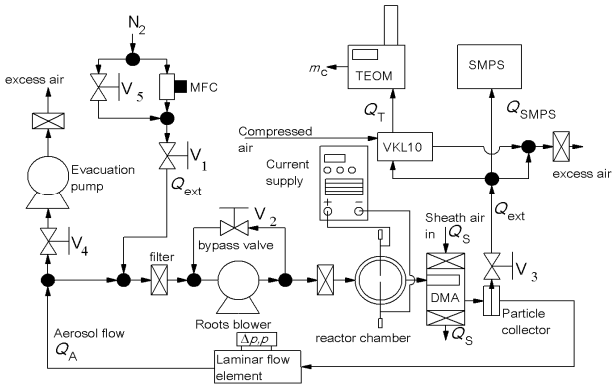

Figure 1. Layout of the aerosol recirculation line.

The quality of the size fractionation is monitored by means of a SMPS and mass production rate is recorded online by a TEOM. We were able to realize geometric standard deviations σ_g less than 1.10 after size classification with aerosol flow Q_A to sheath air flow Q_S ratios of 1/3 and 1/5 (figure 2). Monodisperse silver nanoparticles were delivered at a flow rate of 200 slm. With a Q_A/Q_s ratio of 1/3, the number concentration of particles in the gas was of about 10^5 cm^{-3} (table 1), while the mass yield varied from 10 µg/h to 1 mg/h, depending upon the particle size.

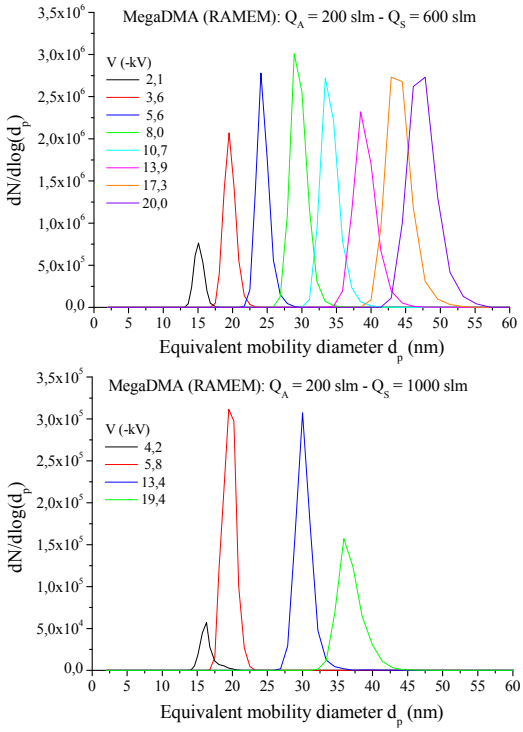

Figure 2. Number size distributions of size-selected silver nanoparticles at Q_A/Q_s ratios of 1/3 and 1/5.

Table 1. Number concentration, mean diameter and standard deviation of size-selected silver nanoparticles.

Direct Transfer and Stabilization of Aerosol Particles into Liquid Suspensions by Means of a Wet Electrostatic Precipitator

C. Anderlohr[1], K. Schaber[1], W. Gerlinger[2]

[1]Institute of Technical Thermodynamics and Refrigeration, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany
[2]BASF SE, Ludwigshafen, Germany
Keywords: Combustion Synthesis, Wet Electrostatic Precipitation, Dispersion, Stabilization, Nanoparticle Deagglomeration
Presenting author email: christopher.anderlohr@kit.edu

Nanoparticles produced by gas phase processes are usually precipitated in (baghouse-) filters forming a more or less agglomerated powder.

However, in many cases the final application of these particles is not as a powder but as a liquid suspension, i.e. printable electronics, heterogenous catalysis, paints etc. This necessitates the dispersion of the particles into a liquid before use.

Due to the increase of inter-particle forces with increasing specific surface area and decreasing particle size, dispersing and deagglomerating these powders become more and more energy consuming, as particle size is reduced. In some cases complete deagglomeration is nearly impossible (Mandzy, 2005). Furthermore, handling of fine powders is somewhat difficult since unlike liquids distribution of powders through pipes is quite complex. In addition there is always the danger of exposure to particle aerosols due to dusting.

In this work the direct transfer and stabilization of SiO_2 and TiO_2 nanoparticles generated by a lab scale flame reactor into stable liquid suspensions by means of a wet electrostatic precipitator (WESP) is studied.

Wet electrostatic precipitation is an energy efficient possibility for gas cleaning with high removal efficiencies. WESPs are employed in numerous industrial applications, i.e. the control of acid mist, the precipitation of sticky or high resistivity aerosol particles, or when fire hazard is an issue. Recently, there have also been approaches of using WESPs for emission control of diesel particulate matter from stationary diesel generators. Other than in dry type electrostatic precipitators particles collected on the precipitation electrode are not removed by intermittent rapping, but are washed off by a liquid flushing the electrode. In these processes the precipitated particles are usually removed from the flushing liquid before it is redistributed onto the collection electrodes (Parker, 1997; Saiyasitpanich, 2007).

The aim of our approach, rather than removing the particles from the liquid, is to produce a stable suspension of product particles, which can be used directly for its later application.

Before the precipitation onto a filter the aerosol particles in the gas phase in our setup show little to no agglomeration. Thus, if the single particles can be precipitated directly into the liquid, no additional energy for dispersion and deagglomeration is necessary. During the transfer into suspension particles can be stabilized and protected against agglomeration and other degrading effects.

This makes the step of dispersing powders unnecessary and eliminates the need of powder handling. Also, the risk of exposure is greatly reduced, since the nanoparticles are contained within a liquid.

Stabilization is investigated by means of adjusting the pH-value of the circulated liquid as well as by addition of different stabilizing agents. The Particle size distributions (PSD) in the liquid phase are measured by Photon Correlation Spectroscopy (PCS) and compared to the SMPS-measurements of the aerosol size distributions (Fig. 1). In order to evaluate the process' effectiveness, the suspensions obtained from the WESP are compared to suspensions from the respective particles in powder.

An Aerosol Process for Fabrication of a Carbon NanoTube Membrane with Tuneable Pore Size

M. Valenti[1], A.C. Zonnevylle[2], V. Vons[1], C.W. Hagen[2], R. van Ommen[1] and A. Schmidt-Ott[1]

[1] Chemical Engineering, Delft University of Technology, Delft, 2628 BL, The Netherlands
[2] IST, Delft University of Technology, Delft, 2628CJ, The Netherlands
Keywords: Metal nanoparticles, Carbon Nanotubes, Membrane
Presenting author email: M.Valenti@tudelft.nl

We introduce an aerosol process combined with Chemical Vapour Deposition (CVD) for fabrication of membranes with equal-sized and size controllable Carbon NanoTubes (CNTs) forming the pores. Membranes have various applications, e.g. in separation processes in chemical industry. A CNT membrane is of special interest for water desalination in a reverse osmosis process, as CNTs around 2 nm in diameter have shown the highest H_2O permeabilities by far with respect to both porous and non-porous membranes (Humplik, 2011). The low salt rejection (~ 60%) achieved to date is due to the non-uniformity of the CNT pores, and it is a goal of the present project to improve this behaviour by gaining full control over the CNT diameter using aerosol processes.

We produce equally sized metal nanoparticles, which serve as catalysts for CNT growth in a CVD reaction. We demonstrated that the CNT diameter is fully controlled by the catalyst diameter under suitable conditions.

Methodology

A monodisperse aerosol of positively charged Pd nanoparticles is generated by means of a Glowing wire (Peineke et al.), and this nanoparticle source is coupled to a Differential Mobility Analyser (DMA). The size selected aerosol of unipolarly charged particles is forced through a porous alumina membrane, and the particles deposit inside the pores. Separate experiments on depositing unipolarly charged particles on insulating material show that there is no agglomeration of particles on the substrate. The deposited particles keep their charge for a while, and Coulomb repulsion avoids that other particles deposit on top of them. This effect is essential for production of uniform CNT diameters. The nanoparticles are typically 20-30 times smaller than the diameter of the alumina pores. The membrane is then transferred to a CVD reactor where each deposited Pd nanoparticle catalyzes the growth of one CNT inside the alumina pores. The alumina pores guide the CNTs to align in the same direction. Subsequently, all gaps inside the alumina pores are filled with low-pressure chemical vapour–deposited Si_3N_4 and etched to expose the CNT's tips and to remove the catalyst nanoparticles.

Results

As shown in Figure 1, nanoparticles of 20 nm were successfully deposited inside the alumina pores with a penetration depth of about 1 µm. Using smaller particles, CNTs with an approximate internal diameter of about 3 nm were grown and vertically aligned.

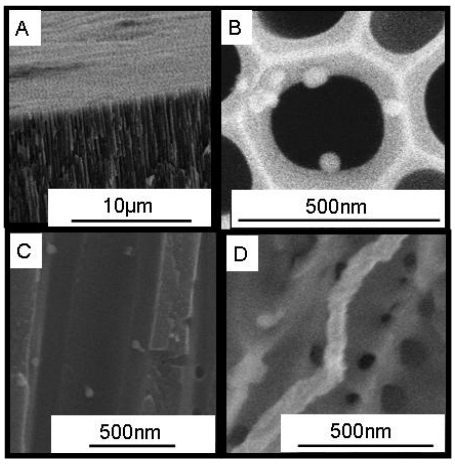

Figure 1. SEM images of A) Edge of the alumina membrane. B) Top view of a single alumina pore with deposited nanoparticles. C) Lateral view of the cross section of a single alumina pore with deposited nanoparticles. D) Vertically aligned CNT.

Conclusions

We have demonstrated that gas phase production of catalyst particles followed by non-agglomerated deposition within alumina pores enables aligned growth of the CNTs within these pores and fabrication of a membrane. The results presented here are seen as a decisive step towards a scalable fabrication of a CNT membrane with a uniform tuneable CNT inner diameter (pore size).

Keywords: Aerosol fundamental, nanoparticles, Ion Mobility, Polarization
Presenting author email: clarriba@umn.edu

In both, field and laboratory settings, the most ubiquitously employed technique for the physical characterization of sub 10-nm aerosol particles is the separation of particles by their electrical mobilities, Z_p. Such particles fall within the momentum transfer free molecular regime, for which the electrical mobility can be expressed as (Mason & McDaniel, 1988):

$$Z_p = \sqrt{\frac{\pi m_{red}}{8kT}}\frac{3ze}{4\rho_{gas}\Omega} \qquad (1a)$$

where m_{red} is the reduced mass for the gas molecule and particle, k is Boltzmann's constant, T is the temperature, z is the net number of excess (positive or negative) charges on the particle, e is the unit electron charge, ρ_{gas} is the gas volumetric density, and Ω is the particle's collision cross section. In the examination of aerosol particles with the common approximation that particles are spherical, following Epstein (Epstein, 1924) and Fernandez de la Mora et al (Fernandez de la Mora et al., 2003), the collision cross section is in turn expressed as:

$$\Omega = \frac{\pi}{4}\xi\left(d_p + d_g\right)^2 \qquad (1b)$$

where d_p is the particle mobility diameter, d_g is the gas molecule diameter (also assumed spherical), ξ is a gas molecule-particle momentum transfer coefficient, and electrical mobility measurements are used to infer mobility diameter with (1b). From mobility measurements in air and N_2, and for varying particle chemical compositions, use of (1b) with ξ = 1.36 and d_g = 0.3 nm leads to inferred d_p values in excellent agreement (within 1-2%) of the particles' volume equivalent diameters (Larriba et al., 2011), down to $d_p \approx 1.3$ nm.

In spite of near-universal observed applicability of (1b), there are pending issues to be resolved with this equation. First, a theoretical basis for ξ = 1.36 is necessary. Deriving from Epstein (1924), the origin of ξ has been attributed to two modes of gas molecule scattering upon impinging on the surface of a particle: (1) specular reflection (deterministic angle and conserved gas molecule kinetic energy) collisions with the assumption that the particle surface is completely smooth, and (2) diffuse/inelastic scattering (random angle with the gas molecule energy resampled from a Maxwell-Boltzmann distribution at the particle temperature as in a perfect thermal conductor). Completely specular collisions lead to ξ = 1.00, while the diffuse model leads to $\xi = 1+\pi/8$. In line with these two collision types, to the present day it has been assumed that $\xi = 1+\pi\alpha_t/8$, where α_t, the accommodation coefficient (i.e. the percent of collisions which are diffuse in nature), must equal 0.91 to lead to the correct ξ (Friedlander, 2000). As ξ = 1.36 is found to apply for particles of all chemical compositions without exception, however, we posit here that the two type collision model of Epstein is only a fit to experimental results; on the contrary, we propose that there is a single description of gas molecule-particle collisions which leads to ξ = 1.36. This description relies on the vibrational modes of freedom of the molecule itself. The fact that it is constantly vibrating allows for an accommodation equivalent to (2) but where all collisions are considered elastic in nature. At the same time, the translational kinetic energy close to the particle is lowered due to an increase in the number of collisions and thus an increase in internal energy. This effect, reminiscent and opposite of the Joule-Thomson effect, causes a decrease in the momentum of the emitted particles and thus leads to a universal 1.36.

The second concern with (1b) is the origin of the deviation between the mobility diameter and the volume diameter for d_p < 1.3, particularly given the recent interest in particles in this size range. Below this size, the mobility diameter is consistently found to be larger than the volume diameter, i.e. there is more drag on the particle's than anticipated with (1b). The most likely origin of this deviation is an enhanced number of collisions with gas molecules due to the attractive polarization (induced dipole) potential between gas molecules and particles. (1b) applies only for hard-sphere interactions, and despite some theoretical effort to calculate particle mobility accounting for potentials (Tammet, 1995), an analytical expression analogous to (1b) but accounting for gas molecule polarization (enabling its use for particles with sizes 1.3 nm) remains undeveloped. We derive such an expression analytically here and confirm its validity through trajectory calculations of gas molecule-particle scattering accounting for polarization as shown in Figure 1 for ξ=1:

$$Z_{pol} = Z_p/\left(\xi\left(1+\frac{U_p(d_p)}{6kT}(1+1/\xi)\right)\right) \qquad (1c)$$

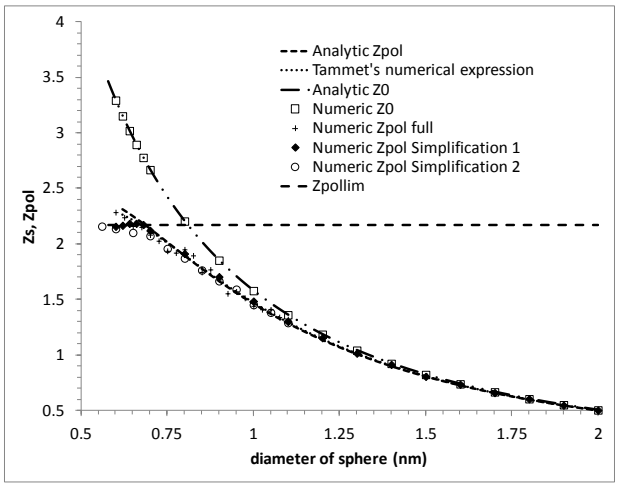

Figure 1. Analytic and Numerical prediction of a particle with and without Mobility for ξ=1. Mobility is shown in cm^2/Vs

Estimation of the aerosol optical depth in the UV region at Cáceres (Spain) by the Ångström formula

M.A. Obregón[1], A. Serrano[1] and M.L. Cancillo[1]

[1]Department of Physics, University of Extremadura, Badajoz, Extremadura, 06006, Spain
Keywords: atmospheric aerosols, UV, CIMEL, optical depth.
Presenting author email: nines@unex.es

In recent years, the interest in studying the aerosol properties (such as aerosol optical depth, τ) in the ultraviolet range (UV) has notably increased. This interest is enhanced by the importance of atmospheric aerosols in the atmosphere attenuation of solar UV radiation (Liu et al., 1991). Thus, in certain cases, the variation in UV radiation caused by changes in aerosol optical depth can be of similar magnitude than that due to changes in ozone content (Jaroslawski and Krzyscin, 2005). In spite of its high interest, there are no measurements of aerosol properties in the UV range until very recent times. These measurements have been notably rare because they require an accurate calibration which has not been always available. Currently the τ at ground level is widely measured at visible and infrared wavelengths but not in the UV range. Therefore, the purpose of this work is to estimate aerosol optical depth values in the UV range based on the spectral measurements of aerosol optical depth in the visible and infrared range at Cáceres, Spain, given by the CIMEL sunphotometer installed at the AERONET station of Cáceres. This instrument also measures the optical depth in the UV range (specifically at 340 and 380 nm), which will allow for the validation of the estimated τ values.

Thus, the aerosol optical depth at 340 and 380 nm is estimated by extrapolating the measurements obtained for the channels in the visible and infrared ranges, i.e. 440, 550, 675, and 870 nm. The extrapolation is performed following the well-known Ångström formula $\tau_a(\lambda)=\beta\,\lambda^{-\alpha}$. The α and β coefficients are calculated by a least-square fit on a log-log plot scale of the experimental optical depth in the visible and infrared range versus the wavelength. According to the recommendations by Cachorro et al., (2000), the range of wavelengths between 440 and 870 nm has been used.

This procedure has been applied to the spectral measurements of τ in the visible and infrared range at Cáceres, during the period from July 2006 - July 2008. The estimated τ (340 and 380 nm) values have been compared with those measured by CIMEL at the same wavelengths (Figure 1 and 2, respectively). In addition to the generally good performance shown by the estimations, the results indicate that at 340 nm, estimated τ values are generally higher than those measured by the CIMEL. The reason is the dependence of Ångström coefficient with wavelength, since decreases towards the shorter wavelengths (Jaroslawski et al., 2003).

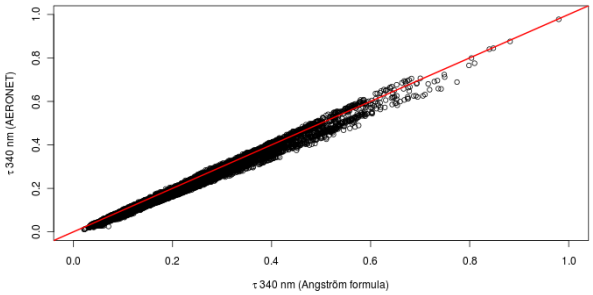

Figure 1. Comparison of τ at 340 nm measured by the CIMEL and estimated by Ångström formula.

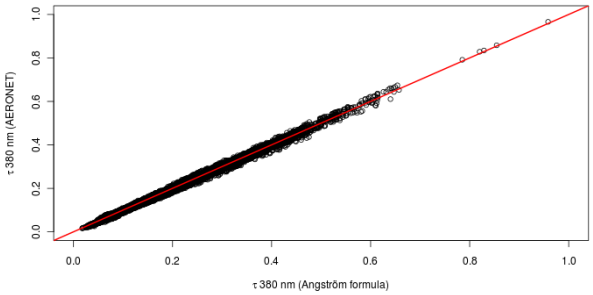

Figure 2. Comparison of τ at 380 nm measured by the CIMEL and estimated by Ångström formula.

The above mentioned results suggest that Ångström turbidity coefficients calculated by a least-square fit in the visible-infrared range can be successfully used to estimate the optical depth at the UV range in Cáceres.

Presenting author email: patternizer@gmail.com

Radiative-forcing by aerosols is the most important and most uncertain of all Earth climate, direct radiative-forcing estimates (IPCC Report, 2001). Reducing this uncertainty calls for the expansion of worldwide aerosol measurements and studies in order to characterize different types of aerosols and sources. Aerosols are characterized by their microphysical properties (AMPs): the aerosol size distribution a_i (in each i^{th} size bin) and complex refractive index Z (Hansen and Travis, 1974), which are accurately retrieved from ground-based instruments (Holben et al., 1998). Unfortunately, their global resolution is very uneven – being densely-situated in industrialized areas and sparsely-located elsewhere.

We report on the initial phase of *AEROMAP* - a new EU-funded project designed to map the global distribution of aerosol microphysical and optical properties (AOPs) by capitalising on the full-Earth coverage provided by satellite remote sensing instruments like MODIS in conjunction with the accuracy provided by ground-based AMP and AOP retrievals provided by AERONET. Figure 1 shows the 5 steps adopted for implementation of *AEROMAP*.

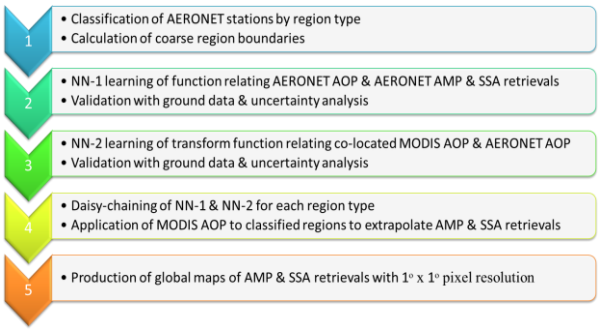

Figure 1. The stepwise implementation of *AEROMAP*.

In step 1, data pre-processing involves the application of a cluster analysis algorithm (Omar et al 2000) to AERONET data and the use of Gobbi coordinates (Gobbi et al., 2007) to classify aerosol regions by type. A nearest neighbour algorithm is used to establish regional boundaries. In step 2, multiple-input multiple-output (MIMO) universal function-approximating artificial neural networks (NN) are trained at selected sites for each aerosol region type. The NN inputs include: the aerosol optical depth (*AOD*) at four wavelengths in the visible wavelength range, the Ångström Exponent (*AE*) at visible wavelengths, and the fine mode fraction (η). The NN outputs include the AMP and SSA retrievals. An indicative NN architecture is shown in Figure 2. To train the NN, AERONET level 2 AOP and AMP products are used, as this data is cloud-screened and available daily.

NNs trained for each aerosol region type are evaluated by: a) analysing uncertainties using the AERONET AMP and SSA retrievals for the training periods, b) validating NN-derived AMPs and SSA for non-training periods using the corresponding AERONET products, c) validating NN results against AERONET products at different sites of the same aerosol type. The results allow assessment of the potential of such NN-derived AMP and SSA retrievals for each aerosol region type.

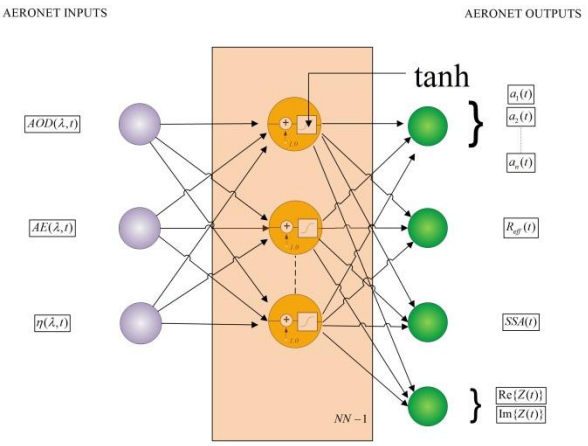

Figure 2. The architecture of the NN in step 2.

Aerosol fine fraction characterization by integrated in-situ and columnar measurements.

M. Calvello[2], F. Esposito[1] and G. Pavese[2]

[1] DIFA- Università della Basilicata, C. da Macchia Romana, 85100, Potenza, Italy
[2] CNR-IMAA, C. da S. Loya, 85050, Tito Scalo (PZ), Italy
Keywords: black carbon, fine fraction mass, columnar properties.
Presenting author email: calvello@imaa.cnr.it

Atmospheric aerosol optical and physical properties have been studied in a semi-rural site in Southwest Italy (Tito Scalo, 40° 35' N, 15° 41' E, 750m a.s.l), not continuously, during 2008, 2009 and 2010 by integrating surface and columnar measurements.

In-situ measurements have been carried out by a 13 stages DLPI impactor (0.03 to 10.0 μm) and an AE31 aethalometer (7 wavelenghts from 370 to 950 nm), while columnar ones by a high resolution (1.5 *nm*) spectroradiometer Ocean Optics (spectral range 400*nm*-800*nm*).

The measurements site belongs to the Mediterranean basin, a very complex area to investigate due to the mix of aerosols originating from different sources as such as marine particles from both Mediterranean Sea and Atlantic Ocean , dust particles from Sahara desert, polluted and smoke aerosols from continental Europe.

The combined use of impactor mass-size distributions, Black Carbon (BC) concentrations from aethalometer and optical parameters from radiometer, could deeply describe all these different aerosol types (Calvello *et al*., 2010). Focusing the attention on the particulate fine fraction, BC is an important component at ground as shown in Figure 1 where surface fine fraction mass M_1, as obtained from DLPI measurements, has been compared with values of BC (surface Black Carbon concentration, 880nm) for the entire period.

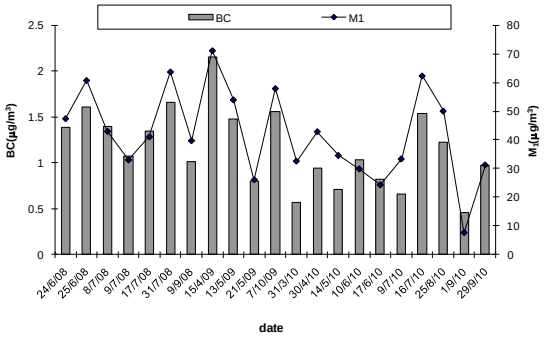

Figure 1. Temporal variations of M_1(daily averaged surface fine fraction mass), and of BC (surface black carbon concentration, 880nm, averaged out over contemporary measurements hours).

The BC concentration daily trend for working days is characterised by two peaks coinciding with rush hours. A less regular behaviour has been found for week-end days without definite modes and with lower concentrations on the whole. This suggests the local traffic to be the main source of black-carbon at the site. But BC concentrations enhancement has been found for pollution long-range transport events (25 June and 31 July 2008, and 15 April 2009 in Fig. 1) when daily trends are lost and minimum concentration threshold is shifted to higher values also for week-end days.

These pollution events, associated with air mass transport from continental Europe, have been identified from radiometric measurements too, with an increase of α parameter and of AOD @ 500 nm. Moreover, even columnar volume size distributions from inverted direct solar radiance, show a prevailing fine mode in all these cases.

Looking at all the measurements dataset, a better agreement has been found, between in-situ and columnar data, in the case of anthropogenic transported and local produced fine particle loading, than in the case of Saharan dust intrusions. In this last case, coarse dust particles seem to affect columnar data in a more intense way than surface ones, thus revealing an underestimate in coarse particle detection at ground level (Lyamani *et al*., 2008). Good agreement for anthropogenic and back-ground aerosols suggests that in these cases, surface aerosols optical properties dominate columnar integrated data.

SPEX: Multi-Angle Spectro-Polarimetry for Aerosol and Cloud Characterization from the ISS

O.P. Hasekamp[1], M. Smit[1], J. Rietjens[1], F. Snik[2], G. van Harten[2] & the SPEX team*

[1] SRON Netherlands Institute for Space Research, Sorbonnelaan 2, 3584 CA Utrecht, the Netherlands
[2]Sterrewacht Leiden, Universiteit Leiden, Niels Bohrweg 2, 2333 CA Leiden, The Netherlands;
Keywords: aerosols &clouds, climate, remote sensing, polarimetry.
Presenting author email: O.Hasekamp@sron.nl

We present the SPEX instrument that is designed to perform multi-angle spectro-polarimetric observations from a low earth orbit satellite in order to derive aerosol and cloud properties in the Earth atmosphere. The effect of anthropogenic aerosols represents the most uncertain factor in the climate system. Aerosols affect the climate directly by scattering and absorption of solar radiation and indirectly by changing the properties of clouds. Here, the effect of aerosols on cloud properties is considered the largest yet most uncertain aerosol climate effect. To improve the estimate of the aerosol effect on clouds and climate, accurate satellite based measurements of aerosol microphysical and optical properties, as well as cloud properties, are required. The SPEX instrument is designed to provide these measurements. SPEX has been proposed in response to the Announcement of Opportunity for International Space Station Experiments relevant to the study of Global Climate Change.

Instrument description

In order to derive the relevant aerosol and cloud properties with accuracy sufficient for climate research, multiple-viewing-angle, multiple wavelength measurements of the intensity as well as the Degree of Linear Polarization (DoLP) of the light reflected by the Earth atmosphere are essential. SPEX will measure intensity, degree- and angle of linear polarization of scattered sunlight between 400 and 1600 nm, sampling each ground pixel with 25-30 viewing angles. SPEX' novel polarimetric technique allows for achieving the extremely high polarimetric accuracy (0.001+0.005DoLP) needed to derive aerosol properties with sufficient accuracy for climate research [Hasekamp and Landgraf, 2007]. SPEX' relatively high spectral resolution enables resolving the spectral feature of the O2-A absorption band, which is important for deriving aerosol and cloud height. SPEX' large number of viewing angles enables resolving the angular features resulting from light scattering by aerosol and cloud particles, and to distinguish between these types of particles.

The novel polarimetric measurement approach works as follows [Snik et al., 2009]: Incoming linearly polarized light passes through a set of birefringent polarizing crystals which, combined, result in an intensity spectrum that has the degree of polarization coded onto it as an amplitude modulated signal. The depth of the modulation is proportional to the degree of linear polarization of the incoming light, and the phase is proportional to the angle of linear polarization. This measurement approach, that uses no filter wheels or multiple apertures to determine the state of polarization, allows for simultaneous measurements of both radiance and polarization for a given ground scene. This is essential to reach the required accuracy. The SPEX geophysical data product will consist at least of: aerosol effective radius, effective variance, number concentration, refractive index of the fine and coarse mode of the aerosol size distribution, aerosol height, cloud effective radius, droplet number concentration, cloud top/base height, and cloud phase.

Keywords: Aerosol size distribution, Backscatter, In-situ measurements, Lidar, Remote sensing
Presenting author email: andreas.held@uni-bayreuth.de

The atmospheric aerosol is highly variable in time and space with respect to particle size, number, and chemical composition. In-situ observations with point sensors cannot fully represent the spatial variability of aerosol particles in the atmospheric boundary layer. Thus, in-situ observations yield spatially averaged data or disjunct information which may, for example, misrepresent the available aerosol surface area for heterogeneous chemical reactions, or the small-scale effect of aerosol optical properties.

Direct observation of the spatial variability of aerosol concentration with high time resolution is possible through remote sensing techniques. For example, the Raman-shifted Eye-safe Aerosol Lidar (REAL; Mayor et al., 2007) can safely transmit high energy laser pulses in order to visualize small-scale atmospheric motions and changes in the structure of the lower atmosphere through aerosol scattering. However, knowledge of the sensitivity of the lidar to small changes in the microphysical characteristics of aerosol particles is a prerequisite to extract information about the spatial and temporal evolution of the atmospheric aerosol from the backscatter signal.

There is a lack of direct intercomparison studies of lidar and high-time-resolution in-situ aerosol measurements. Here, we compare aerosol backscatter data of the REAL with in-situ measurements of aerosol size distributions during two different field campaigns. The REAL backscatter signal is compared with aerosol size distribution measured with a LASAIR optical particle sizer during the Canopy Horizontal Array Turbulence Study (CHATS; Patton et al., 2011) in Dixon, CA, USA, in May 2007, and with a MetOne optical particle counter and a Compact Lightweight Aerosol Spectrometer Probe (CLASP; Hill et al., 2008) during a field experiment at the Chico State University Farm in Chico, CA, USA, in October 2011.

From an intercomparison of the CHATS field data, preliminary results about the sensitivity of the REAL towards particle size were obtained. Figure 1 shows the time series of the REAL backscatter signal and the aerosol surface concentration in the diameter range from 0.5 to 10 µm during a five-day measurement period. Obviously, the two time series do not trace each other perfectly at all times. In part, this may be due to the spatial separation of the remote sensing volume and the in-situ sensor. However, the influence of particles smaller than 0.5 µm on the backscatter signal was found to be negligible at all times.

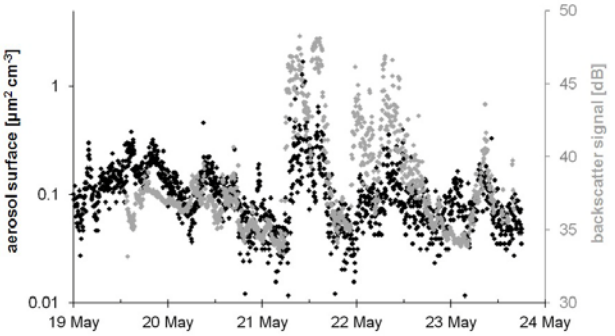

Figure 1: Time series of REAL backscatter signal (grey) and aerosol surface concentration (diameter > 0.5 µm; black) during five days of CHATS 2007.

In 2011, a dedicated intercomparison experiment was carried out. The REAL laser beam was directed horizontally across a very flat field at the Chico State University Farm and passed the inlets of two optical particle counters located approximately 1.3 km away from the REAL within 1 m or less.

We will present additional results from a detailed analysis of the CHATS intercomparison data, and from the Chico intercomparison experiment. After characterization of the sensitivity of the REAL backscatter signal to changes in aerosol size and concentration, this signal can be analyzed for a better representation of the spatial variability of aerosol particles in the atmospheric boundary layer.

SEVIRI based aerosol optical depth and type retrieval

S. Nevens, N. Clerbaux, A. Velazquez Blazquez, E. Baudrez, I. Decoster, S. Dewitte, A. Ipe
Royal Meteorological Institute of Belgium (RMIB), Section Remote Sensing from Space,
Avenue Circulaire 3, B-1180 Brussels, Belgium
Keywords: remote sensing, tropospheric aerosols, optical depth, climate change
Presenting author email: stijn.nevens@meteo.be

Tropospheric aerosol particles form a major uncertainty in predicting climate change due to three main mechanisms. First there is the direct radiative forcing effect of the aerosols which occurs when radiation is scattered or absorbed by the aerosols. Next we have indirect radiative forcing which has its origin in the influence of the aerosols on cloud microphysics. And last, the presence of aerosols can modify the concentration of climate-influencing constituents such as greenhouse gases trough heterogeneous chemistry. Global observations from space are required due to short lifetime and a high spatial variability in aerosol optical and radiative properties.

In the autumn of 2012 the Climate Monitoring SAF (CM SAF) will release an aerosol product of climate quality for which the RMIB is responsible. This will be a retroactively produced data set covering the whole MSG (Meteosat Second Generation) period. The main components of the product are the aerosol optical depth (AOD) and the aerosol type over ocean.

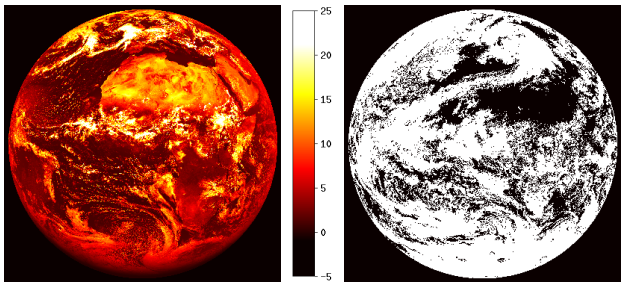

Figure 1: Input data for the algorithm for midday on the 22nd of June 2004. Left: radiance (units = W/m^2sr) from the SEVIRI solar channel at 600 nm. Right: cloud mask where white equals cloudy.

The solar and thermal SEVIRI channels (multichannel imager aboard the MSG satellite) together with the CM SAF cloud mask and wind speed over ocean from ERA-Interim reanalysis (Dee et al, 2011) form the input for the AOD and aerosol type retrieval algorithm.

The heart of the algorithm consists of look up tables for the AOD at 550 nm and all SEVIRI solar channels generated using LIBRADTRAN (Mayer and Kylling, 2005). These have as parameters the wind speed, all relevant angular information and 6 aerosol types. The aerosol types consist of 3 spherical and 3 non-spherical classes taken from (Govaerts et al, 2010) and where originally derived from an analysis of AERONET retrievals.

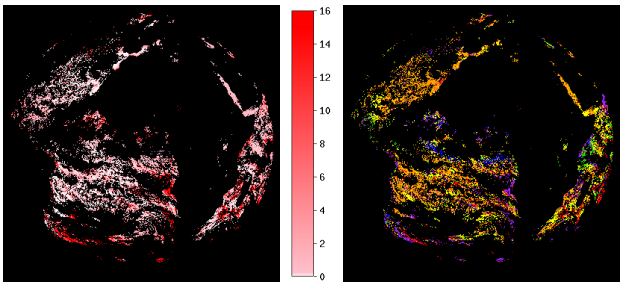

Figure 2: Output found using the input from figure 1. Left: AOD (no units). Right: aerosol type (6 colors to represent the 6 types).

Having all necessary inputs we use our algorithm to retrieve the AOD and aerosol type over ocean in the MSG field of view. The method is inspired by the method developed for AVHRR (Ignatov and Stowe, 2002) which was later adapted for SEVIRI (Brindley and Ignato, 2006). It is currently deployed within the GERB (Geostationary Earth Radiation Budget) processing chain (De Paepe et al, 2007). By doing a least least squares fit on 6 families of curves we can determine which aerosol type and corresponding AOD give the best agreement between the observed and simulated reflectance in all SEVIRI solar channels given the specific solar/observation geometry.

The authors are supported by EUMETSAT and the Belgian Science Policy Office under the contract EUMETGERB and by CM-SAF.

On June 12th, 2011 Nabro volcano, situated in the border between Ethiopia and Eritrea, started a series of eruptions that lasted until September 2011. It released approximately 1.5 - 2 Tg of SO_2 to the atmosphere in the first days - one of the largest SO_2 emissions measured since Nyamuragira volcano in Congo, 1994 and Mt. Pinatubo eruption in 1991, which injected about 20 Tg of SO_2 into the stratosphere. Nabro left a trace of stratospheric aerosols that circulated the globe in both directions, heading eastward and westward at different altitudes and staying in the atmosphere for a couple of months.

Lidars are important tools that help assess the vertical distribution of aerosols in the atmosphere. In this study we report on stratospheric aerosols that were observed over the Northern Hemisphere with the aid of multiple lidar networks such as MPLNET, EARLINET and NDACC, and satellite (CALIOP – Cloud-Aerosol Lidar with Orthogonal Polarization). Measurements in Hefei, China were provided by the Key Laboratory of Atmospheric Composition and Optical Radiation.

Figure 1 shows the average aerosol optical depth (AOD) retrieved from CALIOP over the globe from July 16 to July 31, 2011.

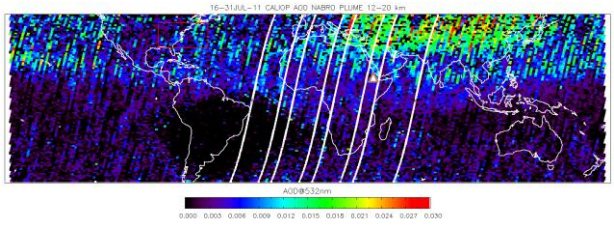

Figure 1. Global CALIOP AOD retrieval from July 16 to July 31 between 12 and 20 km of altitude.

This type of study is important to many remote sensing communities. In the stratospheric trace gases community, being able to determine how volcanic eruptions may affect the load of background aerosols in the stratosphere is very valuable. In other cases, such as in comparative studies of satellite and/or column measurements versus ground-based measurements it is also important to determine the stratospheric contribution of aerosols. During the DISCOVER-AQ mission that took place in the Baltimore-Washington corridor in the United States in July 2011, an offset of approximately 0.03 between AOD measurements from sun-photometer (total column) and airborne high-spectral resolution lidar (down-looking HSRL at ~6km) was observed and we believe that stratospheric aerosols due to Nabro might have contributed with AOD=0.01.

In this study the AOD retrieved from lidar measurements in the stratosphere ranged between 0.01 to 0.04 at 532 nm and from 0.04 to 0.08 at 355 nm. The measurements spanned a good area over the Northern Hemisphere: East and West Coast of the US (Maryland and California, respectively), Hawaii, Canary Islands, Israel, India, Spain, Italy, France and China.

It is unlikely that the aerosols generated by Nabro's eruption would have a significant effect on the radiative balance of the atmosphere like Pinatubo did. However, we show with this study how the synergy of lidar measurements across the globe - as proposed by GALION (GAW Aerosol Lidar Observation Network) - could aid the scientific (and also aviation control) community to rapidly assess the outcome of future, and possibly more explosive, volcanic eruptions.

The NASA Micro-Pulse Lidar Network is funded by the NASA Earth Observing System and Radiation Sciences Program. Lidar work in Hefei site was funded by the National Key Basic Research Project of China under Grant No. 2007FY110700. Lidar work at Universidad de Granada was funded by grants CGL2010-18782 and P10-RNM-6299 and EU ACTRIS project.

Detection of the stratospheric volcanic aerosol plume from the Nabro eruption in summer 2011 in the framework of SPALINET

During the night of 12 June 2011 the Nabro volcano (13.37ºN, 41.70ºE) in the state of Eritrea (Horn of Africa) started its eruption generating large amounts of ashes, water vapour and sulphur dioxide gas that intermittently blocked the air traffic over Eastern Africa. Besides the human and economical factors, the Nabro episode was relevant from the climate point of view by injecting a layer of sulphur aerosol particles, which persisted for months in the stratosphere and was detected over several continents.

The stratospheric aerosols generated from the Nabro's eruption were detected over southern Europe by five stations of SPALINET (the Spanish and Portuguese aerosol lidar network, www.lidar.es/spalinet/en) (Sicard et al., 2009; 2011), namely (m asl):

- GR: Granada (37.16ºN, 3.58ºW, 680 m)
- EV: Évora (38.57ºN, 7.91ºW, 290 m)
- SC: Sta. Cruz de Tenerife (28.47ºN, 16.25ºW, 52 m)
- MA: Madrid (40.46ºN, 3.72ºW, 665 m)
- BA: Barcelona (41.39ºN, 2.11ºE, 115 m)

The capabilities of SPALINET for volcanic aerosol characterization have been demonstrated previously during the Eyjafjallajökull eruption in 2010 (Guerrero-Rascado et al., 2010; Sicard et al. 2011). This study is focused on both geometrical and optical properties of the volcanic particles. On the one hand, the zero-crossing method is used to determine the minimum and maximum heights and geometrical thickness. On the other hand, the transmittance method (i.e. Young, 1995) is applied to pre-processed elastic lidar signals for deriving the aerosol optical depth (AOD) in those isolated volcanic layers. In a further analysis, this information could be used to constrain the retrieval of the Klett's algorithm to estimate a layer-effective lidar ratio.

The first volcanic aerosol particles from the Nabro volcano could be detected over Spain and Portugal after a relatively short time (within the first two weeks after the eruption). All the stations considered in this study observed the first layers on 26 to 27 June and a few of them detected the volcanic layer until the middle of July. Besides the stratospheric volcanic layer, another coupled layer was detected over several stations in the uppermost troposphere during some periods (notice the minimum altitude values in Table 1).

Table 1. Dates when the Nabro volcanic plume was mainly observed between the minimum (z_{min}) and maximum (z_{max}) and AOD at 532 nm (± st. dev.).

Station	Period	[z_{min},z_{max}] km asl	AOD_{532nm}
GR	26/06-30/06	12.6-18.8	0.044±0.013
EV	26/06-02/07	9.1-19.7	0.048±0.016
SC	26/06-10/07	10.5-19.7	0.021±0.011*

Microphysical properties, along with optical ones, play a key role for the understanding of the aerosol radiative effect in climate. Particularly interesting, and however poorly investigated, is the vertical distribution of aerosol microphysical properties. Since last years, several algorithms in the framework of EARLINET try to address this issue based on the analysis of multiwavelength Raman lidar signals, which are mainly restricted to night time. Nowadays, new tools based in the combination of elastic lidars and sun-photometers have been developed within the working package WP20 of the European project ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network). This work focuses on the application of the retrieval algorithm developed by Chaikovsky et al. (2008) for microphysical properties profiling under two different scenarios that took place at Granada (Spain) during the CLIMARENO field campaign.

The CLIMARENO field campaign allowed for the study of atmospheric aerosol particles from a multi-instrumental approach. For further details see Andrey et al. (2012) and Bravo-Aranda et al. (2012). On 14th June 2011 aerosol particles advected from North America and the northernmost part of South America were monitored over Granada especially between 4.0 and 6.5 km asl. The columnar values (derived from sun-photometer, AERONET level 1.5 data) of aerosol optical depth (AOD) at 500 nm were 0.07-0.12, and Angström Exponent (AE) at 440-870 nm were 0.82-1.41 during the morning. The microphysical properties profiling indicated a clear predominance of the fine mode and the spherical-coarse mode in these layers (Figure 1, left). This agrees with the low linear particle depolarization ratios (not shown here) detected by lidar and an expected particle growth during the long-range transport. In contrast, on 27th June there is a clearly marked signature of Saharan dust mineral particles, which were observed up to 5.0 km asl. For this case daily mean AOD (500 nm) was 0.30±0.02 and daily mean AE (440-870 nm) was 0.48±0.06, indicating a dusty scenario. The predominance of both spherical- and spheroid-coarse mode (Figure 1, right) also evidences this fact.

Additionally, the coherence of the results from this algorithm is checked against independent datasets:

(i) simultaneous and co-located microphysical properties measured by in-situ instrumentation aboard aircraft.
(ii) non-simultaneous (night time) and co-located microphysical properties retrieved from Raman lidar through algorithms based on the analysis of Raman signals.

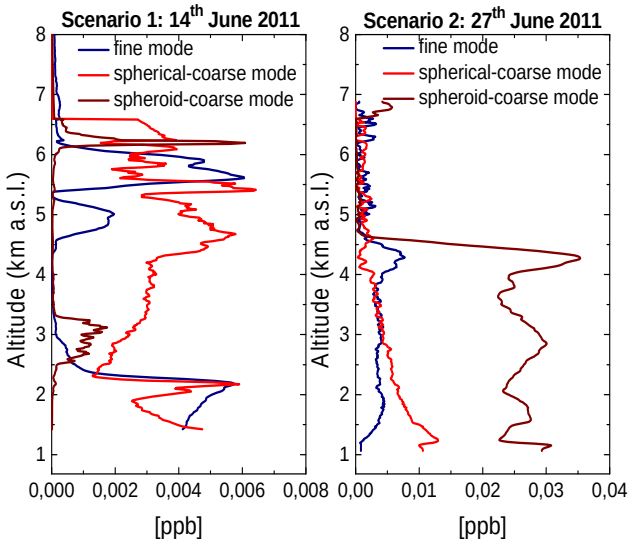

Figure 1. Vertical profiles of aerosol volume concentration for fine, spherical-coarse and spheroid-coarse modes for trans-Atlantic aerosols on 14th June (left) and Saharan dust particles on 27th June (right).

The key for a comprehensive understanding of atmospheric aerosols regarding air quality and climatic relevant processes lies in the research of their chemical composition and microphysical properties. In spite of their relevance, their temporally and vertically resolved microphysical properties are yet only poorly understood. In order to achieve a deeper knowledge of these properties, the analysis of systematic measurements like those performed in the framework of EARLINET (European Aerosol Research lidar Network) is needed.

During the last decades, multiple inversion techniques have been used for retrieving microphysical properties by means of multiwavelength measurements of optical properties. In this study we present the application of a software that allows for retrieving aerosol microphysical properties through the combination of lidar and sun-photometric data obtained at the Évora station (Portugal, 38.6ºN, 7.9ºW, 290 m asl). It was developed by Chaikovsky et al. (2008) and recently disseminated in the EARLINET community. The novelty of this study is based on the features offered by the AERONET+EARLINET station at Évora. On one hand, the privileged location of Évora allows for studying the aerosol particles advected from different sources. On the other hand, the multi-instrumental capabilities of the Évora station (active/passive remote sensing and in-situ techniques) enable a thorough characterization of the aerosol particles.

The method is based on constructing the vertical distribution of aerosol volume concentrations matching both the integrated aerosol properties derived by sun-photometer and the vertical variability of the multispectral lidar signals. Thus, the method provides the fine and coarse fractions with a cutoff radius of 0.5µm. Refractive index is considered to be independent on the altitude. Information in the incomplete overlap range height is modeled as a constant profile.

As an example of the first vertically resolved aerosol microphysical retrievals, a case of long-range transported particles from America to Évora on 23/01/2012 is selected. Aerosol particles were detected up to 7.4 km (agl) (Figure 1). The reference height was selected at 8 km (agl). Noise prevented retrievals in higher altitudes. The microphysical retrieval indicated a clear predominance of the fine mode in the free troposphere in contrast to a predominance of the coarse mode in the lowermost part of the troposphere.

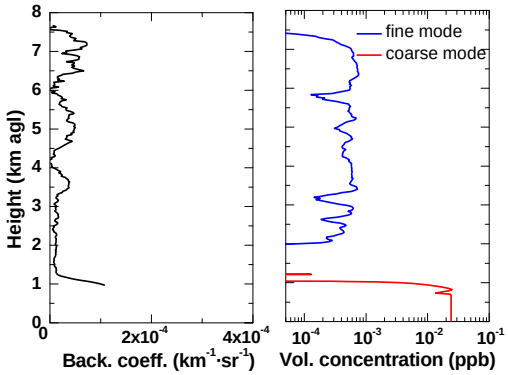

Figure 1. Profiles of aerosol backscatter coeff. at 532 nm (left) and aerosol volume concentrations for fine and coarse modes (right) on 23/01/2011 at 12:00-12:30 UTC.

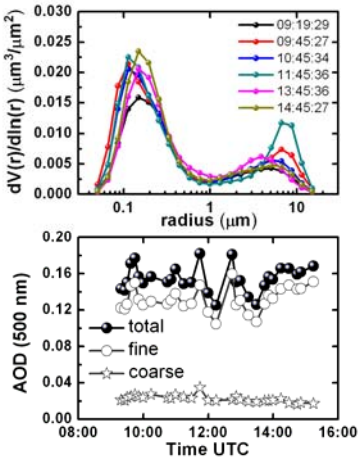

Figure 2. Columnar volume size distributions and AODs, including fine and coarse discrimination, at the same day obtained from AERONET (Évora).

During September-October 2011 the ESA Mobile Raman Lidar (EMORAL) was operating at the complex environment of the large urban coastal city of Herkleion (Crete, Greece).This city combines high aerosol loads originating from different distant (e.g. Saharan desert, biomass burning areas, etc.) and local sources (local sources, such as traffic and industrial activities).

During 7 of September 2011 the handheld sun photometer Microtops II indicated rather coarse particles (AE=0.93±0.12, with AOD at 500 nm=0.41±0.10) at 12:00 UTC. EMORAL operated from 09:30 to 13:00 UTC and detected, indeed, high aerosol loads, and the evolution of this event was monitored over the operational site (Fig. 1). The vertical profiles of the aerosol optical properties (backscatter coefficient at 355 nm and 532 nm, backscatter-related (bp355/bp532) Ångström exponent and the volume linear depolarization ratio) obtained by EMORAL (Fig. 2) delineate two distinct aerosol layers of about 1 km thickness, each (1.5-2.5 km and 3-3.8 km height). The first aerosol layer is probably composed by a mixture of dust and biomass burning aerosols, as demonstrated by air mass back-trajectory analysis (not shown) and by single scattering albedo (SSA) and CO values, obtained in situ (Fig. 3). The backscatter-related Ångström (bp355/bp532) exponent ranged from 1 to 2 (with a mean value of 1.52±0.25) indicating the presence of rather small particles with a large variability of the aerosol type, inside this layer. At this height the volume linear depolarization ratio at 355 nm was of the order of 8.5±0.1%.

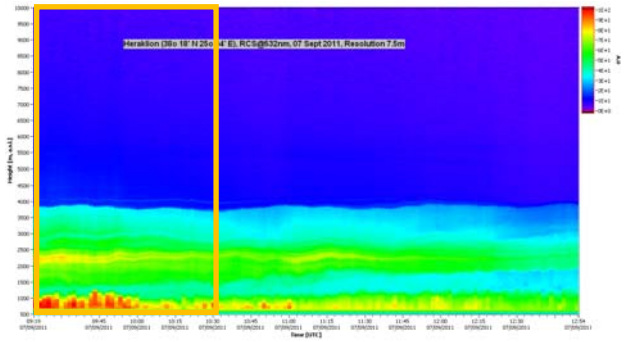

Figure 1. Spatio-temporal evolution of the range-corrected lidar signal, obtained by EMORAL (in a.u.) at 532 nm (7 September 2011).

The second aerosol layer was probably composed by Saharan dust as previously discussed. The backscatter-related Ångström exponent was found to decrease with height, having a mean value of the order 0.3 inside the aerosol layer (indicating the presence of rather big particles), while the volume linear depolarization ratio was found to be ~ 9.2 %.

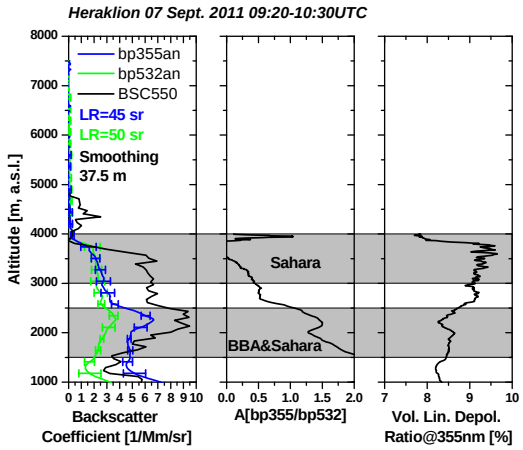

Figure 2. The aerosol backscatter coefficient at 355 nm and 532 nm, the backscatter-related Ångström exponent and the volume linear depolarization ratio at 355 nm of aerosols retrieved by EMORAL over Herakleion, Crete (7 September 2011: 09:20 UTC-10:30 UTC). The aerosol backscatter coefficient at 550 nm (BSC550) was obtained by FAAM in situ instrumentation.

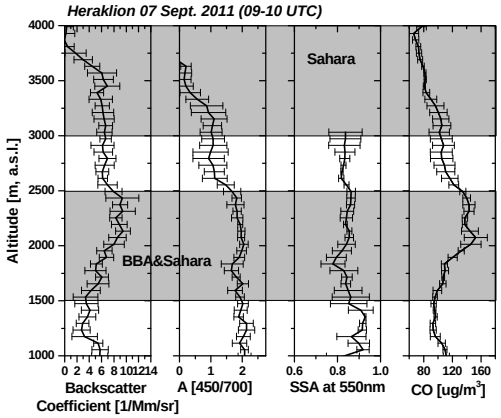

Figure 3. Aerosol backscatter coefficient profile at 550 nm retrieved on board by FAAM aircraft, along with the scattering-related Ångström exponent and the SSA and the CO concentration during the flight of 7 September 2011 (09:00 UTC-10:00 UTC).

PBL determination from ground based lidar over Herakleion-Crete Greece

P. Kokkalis[1], G. Tzeremes[2], A. Papayannis[1], and E. Armandillo[2]
[1]National Technical University of Athens, Laser Remote Sensing Unit, Physics Department, Zografou, Greece
[2]European Space Agency, Noordwijk, Netherlands

Presenting author email: panko@central.ntua.gr

Based on the ESA's mobile lidar system (EMORAL) lidar signals analysis and by calculating the minimum value of the first derivative of the range-corrected signal (RCS) profiles, obtained over the Herakleion, Crete, we were able to determine the mean daily value of the Planetary Boundary Layer (PBL) height, for the first time over Crete, as well as its mean value during September and October 2011 (Fig. 1). According to that Figure, the PBL height for the studied period varied from 1563 to 1079 m, while the mean value for the whole period was of the order 1266±135 m. Moreover, in Table 1 we summarize the monthly diurnal (mean, morning-to-noon and afternoon hours) variation of the PBL height obtained by EMORAL over Herakleion. The mean PBL height value for September 2011 was found to be 1252 m, while that of the cooler month October, was 1101 m. The corresponding mean values for the morning-to-noon hours (<10:00 UTC) were 1159 m and 1037 m, while those for the afternoon hours (>10:00 UTC) were 1267 m and 1152 m, respectively.

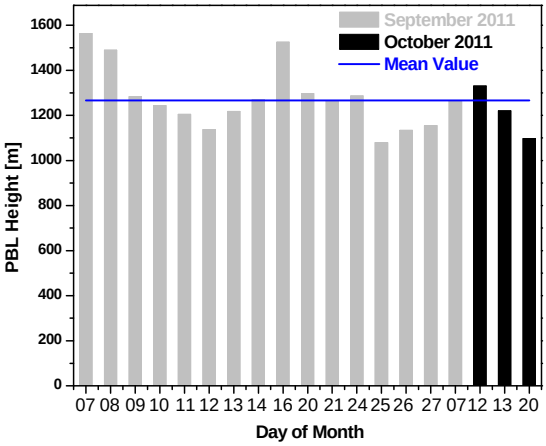

Figure 1. PBL height variation as determined by the analysis of the first derivative of the RCS obtained by EMORAL at the city of Herakleion, Crete, during September and October 2011.

Table 1. Monthly, mean, morning-to-noon and afternoon variation of the PBL height obtained by EMORAL over Herakleion, Crete (September to October 2011).

PBL Height (m)	Mean	Morning	Noon
September 2011	1252	1159	1267
October 2011	1101	1037	1152

Analyzing in more detail the values of the PBL height given in Fig. 2 and Table 2, since the PBL height - due to uprising thermals - is increasing near local noon, we estimated the rate of the relative increase (comparing the PBL height at 12:00 UTC to that at 09:00 UTC) to be of the order of 9.3 % in September and 9.9% in October. In Figures 1 and 2, we present the spatio-temporal evolution of the PBL height obtained during 20 October 2011. During the morning hours (~ 09:00 UTC), when the land is still quite cold, thus no intense updrafts exist, the PBL height is around 1100 m, which keeps strong aerosol loads near ground. During the hotter hours of the day, more intense thermals appear (around 11:00 UTC), thus transferring heat upwards; In this case the PBL height increases up to nearly 1300 m. Later on, the PBL height starts decreasing around the local sunset. Finally, a typical example is given in Figure 2, where the mean PBL height is found at 1096 m height, as retrieved by height minimum of the first derivative of the RCS signal, obtained from approximately 10.000 laser shots averaged from 09:156 UTC to 13:07 UTC at 532 nm on 20 October 2011 (see insert in Fig. 2).

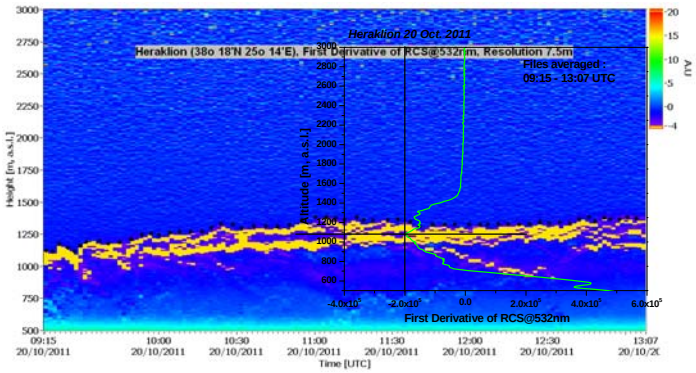

Figure 2. Spatio-temporal variation of the first derivative of RCS, obtained by EMORAL at 532 nm over Herakleion (Crete), from 09:15 UTC to 13:07 UTC (20 October 2011). The black dots show the position of the top of the PBL height. The insert figure shows the averaged first derivative of RCS (green line).

The vertical distribution of dust is a key parameter on aerosol-ozone-UV interactions (i.e., Bonasoni *et al.*, 2004) for atmospheric radiative forcing assessment and climate-related studies (IPCC, 2007). Despite of a great attention has been paid in last years to the aerosols in a global scale and, in particular, to the Saharan dust, a large uncertainty on the sign of the radiative forcing still remains. In addition, height-resolved information of the dust properties is also required in other frameworks as for aerosol forecast modeling (i.e., Pérez *et al.*, 2006) and satellite data validation (i.e., Pappalardo *et al.*, 2010).

Canary Islands offer the most promising site as located downwind of the Saharan outbreaks sources for dust monitoring. The arrival of dust plumes to that area is a common feature, more frequently observed in summertime and extended up to high altitudes, resulting from strong convective activity over the Sahara desert under favorable meteorological conditions. The vertical characterization of individual dust events is significant for the determination of the so-called Saharan Air Layer (SAL), identified as a mass of warm, dusty and dry air which forms over the Saharan desert, in order to evaluate the climate impact of such phenomena, even at local scales.

In general, the synergy between lidar and sun-photometry observations is also widely used for dust research (i.e., Müller *et al.*, 2003; Mona *et al.*, 2006; Papayannis *et al.*, 2008; Córdoba-Jabonero *et al.*, 2011). Since 2005 height-resolved measurements are routinely performed at the AEMET/Santa Cruz de Tenerife subtropical station (SCO, 28.5ºN 16.2ºW, 52 m a.s.l.) by using a Micro Pulse Lidar v. 3 (MPL-3) within the NASA/MPLNET (Micro Pulse Lidar NETwork). SCO is also an AERONET (Aerosol Robotic NETwork) site.

In this work we present the statistical results of the SAL characterization in summertime over SCO from routine lidar measurements. This study focuses on vertical features (single/multi-layered structure, top height, among others) of the dusty episodes, in addition to other optical properties (Free-Tropospheric dust contribution to the total AOD, Lidar Ratio frequency, etc.). Air masses backtrajectory analysis completes this study. For instance, the SAL is examined for a strong dust intrusion occurring on 21 July 2009 over SCO (see Figure 1). Extinction coefficients are retrieved considering a pure dust scenario (Córdoba-Jabonero *et al.*, 2010) and a Lidar Ratio of 55 sr is found. In this case, daily SAL top is ranging between 5.3 and 5.7 km, and a FT dust contribution of 88.3% is calculated.

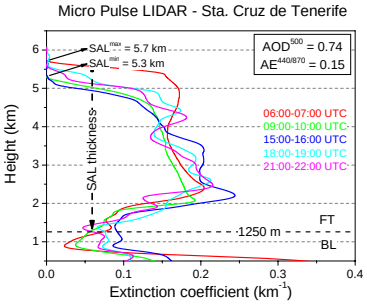

Figure 1. Dust extinction coefficients on 21 July 2009, for instance, over SCO site.

This summertime statistic analysis represents a relevant advance on SAL characterization in aerosol stations fairly close to dust emissions. Moreover, these results can be directly applied to the evaluation of the ozone vertical depletion observed under Saharan dust events (Andrey *et al.*, 2010) and the changes experienced by minor halogen species involved in ozone chemistry.

The use of lidar depolarization is a key tool for climate-related cloud and aerosol studies because depolarization measurements provide information about the shape and/or the thermodynamic phase of the particles in the atmosphere.

In particular, the Polar Stratospheric Clouds (PSCs) depolarization ratio (δ) obtained from lidar observations is usually used as a PSC-type discriminator together with the lidar backscattering ratio (i.e., Maturilli *et al.,* 2005; Pitts *et al.,* 2009). Indeed, this PSC-type identification is critical on polar ozone depletion research, and directly linked to the stratospheric temperature variability. Therefore this δ parameter must be accurately estimated.

Since January 2009 PSC observations are performed over the coastal Antarctica in Belgrano II station (Argentina, 77.9ºS 34.6ºW) by using an improved version of the standard NASA/Micro Pulse Lidar, the MPL v.4 (MPL-4), which includes a built-in depolarization module unlike other MPLs. This study focuses on the analysis of MPL-4 two-channel data, i.e. both parallel (p-) and perpendicular (s-) MPL signals, in order to retrieve the PSC lidar depolarization ratio δ values. Antarctic 2009-2011 winter data, from May to September periods, are used for that purpose.

From the practical point of view, the most general expression to calculate the linear volume depolarization ratio δ in terms of lidar signals is:

$$\delta(z) = K\frac{P^{\perp}(z)}{P^{\parallel}(z)} + \chi \qquad (1)$$

where $P^{\perp}(z)$ and $P^{\parallel}(z)$ are the s- and p- components of the measured MPL signals, respectively, once corrected for intrinsic instrumental factors (see Campbell *et al.* (2002) for details); K is a calibration constant that accounts for the differences of the receiver channel gains; and χ is a correction to account for any slight mismatch in the transmitter and detector polarization planes and any impurity of the laser polarization state (Sassen, 2005). Optimal K and χ values are found by using fitting procedures with molecular backgrounds.

MPL-4 depolarization retrieval is compared to the PSC depolarization ratio reported from the space-borne lidar CALIOP to test the degree of agreement. CALIOP is on board of CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation, www-calipso.larc.nasa.gov), whose closest ground-track overpasses to Belgrano II station are selected. A few examples are shown in this work to illustrate such a comparison analysis. For instance, δ-profiles comparison on 30 and 31 July 2009 is shown in Figure 1.

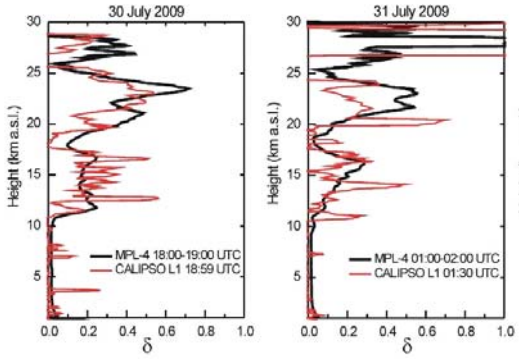

Figure 1. δ-profiles comparison on 30 and 31 July 2009 at the closest CALIPSO overpass distance from Belgrano II station: 25.6 km and 48.9 km, respectively.

Results indicate that there is a good correlation between both linear volume depolarization ratio δ profiles once MPL-4 calibrated depolarization parameters are calculated. This correlation is based on the height range match of the layered structure as well as the δ values found for each layer. As expected, this agreement is much better when the CALIPSO ground-track overpass is much closer to the Belgrano II station.

This work is supported by the Spanish Ministry for Research and Innovation (MICINN) under grant CGL2010-20353 (project VIOLIN). CALIPSO data were obtained from the NASA Langley Research Center Atmospheric Science Data Center. Authors specially thank the DNA/IAA team at Belgrano II station for their valuable assistance and support.

Polar Stratospheric Clouds observations in coastal Antarctica based on Micro Pulse Lidar measurements. II. PSC-type discrimination assessment

D. Toledo[1], C. Córdoba-Jabonero[1], J.L. Guerrero-Rascado[2,3], M. Parrondo[1], M. Yela[1], M. Gil[1] and H. Ochoa[4]

Polar Stratospheric Clouds (PSCs) have been identified as determinant elements for the ozone depletion processes occurring at high latitudes during spring time. In Polar regions PSCs start to form during winter at stratospheric temperatures below the condensation threshold of the Nitric Acid Trihydrate (NAT), which depends on the water vapor and nitric acid partial pressure (Hanson and Mauersberger, 1988). PSCs are classified in two groups (i.e., Toon *et al.*, 1990) depending on the temperature formation threshold: PSC type I (PSC-I) are nitric acid clouds formed above the frost point (T_{NAT} = 194 K at 30 hPa), and PSC type II (PSC-II) are water ice clouds (T_{ice}=185 K at 30 hPa). Therefore, the PSC-type identification is directly linked to the stratospheric temperature.

Lidar measurements have been usually used for PSC classification (PSC-I and PSC-II) on the basis of two lidar parameters: both backscattering (R) and depolarization (δ) ratios (i.e., Adriani *et al.*, 2004; Maturilli *et al.*, 2005; Pitts *et al.*, 2009). According to those R and δ values found, PSC-II present rather higher R and δ values respect to those found for PSC-I.

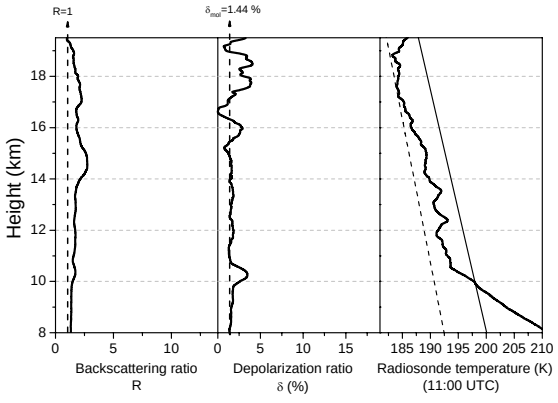

Figure 1. PSC-I backscattering ratio for 1-h averaged profile (11:00-12:00 UTC) (left); volume depolarization ratio (centre), with the molecular value (δ_{mol}=1.44%) also indicated; and the radiosonde temperature profile (right) with the 2-ppmv H_2O and 2-ppbv HNO_3 threshold temperatures for NAT (solid line), and ice (dotted line), on 23 September 2009.

In this work, an improved version of the standard NASA/Micro Pulse Lidar (MPL v.4, MPL-4) deployed in the continental Antarctica Belgrano II station (Argentina, 77.9ºS 34.6ºW) since January 2009 for PSC observations is used to obtain these two parameters. The degree of performance of this kind of micropulse lidars for PSC discrimination is evaluated. An example of each PSC-I and PSC-II as identified by the MPL-4 parameters is shown in Figures 1 and 2, respectively. Radiosonde temperature profiles are also shown on each day. Results show that MPL-4 retrievals are reliable for PSC discrimination between PSC-I and PSC-II over Antarctica. In particular, a more detailed PSC-I discrimination into Ia and Ib, NAT and liquid PSC subgroups, respectively, according the criteria adopted from Adriani *et al.* (2004), requires a more accurate lidar data processing.

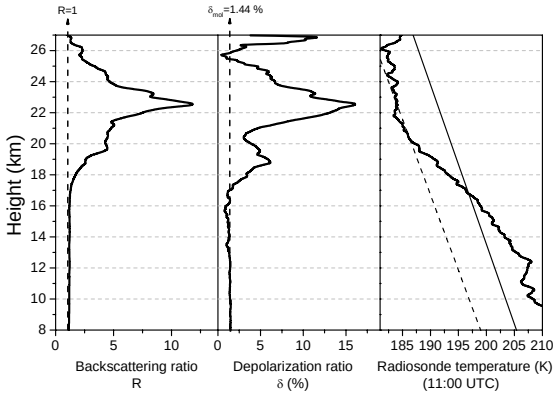

Figure 2. The same as Fig. 1, but for PSC-II on 29 June 2009, and with 5-ppmv H_2O and 8-ppbv HNO_3 threshold temperatures for NAT (solid line) and ice (dashed line).

This work is supported by the Spanish Ministry for Research and Innovation (MICINN) under grant CGL2010-20353 (project VIOLIN). Authors also wish to thank the DNA/IAA team at Belgrano II station for their valuable assistance and support in lidar and radiosounding measurements.

High quality case studies characterizing vertically resolved aerosol optical properties of specific aerosol types have been made world-wide with ground-based Raman lidars (e.g. Müller *et al.*, 2007). During the past decade, sophisticated computational procedures have been developed and successfully tested for multiwavelength Raman lidar observations that permit the retrieval of particle microphysical properties (Müller *et al.*, 1999).

Figure 1 shows one such measurement taken on 13th of July 2008 at Gual Pahari site, India (28.43° N, 77.15° E, 243 m) from 20:00 to 20:50 UTC. The measurement was conducted with a seven-channel Raman lidar called "POLLYXT–POrtabLe Lidar sYstem eXTended" (Althausen *et al.*, 2009). A detailed description of the site can be found in Hyvärinen *et al.*, 2011.

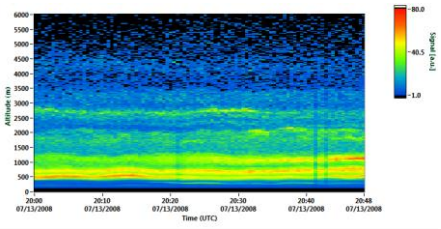

Figure 1. Range corrected signal at 1064 nm measured at Gual Pahari, India on 13th July 2008.

Distinct aerosol layers are observed throughout the atmosphere and reached top heights of approximately 4.5 km height above sea level. Vertically resolved lidar measurements of aerosol extensive parameters (extinction and backscatter coefficients) as well as intensive parameters (lidar ratio, depolarization, Ångström exponent) are calculated. No significant spectral behavior between lidar ratio values was found. The mean lidar ratio is 96± 29 sr and 94 ± 65 sr at 355 and 532 nm respectively. The extinction-related Ångström exponents (355/532 wavelength pair) vary between 0.9-1.9. The profile of the linear depolarization ratio indicates that the particles observed are nearly spherical.

The HYSPLIT trajectory model (Draxler and Hess, 1999) is used to identify the source regions of the plumes that are observed over Gual Pahari (Figure 2). According to the backward trajectory analyses the air masses that arrived over Gual Pahari at 500 m and 1000 m height had crossed over the Arabian sea. The signature of a strong thin particle layer at 500 m is evident during the whole observation time and is probably related with maritime aerosols. Nevertheless, aerosol layers observed at heights between 1500 and 4500 m have different origins. The air masses were rising during their travel in central India carrying probably anthropogenic aerosols before their arrival at Gual Pahari.

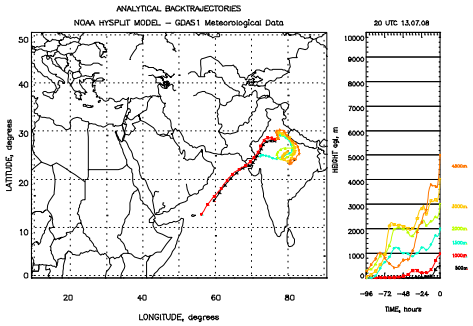

Figure 2. Four-days backtrajectories obtained from HYSPLIT on 13th July 2008 at 20:00 UTC for arrival height of 0.5, 1.0, 1.5, 2.0, 3.0 and 4.5 km.

To retrieve the microphysical properties at different altitudes, lidar profiles are separated into distinct aerosol layers. The mean values of optical properties calculated within the defined layers are then used as input in the inversion algorithm.

Preliminary results from the new portable backscatter aerosol lidar in Turkey

K. R. Allakhverdiev[1, 2], A. Secgin[1], M. F. Huseyinoglu[1] and Z. Salaeva[1]

[1]TUBITAK, Marmara Research Center, Materials Institute, P.K. 21, 41470 Gebze/Kocaeli,Turkey

Presenting author email: alper.secgin@mam.gov.tr

Aerosols are recognized to have various effects on the earth on different levels. They increase air pollution and thus reduce airspace visibility, and have hazardous effects to human health when inhaled. By altering the radiative properties of the atmosphere, aerosols also affect global warming and cooling, even though they are one of the biggest uncertainties of the climate system (Salomon *et al*, 2007).

Lidars have been used for the past few decades to have better and efficient remote study of the aerosols in the atmosphere and the instrumentations for these studies have been extremely sophisticated in time. It is also possible to have *in situ* information about the properties of atmospheric particles without disturbing their microphysics. A portable backscatter lidar using Nd:YAG laser with its harmonics has become an significant device for the measurement of aerosols in the lower atmosphere with the advantage of being easily transported to various locations (Veselovskii *et al*, 2002).

In Gebze region there are different types of aerosols related to industrial pollution, urban development, marine and desert dust. A stable multiwavelength Raman lidar using an Nd:YAG laser with its second and third harmonics has been built in the Scientific and Technological Research Council of Turkey (TUBITAK), Marmara Research Center (MRC), KA09 Laser and Lidar Laboratory to get information about atmospheric particle parameters for different seasons and meteorological conditions in different regions. This lidar (EARLINET name, MRC K09) measures aerosol backscattering, extinction coefficients and polarization, and from the obtained data, the particle microphysical parameters such as volume, surface area and number concentrations, effective radius, size distribution, particle and volume polarization, and complex refractive index are retrieved through inversion with regularization, principal component analysis and linear estimation techniques (Veselovskii *et al*, 2011).

A portable backscatter lidar has been built in the same laboratory to obtain information about the aerosol parameters at heights within the Planetary Boundary Layer (PBL) and slightly above. It has an Nd:YAG laser transmitter with its second harmonic emitting 10 GHz pulses with 4 W average power. Receiver is a 20 cm aperture Cassegranian telescope. Licel TR20-160 is used with Newport LP-1A Avalanche Photo Diode (APD) at 1064 nm and with PMT's for polarization measurements at 532 nm. Figure 1 illustrates the above mentioned portable backscatter lidar.

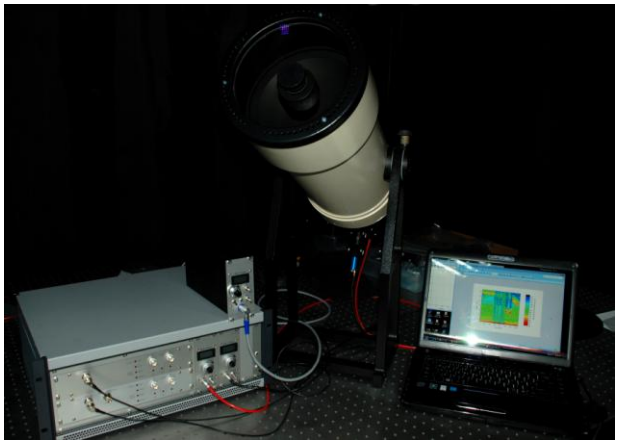

Figure 1. Portable backscatter lidar at MRC, Scientific and Technological Research Council of Turkey (TUBITAK).

The aim of this paper is to describe the experimental details and to demonstrate the first results of the new portable backscatter lidar sounding over the industrial zone of Gebze, Kocaeli district, Turkey located at the shore of Marmara Sea, Gulf of Izmit, about 40 km East from Bosphorus, Istanbul.

This work was supported by State Planning Committee of Turkey.

Aerosol vertical distribution and its variability over Sweden during nighttime: A view from the CALIOP-CALIPSO and AIRS instruments

M.A. Thomas[1], A. Devasthale[1] and M. Kahnert[1,2]

[1]Swedish Meteorological and Hydrological Institute, Research Department, Norrköping, SE-60176, Sweden
[2]Chalmers University of Technology, Department of Earth and Space Science, SE-412 96 Gothenburg, Sweden
Keywords: Atmospheric aerosols, Satellites, Vertical distribution
Presenting author email: manu.thomas@smhi.se

An accurate knowledge of aerosol properties is a key to understand its direct and indirect radiative effects. Especially the vertical distribution of aerosols determines the degree with which it would interact with clouds, influence air quality and the atmospheric heating profiles, among others. Most of the passive satellite imagers have difficulties in retrieving accurate aerosol properties over Sweden due to large solar zenith angles during most part of the year, snow and ice covered surfaces etc. CALIPSO offers a viable alternative to overcome this difficulty. It also has a distinct advantage of providing vertical structure and nighttime observations [1]. Furthermore, the orbital track of CALIPSO is aligned very well with the semi-major axis of Sweden's elongated topography during nighttime (Fig. 1), thus making it extremely appealing for generating statistics of aerosol properties. Here, we use 5 years of Aerosol 5km Layer product from CALIPSO and investigate statistics of aerosol properties. We further investigate the role of temperature inversions in influencing vertical distribution of aerosols.

For the present study we use the standard CALIPSO 5km Aerosol Layer Product (Version 3.01) [1], specifically the aerosol retrievals of aerosol layer base and top heights, and optical depth at the 532nm wavelength. A rigorous quality control is applied while selecting the data for analysis. For example, if a feature is classified as aerosol and the classification quality flag is set to "high", only then are the results used for the analysis. The aerosols are further categorized into six different types, based on their integrated attenuated backscatter and volume depolarization ratio along with ancillary information on surface type and altitude [2]. The six aerosol types analyzed are "clean continental", "polluted continental", "dust", "polluted dust", "clean marine", and "smoke".

The data used in the present study cover the period from June 2006 through May 2011 and is analyzed for four seasons separately, winter (December, January, and February; DJF), spring (March, April, and May; MAM), summer (June, July, and August; JJA), and autumn (September, October, and November; SON).

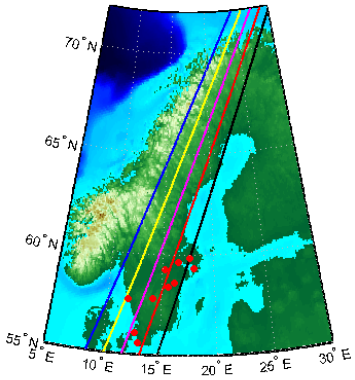

Fig. 1: CALIPSO track over Sweden during nighttime. The red dots show top 10 populated cities.

We investigate the seasonality of:

1) The vertical distribution of aerosols along five selected curtains over Sweden shown in Fig. 1.
2) Aerosol layer optical thickness.
3) Number of aerosol layers present.
4) Relative distribution of aerosol types.
5) Aerosol verticality with respect to temperature inversions derived from AIRS [3,4].

Aerosols play a very important role for the Earth-atmosphere energy budget as they modify it through various atmospheric processes. Aerosols found in the Mediterranean are due to a superimposition of a marine component, a mineral dust component (Saharan dust outbreaks and local dust suspension) and the local and long range transported anthropogenic component (Lelieveld *et al.*, 2002).

Lemesos is an Eastern Mediterranean seaside city, located in Southern coast of Cyprus. Under favorable meteorological conditions (sea breeze and calms) and due to the trans-boundary pollution (forest/biomass burning fires, dust from Desert regions, etc.), the concentration of air pollutants at ground may exceed the air quality standards of the European Union and the World Health Organization (WHO).

Sunphotometric measurements that have been conducted at the ground based AERONET station of Lemessos (34°67' N, 33°04' E) from April 2010 to December 2011, depict the strong variability of aerosol optical properties at this site. Figure 1 presents the temporal variability of aerosol optical depth (AOD) at UV, Vis and IR as well as the Ångström exponent (a) at 380/500nm over Lemesos. The seasonal variability of the aerosol optical properties is strongly related to the seasonal characteristics of aerosol production and transportation processes over specific regions.

In this study, the aerosol variability over Lemessos is examined, using longer AOD records than the ones available from the AERONET station, taken from the satellite-based MODerate resolution Imaging Spectro-radiometer (MODIS) on-board Terra and Aqua satellites. The optimum spatial resolution of the MODIS AOD product has been depicted by Mamouri et al., (2012), using the available ground-truth AERONET data. In this study, the AERONET derived aerosol optical properties are compared with those calculated from MODIS products, using various spatial resolutions. MODIS-Terra platform, with 50km diameter spatial resolution with respect to CUT-AERONET station, showed the highest correlation coefficients for the AOD (Mamouri *et al* 2012).

Based on the good correlation between the two instruments a climatology before 2010 is presented here using MODIS.

Additionally, BSC-DREAM8b model simulations are used in order to provide information on the dust contribution in Cyprus region both, at surface level and atmospheric column. Model's simulations for PM10 at surface are compared also with PM10 measurements available at Lemesos site. Several case studies have outlined the good performance of BSCDREAM8b (e.g. Pérez *et al.*, 2006a,b; Amiridis *et al.* 2009) concerning both the horizontal and vertical extent of the dust plume in the Mediterranean Basin. The model simulations are used in this study complementary with the MODIS aerosol products and in situ measurements of PM10, from the air quality monitoring network operated by Department of Labour Inspection (DLI), Ministry of Labour and Social Insurance of Cyprus.

The present study establishes the first long-term characterization of aerosol seasonal variability over the northern continental region of the Iberian Peninsula, based on remotely sensed aerosol optical properties, with a focus on the Aerosol Optical Depth (AOD) and Ångström exponent (Alpha) parameters. This work uses direct Sun data from the AERONET-RIMA (Aerosol Robotic NETwork - Iberian Network for Aerosol Measurements) site of Palencia (Spain, 42N, 4.5W). This site can be considered as representative of the background atmospheric conditions of the "Castilla y León" region, and has one of the longest AERONET time series in Europe, starting back in 2003.

In this work, which is similar to that carried out for the AERONET-RIMA site of El Arenosillo (Bennouna et al., 2011), the annual cycle of the two parameters was built for the period 2003-2011, and the interannual variability during the whole period was also examined. The ability of satellite data to reproduce the seasonal patterns and anomalies was investigated using MODIS (Moderate Resolution Imaging Radiometer) aerosol products for Terra and Aqua corresponding to the same period. MODIS instantaneous fields were validated against ground-based sun photometer data, and the differences between monthly values were estimated.

The Palencia site is characterized by a mean daily AOD(440 nm) of 0.15±0.10 and an Alpha(440-870 nm) of 1.25±0.35, thus presenting values typical of a clean continental background. The seasonal pattern correspond to mid-high AOD values during a period starting in mid-spring to the end of the summer (max 0.19), and to a lower AOD during fall and winter months (min 0.09). Although the Alpha parameter is nearly constant throughout de year, the latter shows a slight increase in summer, which is correlated with the high AOD values. This might be explained by the frequent occurrence desert dust intrusions and recirculation processes that have the effect to trap pollutants and aged desert dust aerosols.

When using MODIS data, the overall results for Palencia give a higher AOD(470 nm) with 0.19±0.15 and a much lower Alpha (470-660 nm) of 0.70±0.20. The aforementioned numbers reflect substantial differences, with overestimations of the monthly means that can be almost double those of AERONET in the summer months. However MODIS satisfactorily reproduces the increase-decrease cycle in the AOD. These large differences tend to be more attributed to the aerosol models used in the MODIS algorithm rather than to the sampling difference between ground and satellite in this season. Despite the poor sampling in winter and the small AOD (<0.1) observed over the area, the best agreement between satellite and ground is found during this period. The seasonal pattern of the Ångström exponent derived from MODIS was found to be very different from that of AERONET, the former showing apparently no consistency with the latter. Given the aforementioned results and the fact that the AERONET Alpha value for 470-660 nm is 1.41±0.37 (wavelengths used in the comparison with MODIS), we can conclude that the Alpha derived from MODIS is not representative of the aerosol type characterizing this region of the globe.

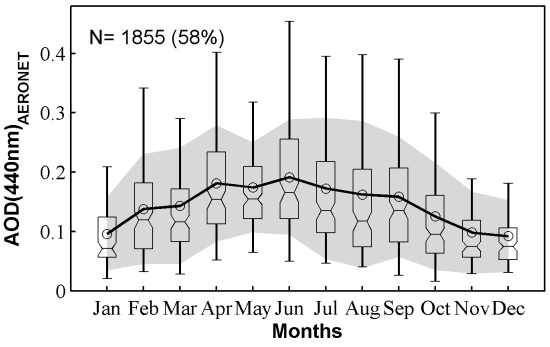

Figure 1: Monthly statistics of the daily AERONET AOD (440 nm) for 2003-2011. N is the total number of days with measurements.

A first approach to study the aerosol indirect effect over Madrid by means of multiwavelength Raman lidar

A.J. Fernández, F. Molero and M. Pujadas

Keywords: Lidar, Aerosol, Water vapour, Indirect effect
Presenting author email: alfonsoj.fernandez@ciemat.es

Atmospheric aerosols and water vapour play key roles in the atmospheric radiation budget as recent studies have shown (Wang et al., 2010). Water vapour is one of the most important absorbers of infrared radiation in the atmosphere, responsible for about sixty percent of the natural greenhouse effect. As regards atmospheric aerosols and according to the Intergovernmental Panel on Climate Change (IPCC), a cooling effect quantified by -0.5 W m^{-2} has been found when they act as scattering and absorption center of the incoming solar radiation, (the so-called direct effect) (Forster et al. 2007). In addition, aerosols also play an important role as cloud condensation nuclei which produce a latent heat exchange in the condensation process as well as an increase of the earth's albedo by clouds. This latest effect is known as indirect effect and quantified by -0.7 Wm^{-2}, nevertheless the IPCC still considers the indirect effect of aerosol the most uncertain component in forcing of climate change over the industrial period. Therefore further studies are required in order to improve the level of understanding of the interaction between aerosols and water vapour.

As the indirect effect occurs at altitudes where the atmospheric parameters reach cloud formation conditions, remote sensing systems are required to study this effect. Lidar techniques represent a powerful tool because of their capability to provide aerosol and water vapour profiles with high resolution both in time and vertical dimension. In this work we present the results obtained by the CIEMAT-Madrid Lidar system (Madrid Lidar station is integrated in EARLINET since 2005). This multiwavelength Raman Lidar system is based on a monostatic biaxial configuration and emits the fundamental, second and third harmonic of a Nd:YAG 30 Hz laser. The receiver is a 30-cm-diameter telescope with a multiwavelength detection module for the three elastic channels at 355, 532 and 1064 nm and three Raman channels at 387 and 607 nm (nitrogen Raman-shifted signals) and 408 nm (water vapour Raman-shifted signal). This experimental configuration has been designed for retrieving water vapor and aerosols properties with maximum accuracy in a maximum vertical range. The water profiles are determined by the ratio between the water vapour 355 nm-Raman-shifted signal and the nitrogen 355 nm-Raman-shifted signal (Whiteman et al., 1992) and are provided in mixing ratio units.

The calibration methodology has been based on the comparison between lidar profiles and radiosoundings launched from Barajas Airport, 15 km east of the lidar site. The influence of different synoptic situations occurred during these measurements are discussed.

Additional information on aerosol characteristics can be provided by multiwavelength lidars because the wavelength dependence of the backscatter and extinction coefficients allows to retrieve vertical profiles of microphysical properties of the aerosols (Müller et al., 2001). Backscatter-related and extinction-related Angstrom exponents provide information of the size of the observed particles. Lidar ratio, the ratio between the extinction and the backscattering coefficients obtained independently by the Raman lidar, characterizes the type of aerosol. Quantification of these aerosol microphysical and optical properties and their dependency on relative humidity is needed to reduce the large uncertainty associated with radiative forcing calculations.

Tropospheric aerosol microphysics and water vapour profiles are simultaneously investigated with unprecedent temporal and vertical resolution in different atmospheric situations. Several features of the profiles are discussed in this work, especially in situations when low-level water clouds are present. In these synoptic situations, the measurements provide relevant information about the role of aerosol properties in cloud-formation processes in the lower atmosphere.

The research leading to these results has received funding from the EU 7th Framework Programme (ACTRIS project, grant agreement n° 262254) and also from the MICINN (Spanish Ministry of Science and Innovation) under project CGL2010-17777.

Presenting author email: edith.rodriguez@fmi.fi

The Single Scattering Albedo (SSA) and the Fine Mode Fraction (FMF) are new retrieval products using the Advanced Along Track Scanning Radiometer (AATSR) satellite instrument. In addition to the Ångström Exponent (AE) which is a very sensitive parameter to measurement and modeling errors in the AOD retrieval, AATSR retrieves include now the FMF which is the contribution of the fine particles in the total AOD. We consider the FMF to be a more robust aerosol size describing parameter than the AE. The SSA and the FMF are obtained with a new method, based on Lookup Tables (LUT), for selected aerosol size distribution, with given refractive index. The LUTs are used together with the contribution in the AOD retrievals of absorbing and not absorbing aerosol particles. The SSA is retrieved at 659 nm. To validate the results two years of retrievals are compared with the SSA and the FMF retrieved from AERONET at level 2.0. The results are compared as well with the results obtained using some other satellite product like MODIS-Terra FMF and the fine mode AOD over land from Parasol. The SSA is compared with the Ozone Monitoring Instrument (OMI) products.

The Advanced Along Track Scanning Radiometer (AATSR), on board the ENVIronmental SATellite (ENVISAT), the successor of ATSR-2 (on board ERS-2), is designed mainly for monitoring land and sea surface temperatures. The special feature of the AATSR instrument is that it provides measurements at two viewing angles, a 55° forward one and about two minutes later a nadir one. This feature is used in the AATSR dual view (ADV) algorithm for aerosol retrieval over land to eliminate the surface contribution from measurements at the top of the atmosphere (TOA) reflectance. The ADV aerosol retrieval algorithm is based on the ATSR-2 algorithm that was initially developed by (Veefkind et al 1998, Veefkind et al 2000) and is described in Curier et al 2009. Hence, an additional surface reflectance model is not needed. The spatial resolution is approximately 1x1 km^2 at nadir and the swath width is 512 km. The AATSR instrument has seven wavelengths in the visible and infra-red regions, centered nominally at 0.555, 0.659, 0.865, 1.61, 3.70, 11.00, and 12.00 µm. At mid-latitudes the return time of AATSR is about three days, and to reach the global coverage takes about five days.

Preliminary results shows predominance of fine particles over Europe with influence of large particles over Spain and North Africa mainly related with dust events. The SSA from AERONET and AATSR has a good agreement between them when the particles are not strongly absorbing.

Keywords: Saharan dust aerosol, lidar, depolarization, microphysics
Presenting author email: fguzman@ugr.es

Studying the influence of non-spherical cloud and aerosol particles on the radiation budget of Earth's atmosphere is of growing importance in remote sensing. Saharan dust storms and volcanic eruptions, e.g., are main sources of non-spherical aerosol particles which are of importance for a better understanding of the direct and indirect climate effects of such global events. There exist essential differences in the light scattering behavior between spherical and non-spherical particles. For this purpose, we consider an ensemble of spheroidal particles characterized by the complex refractive index m, the aspect ratio a and the size parameter r of volume equivalent spheres. I.e., the aspect ratio is the additional microphysical parameter which goes beyond the conventional Mie theory. Such spheroidal particles are used as microphysical model in recent measurement campaigns like EARLINET, SPALINET and SAMUM to study the effect of non-spherical particles on different measurement scenarios and to estimate their influence on the radiative forcing, e.g. [1].

The inversion will be performed with the following data Γ_j : direct-polarization at 355, 532 and 1064 nm and cross-polarization backscatter at 532 nm as well as extinction at 355 and 532 nm (3+1+2 wavelengths λ). We can write this with the particular efficiencies Q_j and surface S as

$$\Gamma_j(\lambda) = \int_{a_{\min}}^{a_{\max}} \int_{r_{\min}}^{r_{\max}} \frac{3S}{16\pi r^3} Q_j(r,\lambda,m,a) v(r,a) \mathrm{d}r\mathrm{d}a.$$

Thus, we are looking at two-dimensional distributions. In this work we present an analysis of a Saharan dust event detected from 2 to 8 April 2011 over Granada, Southern Iberian Peninsula. The event has been monitored with both active and passive remote sensing instrumentation. Back-trajectories analysis indicates air masses coming from North Africa fundamentally. In addition, NAAPS and DREAM models forecast the presence of a mineral dust plume over Southern Iberian Peninsula. Extensive and intensive vertically resolved aerosol properties were obtained from multiwavelenght Raman lidar during the night on 7 April 2011. Particle volume depolarization ratio at 532 nm reached values around 15 % (Fig. 1). Angström exponent values were close to zero.

Note that we are implying spheroidal particles here, with moderate aspect ratios between 0.67 and 1.5. We do not have a physical or meteorological justification for that; the results do look promising though, as in our experience, data not fitting the model will neither lead to

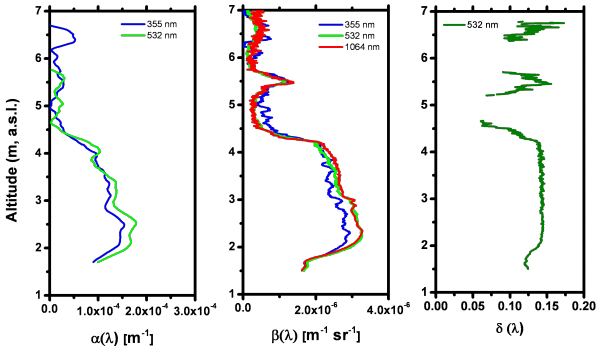

Figure 1: Optical profiles, April 07, 2011, 20:30 UTC.

diagonal structures in the refractive index grids nor to roughly lognormal distributions in the particles. The retrieval of the refractive index grid resulted in a distinct diagonal structure with a sharply defined minimum around $m = 1.4 + 0.01\mathrm{i}$ (not shown here). In the distribution retrieved, there seem to be two distinct modes; first, there is a mode of roughly spherical particles of about 0.5 μm in size, and another mode of larger prolate particles, [2]. The retrieved microphysical properties can be found in Table 1. A total effective radius around 1 μm was found for this layer. This value is higher than the obtained during late afternoon by means of sun-photometer inversion (0.6 μm). This discrepancy could be explained by the fact that whole column sun-photometer measurements could be affect by anthropogenic particles at lower altitudes, this will cause a shift of columnar total effective radius to smaller sizes.

$\Re(m)$	$\Im(m)$	r_{eff} μm	a_t $\mu\mathrm{m}^2\mathrm{cm}^{-3}$	v_t $\mu\mathrm{m}^3\mathrm{cm}^{-3}$

Presenting author email: fguzman@ugr.es

The importance of atmospheric aerosols for the Earth's climate has been widely recognized. They affect solar radiation and hence climate directly by scattering radiation back to space, but also indirectly by acting as cloud condensation nuclei (Twomey, 1974). An important factor affecting the role aerosols play in climate change is their hygroscopicity. Although numerous studies have investigated the relationship between aerosol scattering and relative humidity (RH) from in-situ techniques (e.g., McInnes et al. 1998) remote sensing techniques provide the opportunity to investigate hygroscopic growth of aerosols beyond this RH range, under ambient atmospheric conditions and without perturbing the sampled air.

By virtue of its ability to provide both high spatial and temporal resolution measurements of water vapour throughout much of the troposphere, Raman lidar has emerged in recent years as a potential tool for providing the detailed water vapour profiles required for modelling the complicated processes occurring in the troposphere. However, most of these systems are unable to provide RH profiles due to necessity of simultaneous temperature and water vapour mixing ratio profiles.

This work presents an alternative procedure to obtain RH profiles from two instruments, microwave radiometer and Raman lidar. The study has been developed at Andalusian Center for Environmental Studies (CEAMA), located in South-eastern Spain in the urban area of Granada (37.18ºN, 3.58ºW and 680 m asl). A Raman lidar LR331D400 (Raymetrics S.A.) included in EARLINET was used to retrieve mixing ratio profiles during night time. This information was combined with continuous tropospheric temperature profiles measured by a ground-based multifrequency passive microwave radiometer (RPG-HATPRO, Radiometer Physics GmbH). Additionally, air pressure profiles were estimated assuming standard atmospheric conditions. All these information allowed us to retrieve RH profiles.

A radio-sounding campaign was carried out in our station during summer and autumn in 2011. A total of six launches performed during night-time were used to calibrate lidar water vapour vertical profiles. Besides, these data allowed us to compare the RH profiles derived from Raman lidar and microwave radiometer and those retrieved from radiosondes.

Figure 1 shows an example where RH and temperature profiles are presented. The result shows a good agreement between the RH profile retrieved from lidar and microwave radiometer and that obtained by radiosonde. The biggest discrepancies were found around 3.4 m (asl), where radiosonde reaches RH values around 15% bigger than those retrieved from Raman lidar and microwave radiometer. These bigger differences in RH are due to the deviation between the temperature measured with the radiosonde and those retrieved from microwave radiometer. However, the agreement in the rest of the RH profiles is quite good and the relative differences are below 10 %. These results show the capacity to obtain RH profiles from Raman lidar and microwave radiometer with a high temporal and spatial resolution allowing us perform hygroscopic growth studies.

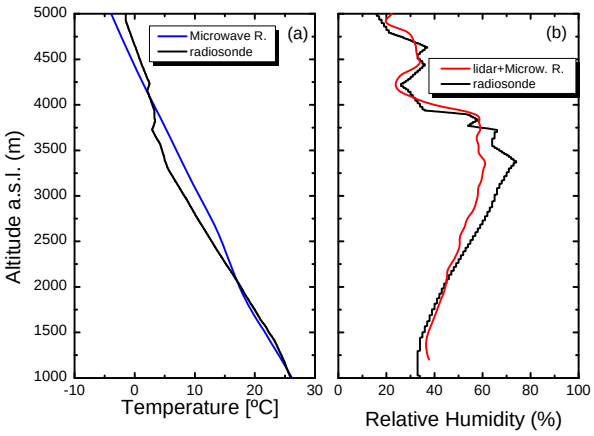

Figure 1. Nighttime measurements performed on 25 July 2011. (a) Temperature profiles from microwave radiometer and radiosonde. (b) RH profile obtained from lidar-microwave radiomenter and radiosonde.

Presenting author email: ifoyo@ugr.es

In this work we study the aerosol radiative forcing (ARF) at Málaga, a coastal location in the Western Mediterranean (36.72ºN, 4.5ºW, 40 m a.s.l) using the direct method (Satheesh and Ramanathan, 2000). In this method the knowledge of the net flux free of aerosols is not required. Others authors have also employed this method recently (Di Biagio et al., 2010; Antón et al., 2011). The analysis uses measurements gathered from January 2009 to December 2010. Columnar aerosol properties were measured by a CIMEL sun photometer included in the AERONET network (Holben et al., 1998). Measurements of global irradiance to calculate the surface net flux have been provided by AEMET.

The aerosol optical depth (AOD) at 440 nm shows values ranging from 0.21 ± 0.10 in summer to 0.11 ± 0.07 in winter, indicating larger aerosol loading during summer than in winter. The seasonal variation of the Angström exponent (α) also shows an evident seasonal cycle but opposite to that of AOD, ranging from 1.1 ± 0.4 in winter to 0.8 ± 0.3 in summer, indicating the dominance of fine particles during winter.

In order to classify additional aerosol properties using AOD measurements, we have followed the framework considered by Gobbi et al. (2007). Figure 1 shows the results. It can be seen the low variability of radius for fine mode (average value close to 0.11 μm), contributing less than 70% by AOD for cases with low AOD. Values with high AOD (AOD>0.7) and lowest α (α<0.5), corresponding to r_f~0.2 μm, showed AOD contributions of the fine mode lower than 35%. This fact indicates the predominance of coarse particles at the site for high AOD. So, it is evident the great influence of the Sahara dust particles at Málaga.

ARF estimations have been done using the direct method to compute the aerosol surface shortwave forcing efficiency (AFE), which is the ARF produced by atmospheric aerosol with AOD equal to 1. Direct measurements of A at Málaga are not available. Taking into account estimates obtained by AERONET network for the two years we have used an average value of 0.14 independently of solar zenith angle (θ_o).

Table 1 shows the retrieved values of AFE for the solar zenith angle intervals considered. We have observed a lower efficiency as increasing solar zenith angle. At 500 nm, the AFE show values close to -(210±20) W/(m^{2}δ) for low solar zenith angles. At Lampedusa, a Mediterranean island, Di Biagio et al. (2009) found AFE values (θ_o= 20º, 495.7 nm) ranging from -250 to -170 W/(m^{2}δ) -rely on the aerosol type-, with a mean value of -210 W/(m^{2}δ).

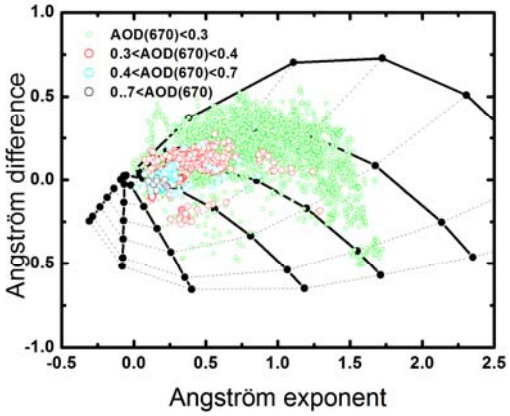

Figure 1. Angstrom exponent difference, α=(440, 675)−α(675, 870), as a function of α (440–870 nm) and AOD at Málaga

Then the value of ARF is derived multiplying AFE by the corresponding value of AOD.

Table 1. Values of AFE for different solar zenith angles

Solar zenith angle (º)	AFE ± σ (Wm^{-2}δ^{-1})
15º≤θ_o<25º	(-210±20)
25º≤θ_o<35º	(-150±20)
35º≤θ_o<45º	(-120±20)

Keywords: Atmospheric Aerosol

The fourth Intergovernmental Panel on Climate Change notes the importance of studying the atmospheric aerosol radiative effects to fully understand its role on climate change. To characterize aerosol columnar effects, passive remote sensing techniques are widely used. This techniques take advantage of the modification of the radiative field due to the atmospheric aerosol.. During the last decades, sun photometry has been developed considerably, and the international network AERONET has been established to study day-time columnar aerosol properties worldwide. This last network has established and standardized the measurement protocol, data processing and quality control of data (Smirnov et al., 2000). Currently, columnar aerosol properties at night-time are poorly known, and their studies are taking an ongoing interest, which include the development of appropriate instrumentation to fill the night-time gaps in large temporal observations that rely on the sun. In this sense, different approaches have been developed using the moon (Berkoff et al., 2011) or the stars (Perez-Ramirez et al., 2008).

As for sun photometry, one of the critical points of star photometry measurements for aerosol characterization is the separation between cloud-affected and cloud-free data. In principle, human observers can detect clouds based on subtle textural and spatial patterns. But the development of automatic instruments posed the problem of defining an effective and automatic cloud-screening procedure.

This work present the development and set up of a cloud screening and data quality control algorithm for a star photometer based on CCD camera as detector. This kind of algorithms is necessary for passive remote sensing techniques to retrieve the columnar aerosol optical depth, $\delta_{Ae}(\lambda)$, and precipitable water vapor content, W, at night-time. This cloud screening procedure consists of calculating moving averages of $\delta_{Ae}(\lambda)$ and W under different time-windows combined with a procedure for detecting outliers. Additionally, to avoid undesirable $\delta_{Ae}(\lambda)$ and W fluctuations caused by the atmospheric turbulence, the data are averaged on 30 minutes. The algorithm is applied to the star photometer deployed in the city of Granada (37.16°N, 3.60°W, 680 m a.s.l; South-East of Spain) for the measurements acquired between March 2007 and September 2009.

The algorithm is evaluated with correlative measurements registered by a lidar system and also with all-sky images obtained at the sunset and sunrise of the previous and following days. Figure 1 shows an example of the cloud screening procedure presented. After applying the moving averages procedure for all-night-window, many data are eliminated (Figure 1a). Figure 1b shows the final day and night time evolution for $\delta_{Ae}(\lambda)$ and the Angström parameter. Some all-sky images are shown at sunrise.

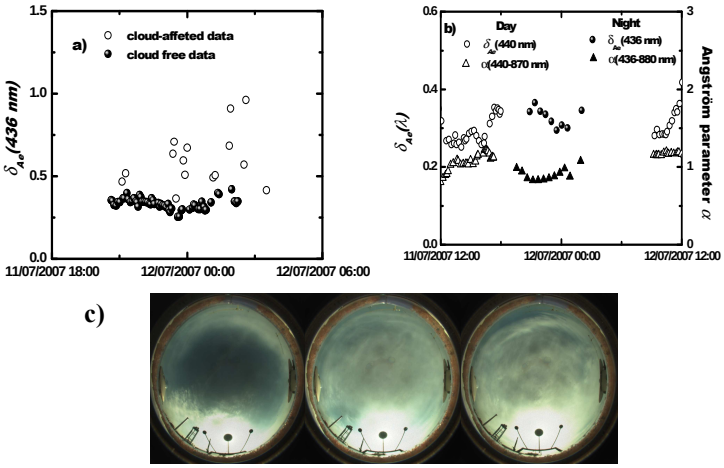

Figure 1: Application of the cloud screening algorithm proposed for the data acquired on 11 and 12 July 2007. All-sky images are also presented.

Promising results are obtained detecting cloud-affected data. Additionally, the cloud screening algorithm has been evaluated under different aerosol conditions including Saharan dust intrusion, biomass burning and pollution events.

Presenting author email: jesusfg@ugr.es

Inputs of aerosol particles and gases from the surface into the atmosphere disperse horizontally and vertically. The mixing height determines the available volume for pollutant dispersion and therefore plays an important role in climate modelling and air pollution. It depends on meteorological parameters, surface turbulent fluxes and physical parameters, and follows a diurnal cycle. Determination of the mixing layer height is not direct but indirect estimates are possible from atmospheric profile measurements. A number of methodologies are already developed depending on the available information (Holzworth, 1964; Vogelazang et al., 1976; Morille et al., 2007) but due to limitations in atmospheric monitoring, continuous values of the mixing height are not easily available. This work shows first results from continuous high temporal resolution estimates of the mixing height over Granada.

Passive microwave remote sensing allows continuous temperature and humidity profiles for nearly all weather conditions under no supervision, representing an advantage to active sensors from the operational point of view. Although temporal resolution is high, passive remote sensing has lower vertical resolution than both radiosounding and active remote sensing.

A ground-based passive microwave radiometer (RPG-HATPRO, Radiometer Physics GmbH) has been used for continuous mixing height estimates under conditions established by the parcel method (Holzworth, 1964). The methodology determines the mixing height as the equilibrium level of a hypothetical rising parcel of air representing a thermal. Surface temperature is independently monitored from a meteorological station located next to the microwave radiometer. Continuous profile measurements are available since October 2010 and an automatic algorithm is capable for monitoring mixing height automatically. Nevertheless, a high uncertainty in the mixing height may result in situations without a pronounced inversion at the convective boundary layer top.

The vertical resolution of the microwave radiometer decreases with height then, when the determination of the mixing height is possible, the maximum error in its estimate is lower than 100 m. Profile data are available every 15 minutes and also the mixing height. Figure 1 shows the temporal evolution of the mixing layer height together with the surface temperature for two representative days in summer and winter. In summer, strong convective conditions promote the growth of the mixing height from early morning to late afternoon, with maximum mixing height about 1800 m agl between 10:30 and 16:30 UTM. During winter time, temperature inversions dominate the rate of growth of the mixing layer and maximum heights are lower than in summer time. Particularly for 8 February 2011 the mixing height rises from around 10:00 to 17:00 UTM with a maximum height of 1500 m agl. After surface temperature start to decrease convective conditions disappear and the mixing layer drops.

The capability of this methodology allows a detailed analysis of the daily evolution of the mixing layer height with applications in a large number of disciplines.

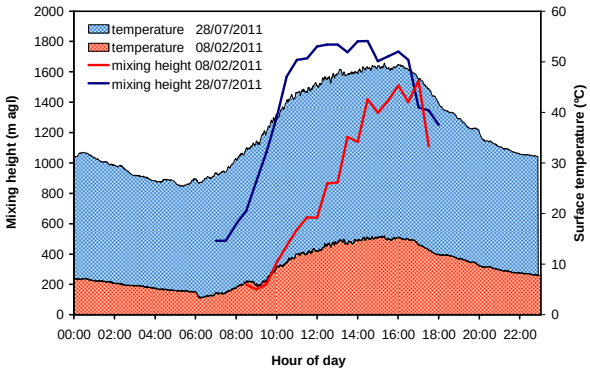

Figure 1. Temporal evolution of the mixing height and surface temperature for two representative days in summer and winter 2011.

Two international measurement campaigns are planned for the summer 2012: ChArMEx (The Chemistry-Aerosol Mediterranean Experiment) pre-campaign planned from June 8 to July 12 and PEGASOS (Pan-European Gas-AeroSOls-climate interaction Study) campaign using the Zeppelin airship planned in two phases from June 8 to July 2 in Po-valley and France and possibly Eastern Europe and 3-9 July over Bologna and surrounding regions [http:// http://charmex.lsce.ipsl.fr/; http://pegasos.iceht.forth.gr/].

On the one hand, the main objective of the ChArMEx pre-campaign is the characterization of dynamic processes of exportation of contaminated air masses from source regions around the Mediterranean coast and the quantification of the exchanges between the boundary layer and the free troposphere above the Mediterranean Basin. On the other hand, PEGASOS campaign goal is to provide detailed measurements of HO_x, trace gases and aerosols throughout the PBL in certain regions. The main focus of the campaign is the boundary layer chemistry (0-3000 m). EMEP (European Monitoring and Evaluation Programme) is also planning an intensive measurement campaign from June 8 to July 17 in coordination with the PEGASOS campaign. The main focus of the EMEP intensive campaign in 2012 is aerosols in terms of PM and chemical speciation (EC/OC, inorganic aerosols and minerals).

Besides measurements performed by EARLINET (www.earlinet.org) stations accordingly to EARLINET schedule, additional measurements will be performed at certain sites during these international campaigns accordingly to specific atmospheric conditions and in support to aircraft measurements. EARLINET lidar measurements will provide the needed additional information about aerosol vertical profiling and aerosol typing. Furthermore some EARLINET stations will participate in an exercise of lidar data assimilation in an air quality model.

Climatology of aerosol optical properties over a tropical –urban location in western India

G. R. Aher and G. V. Pawar

Physics Dept., Nowrosjee Wadia College, Pune (India), 411 001, +91(020) 26162944, +91(020) 26163108,

Keywords: Aerosol optical thickness, Angstrom Exponent, turbidity coefficient.
Presenting author: aher.g.r@gmail.com.

Atmospheric aerosols of natural and anthropogenic origin contribute substantially to global climate variability (IPCC, 2007). Changes in the columnar content of aerosols constitute a major forcing mechanism affecting the radiative balance of the climate system. Understanding of the regionally dependent aerosol optical properties and their spatio-temporal distribution is required for the accurate evaluation of aerosol effects in the climate system. Long term measurements of aerosol optical thickness and Angstrom exponent were analyzed and compiled into aerosol optical properties climatology for tropical–urban location, Pune in western India. Monitoring of aerosol parameters have been made by operating multiple wavelength solar radiometer (MWR) and MICROTOPS-II Sunphotometer on cloudless clear sky days during the period 1998- 2011. The observing season normally spans over December to May months in a year. This formed the core source of database in the present study.

Results show that the seasonal variation of the aerosol optical thickness at 500 and 1020 nm are characterized by low values during winter and high values during pre-monsoon (Fig.1). It is found that the long term mean AOT at 500 nm ranged between 0.61±0.13 during winter and 0.67±0.14 whereas the corresponding range for AOT values at 1020 nm is found to 0.36±0.12 and 0.51±0.17. The pre-monsoon increase is found to be due to the high wind speed producing larger amount of wind driven dust particles. The winter AOT values decrease more at larger wavelengths indicating a general reduction in the number of bigger particles. The quantity of AOT values in pre-monsoon is higher (low during winter) for wavelength, such as near infra-red (NIR), which shows that coarse particles contribute more compared with sub-micron particles.

The Angstrom exponent (α), which represents the particle size distribution and the turbidity coefficient (β), which represents the aerosol loading, are almost opposite to each other which implies higher values of β are associated with smaller value of α (Kumar et al., 2009). In the present case, inverse relationship between α and β is found with a correlation coefficient assuming a value equal to 0.99. Thus, low exponent α values are associated with high β values and vice versa. This indicates that as aerosol loading increases, the relative dominance of fine-mode aerosol decreases. In other words, the increase in loading is due to more increase in coarse-mode aerosol loading. The overall mean value of the Angstrom size exponent (α) at this location is 0.47 and the mean turbidity coefficient is 0.48. The value of α is higher in winter season compared to the pre-monsoon season which indicates the presence of coarse-mode aerosol particles.

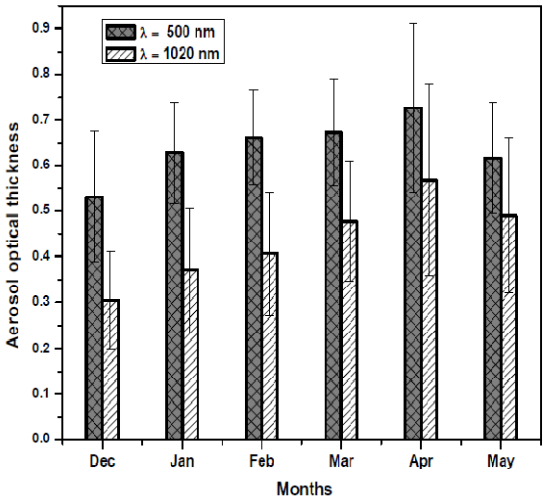

Fig. (1): Multiyear monthly mean variation of aerosol optical thickness during 1998-2011 at Pune

Presenting author email: fj.gomez@ciemat.es

There are currently six groups in Spain involved in the measurement of atmospheric particle size distributions by means of Differential Mobility Analyzers (DMAs). These groups are: IUMA-UDC, IDÆA-CSIC, INTA, IARC-AEMET, University of Granada and CIEMAT. All the groups have to solve many common problems related with the instrumentation required for this type of measurements. For this reason, the Spanish network on environmental DMA (Red Española de DMAs Ambientales, REDMAAS) has been working during 2010-2011 (Gómez-Moreno et al., 2011). The REDMAAS has as main objective the cooperation between the groups, which will lead to solve common problems and to optimize their facilities and protocols. In this work, the main results obtained during these two years will be discussed.

The main activities developed in the network include: DMA calibration; CPC, SMPS and UFP intercomparison; measurement quality control program; losses in sampling lines; support for the radioactive facility license; webpage; and new DMA applications. In the current work, we show the results obtained in the calibrations and intercomparison performed this last year 2011.

Four DMA calibrations have been checked. First, it was necessary to check the DMA (sample, sheath and excess) and CPC (monodisperse) flow rates and then, a monodisperse aerosol, latex, was introduced into the DMA to calibrate the electrical mobility. Two particles sizes have been selected: 80 and 190 nm. In the case of the first particle size, the instruments measured 80 nm, with a -2.3-0.6% deviation, except one of the instruments with 5.8%. The second particle size gave a deviation of 0-2.8%, with the same exception again 9.3%. There is a clear shift in the calibration of one of the instruments. This result shows the need for an environmental DMA network.

A field intercomparison exercise was performed during October 2011 in the INTA facilities (El Arenosillo, Huelva). There were 4 complete SMPS systems, an UFP and two additional CPCs. After calibrating all the flow rates and the DMAs, a CPC intercomparison was performed, see figure 1. The main result obtained was that the CPC3022 was measuring properly concentrations below 10^4 cm^{-3}, but above this value the counter uses the photometric mode which was clearly uncalibrated.

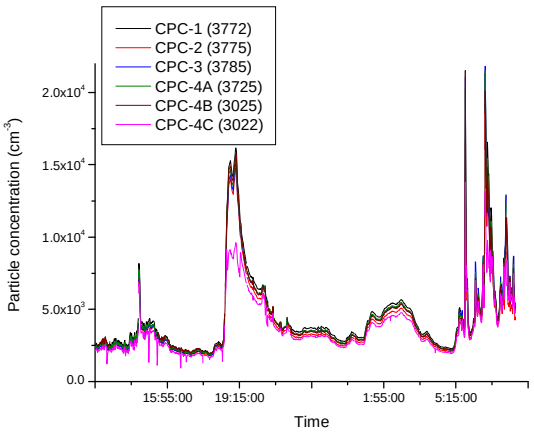

Figure 1. CPC intercomparison

The four SMPS systems and an UPF were compared. As during the 2010 field intercomparison, different concentrations were measured for the nucleation mode, depending on the sheath flow rate. Taking into account the diffusion correction included in the TSI software, these differences were reduced very much.

This network is financed by the Ministry of Science and Innovation (CGL2011-15008-E).

Influence of the thermophoresis on aerosol deposition on warm urban surfaces

Keywords: dry deposition, deposition velocity, thermophoresis, urban areas, submicron particles
Presenting author email: pierre.roupsard@irsn.fr

In the case of an accidental or chronic atmospheric pollution by a nuclear plant, aerosols' deposition transfer coefficients must be known. A major issue is to determine the impact of aerosols contained in the radioactive plume on urban areas with the smallest uncertainties. In this case, deposition must be determined locally in urban canopy. In dry atmospheric conditions, transfer coefficients are defined by the dry deposition velocity V_d (m s^{-1}) which is defined by the ratio between the aerosol dry deposition flux (particles m^{-2} s^{-1}) and the concentration of aerosols (particles m^{-3}). Commonly, dry deposition is considered dependent on aerosol diameter, atmospheric turbulent conditions and deposit surface type. Recently, Maro *et al.* (2010) have observed diminution of submicron aerosol deposition on urban surfaces warmed by the sun during the French Salifa-Primequal experimental campaign. Their results show clearly, and for the first time, the influence of thermophoresis on dry deposition on urban surfaces. Thus, in the frame of our *in situ* submicron aerosol deposition experiments on urban surfaces, a particular interest falls on the quantification of the thermophoresis effect for different surfaces and atmospheric conditions. In parallel, a wind tunnel study has been conducted. Dry deposition velocity of a submicron aerosol has been measured both in wind tunnel and *in situ*, in function of temperature difference between air and warmed surface and wind speed.

Studied submicron aerosol was a monomodal polydispersed fluorescein aerosol (d_p = 0.27 µm), already used by Roupsard *et al.* 2011. This aerosol was taken for both wind tunnel and *in situ* experiments. Wind tunnel experiments were conducted in the IRPHE closed-circuit wind tunnel (8.7 m x 0.7 m x 0.3 m). The tunnel was equipped with a heating board (1.8 m x 0.7 m) at its centre. The bottom of the tunnel was alternatively recovered with each studied surface from the entrance of the tunnel to the end of the heating board. Studied surfaces were horizontal glass (smooth) and horizontal cement facing (rough). Deposition fluxes were sampled with squares substrates (200 mm x 200 mm) made in the studied surface. We used two filter sampling units to measure aerosol concentration in the wind tunnel. One was located 10 mm above substrates and the other was located at the centre of the wind tunnel section. Air temperature was measured at the top of this section, above sample units. Substrates surface temperature was measured with thermocouples. Deposition velocities were measured for four temperature difference ΔT between air and surface (2, 5, 10 and 30 K) and at three wind speeds u_{ref} (1.3, 5.0 and 10 m s^{-1}). Vertical temperature profiles were measured with a rack of thermocouples with the aim of determining temperature gradients to compare experimental results to models. *In situ* experiments were realized at IRSN laboratory (Cherbourg-Octeville). Aerosol deposition was measured on vertical glass and on cement facing, horizontal asphalt, and oblique (30°) zinc, tile and slate. Surfaces were exposed to atmospheric conditions from the day before the experiment to be in real temperature conditions. Fluorescein aerosol was generated and dispersed by wind over the studied surfaces. Surface temperature was measured with thermocouples. Wind speed was measured near surfaces with an ultrasonic anemometer. Ambient temperature and other meteorological parameters were measured with a meteorological station.

Wind tunnel results for heated surfaces are compared with results for the same non-heated surfaces from Roupsard *et al.* (2011). Significant thermophoresis effects were measured from the lowest temperature gradient (ΔT = 2 K) onwards at all wind speeds with minimum decreasing of 40 % of V_d for all surfaces. Deposition velocity appears to be a decreasing logarithmic function of increasing air/surface temperature difference. Impact of thermophoresis is not the same for smooth and rough surfaces. For glass, V_d does not vary with u_{ref} for the same ΔT, except for ΔT = 2 K. For cement facing, V_d decreases in the same way for increasing ΔT and increases with u_{ref}. Temperature profiles have logarithmic patterns with decreasing temperatures for increasing vertical position above the surface. Temperature gradient must be taken near the surface to compare experimental results and physical models. *In situ* deposition velocities present some variations for same wind speed conditions, depending on sunshine conditions. Obviously thermophoresis plays a major role on aerosol deposition on urban surfaces.

The results of this study confirm Maro *et al.* (2010) preliminary observation. In addition, our measurements show that thermophoresis is one of the most important physical phenomenon that should be taken into account in urban area aerosol deposition models.

Presenting author email:hopkepk@clarkson.edu

Introduction

Carbon, primarily a byproduct of incomplete combustion of fossil fuel and biomass burning constitute only a few % of the total PM mass, but disproportionately affect the global climate by absorbing the incoming sunlight and directly warm the atmosphere. BC coated with sulfate is even more effective than externally mixed BC and SO4 particles. Recent studies have indicated that substantial radiative forcing in the Arctic is due to the indirect impact of BC on the albedo of snow and ice surfaces. We are determining the concentrations of BC, EC, MSA, SO_4, and selected trace elements in weekly samples collected at Kevo, Finland from 1964-2010 to assess the impact of aerosols on (1) radiative forcing, (2) source regions that have contributed to the burden of BC/EC and SO4 in the Arctic region, and (3) how the regional emissions impacting Arctic have changed with time.

Methods

Samples were collected over 7 day periods beginning in October 1964 through the present in Kevo [Yli-Yuomi et al., 2003a,b], Finland in an automated system to measure airborne radioactivity. The filters from 1964-1978 have been analyzed for trace metals by neutron activation (INAA) and inductively coupled plasma mass spectrometry (ICP-MS), major ions and methane sulfonate (MSA) by ion chromatography, black carbon, and elemental carbon [Yli-Tuomi 2003a,b]. Filters after 1978 have been analyzed for total and soluble trace elements by inductively coupled plasma mass spectrometry (ICP-MS), and major ions and methane sulfonate (MSA) by ion chromatography. Black carbon, and elemental carbon were analyzed using the approach developed by Li et al. [2002]. The light absorption of each new filter was measured with a Magee OT21 transmissometer. EC was measured using a Sunset Analyzer and the NIOSH protocol [Birch and Cary, 1996].

Results and Conclusions

Figure 1 shows the annual average BC values for 1965 to 2000. The concentrations of BC aerosols during 1965 were 430 ng m^{-3}. From 1966 thru 1987 it varied from ~250 to 430 ng m^{-3}. Beginning in 1989, concentrations showed a systematic decrease to about 150 ng m^{-3}. From 1989 to 2002, the concentrations have remained between 150 and 230 ng m^{-3}. The data from 2003 to 2010 is not yet available. These data show that there was a substantial decrease in BC concentrations around the time of the collapse of the Soviet Union and the change in political systems in eastern Europe.

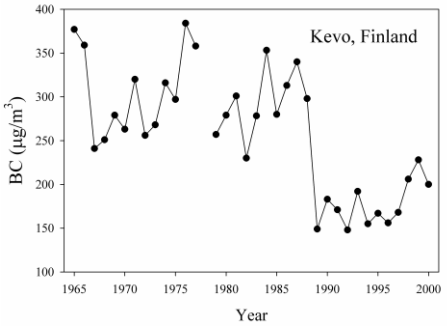

Figure 1. Time series of annual average concentrations of BC at Kevo, Finland

. The solubility of certain elements can provide information about the origin of the aerosol and formation processes. Trend analysis will be performed on individual species. The complete data set will be analyzed by Positive Matrix Factorization (PMF). The receptor modeling results will be connected with back trajectory data in a Potential Source Contribution Function (PSCF) analysis to determine possible source areas. Future work includes complete chemical analysis of the weekly filters through 2010 for trace elements and soluble trace elements by ICP-MS, major ions and methane sulfonate (MSA) by ion chromatography, and black carbon by light-absorption and thermo-optical techniques. This complete dataset will be able to provide insight into the long term trend of Arctic aerosol chemical species and the possible implications of global climate change in the Arctic.

Hygroscopicity of organic/inorganic internally mixed particles by infrared spectroscopy

Lorena Miñambres, Estíbaliz Méndez, María N. Sánchez, Fernando Castaño and Francisco J. Basterretxea[1]

[1]Departamento de Química Física, University of the Basque Country, UPV/EHU,
B. Sarriena, s/n, 48940 Leioa, Bizkaia, Spain
Keywords: tropospheric aerosol, hygroscopicity, deliquescence.
Presenting author email: lorena.minambres@ehu.es

Tropospheric aerosols are composed of inorganic and/or organic material and elemental carbon in varying proportions [Seinfeld and Pandis, 1998]. Among the inorganic fraction, sulfates are important components of continental aerosol. The organic fraction, which can be made up of an enormous variety of compounds, is found either in the surface of the inorganic particles or internally mixed. Organic compounds can alter the hygroscopic and optical properties of the inorganic particles and their chemical reactivity. Much information is still needed to construct more detailed atmospheric models that include the influence of organic compounds in the properties of inorganic particles.

In this work we present a laboratory study of the influence of several dicarboxylic acids (oxalic, malonic, maleic, glutaric and pimelic) in the water uptake properties of submicrometer ammonium sulfate (AS) particles monitored by infrared extinction spectroscopy. Dicarboxylic acids (DA) have been identified at a variety of sources, urban and remote [Prenni et al., 2001]. Infrared spectroscopy is a sensitive technique to characterize aerosol composition, water content and particle phase, and has been used to study other internally mixed organic/inorganic particles [Brooks et al., 2003].

Aerosols are prepared by atomizing aqueous solutions of desired concentrations to yield submicrometer aerosol particles. The relative humidity (RH) of aerosols is controlled by mixing dry and humid flows of nitrogen. The extinction spectra of particles flowing through an aerosol cell are recorded from 800 to 4000 cm^{-1} with a FTIR spectrometer. Particle phase, composition and water content can be monitored by measuring the absorption bands of the various species.

Deliquescence curves of the mixed particles at various solute mass fraction ($0 \le f(DA) \le 1$) have been recorded. The results show that water uptake behavior of internally mixed particles changes noticeably with the organic acid, in some cases favoring the uptake of liquid water at lower RH values than in the pure components. The results are qualitatively explained in terms of intermolecular/interionic forces in the internally mixed solids, which are evidenced in their infrared spectra in terms of shift and broadening of the ν_3 spectral band of sulfate. When the Gibbs free energy of the internally mixed organic/inorganic solid is similar to the sum of Gibbs free energies of the pure solids ($G_{mix} \approx G_{DA} + G_{AS}$), the deliquescence properties are simply intermediate between those of the pure components. However, for the systems where $G_{mix} > G_{DA} + G_{AS}$ (malonic, maleic and oxalic), the intermolecular interactions raise the energy of the mixed solid (as evidenced by intense spectral band broadening) and makes it more unstable than the pure solids, favoring the admittance of water molecules in the net in order to energetically stabilize the system. These results can be of interest to scientists working in atmospheric modelling to be able to predict more accurately the physico-chemical behavior and chemical reactivity of organic/inorganic atmospheric aerosols.

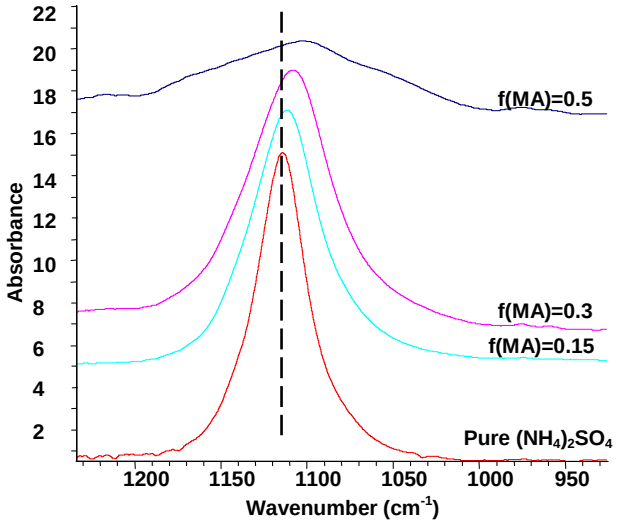

Figure 1. Infrared $\nu_3(SO_4^{2-})$ absorption band of internally mixed dry particles of malonic acid and ammonium sulfate at several f(DA) compositions, showing the changes in bandwidth and band center with solute composition. The spectra have been shifted in the vertical scale.

During the autumn of 2011 particle number concentrations were simultaneously measured in two different environments. The first one represented a regional background site (RS). The sampling point (38°39´N; 0°16´W; 1558 m a.s.l) was located on top of a mountain range, in a military area (EVA nº 5) of the Ministry of Defence, 25 km from the Mediterranean coast. The second monitoring site, about 60 km SE of RS, represented an urban background environment (US). The station was placed in the city of Elche (38°16´N; 0°41´W; 95 m a.s.l), 12 km from the coast.

The study aims to obtain the main factors affecting the particle number concentrations measured at each station and analyse the degree of anthropogenic influence on RS. Anthropogenic emissions from the major coastal cities could reach RS under the appropriate meteorological conditions (e.g. sea breezes).

The instruments used to measure particle concentrations were two optical counters: Grimm 365 (US) and Grimm 190 (RS). These instruments determine particle number concentrations in 31 particle size channels from 0.25 to 32 µm. Previously to the measurement campaign, an intercomparison between the two counters was performed: $N_{360}=1.04 \cdot N_{190}+21$ (Part./l) / $R^2=0.996$; where N is the total particle number concentration.

At the RS site, meteorological data were obtained from a weather station located about 5 m from the ground. For the US site, the data provided by one station of the air quality network of the Government of Valencia, located ~ 2 km south of the measurement site, were used. Meteorological maps from the Spanish Meteorological Agency (AEMET) were consulted. A data base related to Saharan dust intrusions and other differential events affecting the Iberian Peninsula and Canary Islands (http:www.calima.ws) was also used.

For an initial analysis of the hourly variations of particle number concentrations, we selected five consecutive labour days (from 10 to 14 October 2011) without differential events. The synoptic situation during these days was mainly anticyclonic. Table 1 shows the average values of meteorological parameters and total particle number concentrations obtained at each station. As can be calculated from the data shown in Table 1, N at RS represented ~ 30% of that measured at US.

The predominant wind direction in RS during the study period (SE) was appropriate to identify a possible anthropogenic influence from the coastal urban nuclei on the RS site.

Table 1. Average values of meteorological data and particle number concentration

Station	T (°C)	v (m/s)	Wind direction	HR (%)	N (Part./l)
Regional	15.7	2.8	SE	46.7	17218
Urban	22.7	0.5	NW	74.3	63485

Figure 1 presents the average hourly evolution of the total particle concentration N(t) at each station.

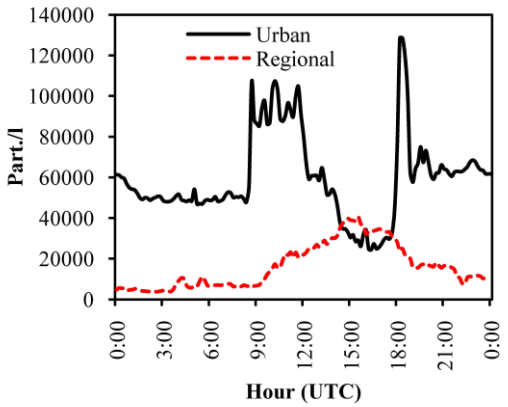

Figure 1. N(t) at both stations

$N(t)_{US}$ presented a similar pattern to that of road traffic intensity in the city, with a peak in the morning and a maximum between 18-20 h (UTC), when people come home from work. On the other hand, $N(t)_{RS}$ showed a wide peak coincident with the hourly variations of solar radiation. Thus, no urban influence on RS was initially observed. Another evidence supporting this assertion is the shape of the particle size distribution obtained at each station. For all particle sizes, the number concentration was higher in US than in RS. However, the relative difference between concentrations measured at both locations was not constant. So, in RS particles belonging to the accumulation mode represented 25% of those measured at US, while this percentage rises to 75% for the coarse mode. This could be due to RS being situated above the mixing layer (ML) (~700 m during the study period). This situation could change if RS is located within the ML, but this scenario is more frequent during spring and summer.

Presenting author email: weigelr@uni-mainz.de

In-situ measurements with a 4-channel condensation particle counter (COPAS, Weigel et al., 2009) with different d_{p50} (50 % detection efficiency cut-off particle diameter) were conducted in the altitude range of 12.0-20.5km on board the M-55 *Geophysica*. One of four channels has a heated aerosol inlet line (at 250°C) which additionally allows for counting non-volatile particles.

Kiruna, North Sweden, was the operations base from where research flights towards the Arctic Winter Vortex (AWV) were performed during three scientific missions: EUPLEX (Jan.-Mar. 2003, 15 flights); RECONCILE, (Jan.-Mar. 2010, 13 flights); and ESSENCE, (Dec. 2011, 2 flights).

For potential temperatures $\Theta > 400$K the progression of the vertical profiles strongly depends on whether the measurements occurred in- or outside the AWV (Figure 1, left). Outside the AWV the particle mixing ratio N remains nearly constant with altitude while inside the AWV N increases with ascent.

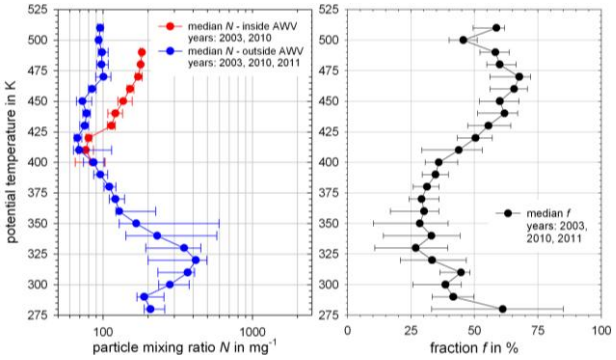

Figure 1. Vertical median profiles with 25- and 75-percentiles of particle mixing ratio N and the fraction f of non-volatile particles.

The fraction f of non-volatile aerosol in the AWV region is generally increasing at altitudes with $\Theta > 400$K from about 35% up to 70% at $\Theta = 475$K (Figure 1, right), which is high compared to f measured elsewhere in the stratosphere at same altitudes (cf. Borrmann et al., 2010). Hence, subsiding air masses inside the AWV entrain particles into the Arctic lower stratosphere from aloft. Up to 7 of 10 of these particles contain solid, not vaporizable material and were previously assumed to mainly stem from meteoritic ablations at mesospheric altitudes (Curtius et al., 2005).

During RECONCILE and ESSENCE particles were collected with an impactor at altitudes of $\Theta > 410$K. The chemical analysis of these aerosols with Environmental Scanning Electron Microscopy (ESEM) and Energy Dispersive X-ray (EDX) analysis techniques yields (apart from found residuals of the volatile nitric- and sulfuric acid compounds):

A) Non-volatile particles with $d_p < 500$nm mainly consist of soot, sometimes with bearings of lead.

B) Particles with $d_p > 500$nm (and $d_p < 6$µm) are partly amorphous, most likely of crustal material. In the same size range also molten spheres were found, alloy particles, metals or metaloxides and silicates.

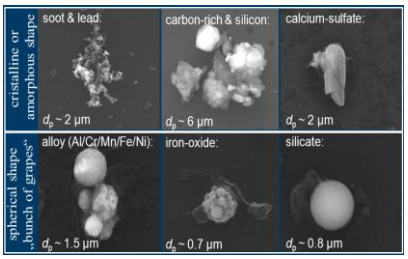

Figure 2. ESEM images of collected particles in the AWV region.

The fly-ash habit indicates that some particles were exposed to high temperatures for a sufficient duration.

These non-volatile particles in the AWV region provide condensation surfaces and thus could contribute to the formation of Polar Stratospheric Clouds (PSCs).

Geophysica missions were funded by the EC within the FP5 and FP7 (EVK2-CT-2001-00119and 226365-FP7-ENV-2008-1) and by the European Space Agency (ESA). Further support was provided by the Universities of Mainz and Darmstadt and the Max-Planck-Institute for Chemistry.

Chemical Characterization of Impactor Samples from seven Sites in Germany

K. Müller, G. Spindler, T. Gnauk, Y. Iinuma, H. Herrmann

[1]Department of Chemistry, Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany
Keywords: aerosol, chemical size distribution, seasonality, spatial distribution
Presenting author email: konrad@tropos.de

Within the German Ultrafine Aerosol Network (GUAN) the collection of size-segregated PM was carried out simultaneously at seven sampling sites in Germany by identical equipment. The seven sites were distributed between one traffic site (Leipzig), two urban sites in residential areas (Augsburg, Leipzig), two rural sites (Bösel, Melpitz), and two mountain background sites (Hohenpeißenberg, Schauinsland). Using weather forecast days with a mainly uniform air mass inflow to Germany and without precipitation were selected to collect PM. After collection of five size fraction in BERNER-LPI 80/0.05 the samples were stored and transported frozen to Leipzig.

All chemical analyses were carried out at the IfT. The main interest was directed to OC/EC distribution and the concentration of single organic species as well as the major ionic constituents. During a period of two years (2009-2010) 48 sampling events of 24 hours took place. At the both sampling sites in Leipzig at fall 2010 five events were applied to test ten-stage LPI. Seasonality and air mass origin were major criteria of the selection of sampling days (Tab.1).

Table 1. Sampling days selected by season and air mass origin.

Season	continental	maritime
Summer	4	22
Winter	12	10

With the exception of the mountain background sites a clear difference between Winter-continental and Winter-maritime air masses was found in all samples. In the long-range transport fractions (0.14-0.42 and 0.42-1.2 µm) highest mass concentrations were determined for OM (Organic Matter), EC (Elemental Carbon), and secondary inorganic compounds. The percentage of carbonaceous material (EC+OM) in the size fraction mass is decreasing from ultrafine to coarse mode particles from 60 to 13 % as a mean for the traffic site and from 55 to 24 % for a rural site (Fig.1). Highest relative concentrations were found in ultrafine particles during summer at the traffic site and in Augsburg.

For the secondary ions sulphate and nitrate the maximum was observed in winter samples in the submicron fractions with a concentration gradient from East to West, depending on long range transports from Eastern Europe. The seasonal variation of nitrate and ammonium is more pronounced than for other ions because of the volatility of ammonium nitrate.

Winter concentrations of PAH were found highest in Melpitz, Leipzig and Augsburg depending on long range transports and emissions of wood burning in the major cities. According to previous works (Poulain et al., 2011) the amounts of PAH are well correlated to the levoglucosan concentrations, which were found to be highest during winterly days with air mass origin in Eastern Europe.

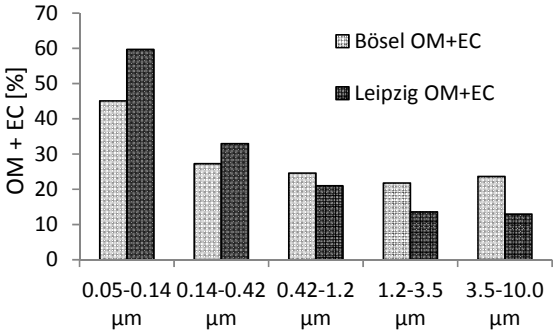

Figure 1. Percentage of carbonaceous material in size fractions of PM at traffic site in Leipzig and at rural site in Bösel (mean values for summer).

During the summer measurement days the OM concentrations at the background mountain sites are comparable to winter measurements while at all other sites in winter samples the submicron particles show higher concentrations than in summer samples. In coarse mode PM higher summer concentrations of OM were observed depending on higher emissions of biogenic material. Fig. 2 shows results from Bösel as an example.

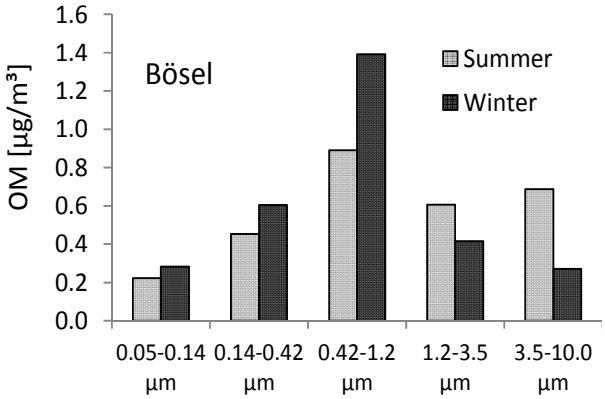

Figure 2. OM concentration in Bösel depending on season

The Aegean Sea is a region of the globe that is influenced by maritime and continental aerosol sources. Very often the dominance of summer northerlies transport polluted air masses from the main continental Europe to the region, thereby affecting the physicochemical properties of the aerosol particles and thus their impacts on regional climate (e.g., Lelieveld et al. 2002; Bougiatioti et al. 2009). The objective of the AEGEAN_GAME field campaign that took place from 25 August to 10 September 2011 was to investigate the properties of aerosol particles in the region and identify their sources. One of the two ground monitoring points of the campaign was at Vigla, a remote location on the NorthWest of Lemnos island.

Dry particle size distributions and scattering coefficients were measured with a Scanning Mobility Particle Sizer (TSI Model 3034) and a Nephelometer (TSI Model 3563), respectively. For the chemical composition of the particles (inorganic species and organic/elemental carbon) we collected size segregated samples using a cascade impactor (MOUDI Model 110 MSP) and a TSP sampler. Concentrations of O_3, SO_2 and NO_x were also measured using gas analyzers (Model 400A for O_3, Model 100A for SO_2, and Model 200A for NO_x).

Time-series of the average number concentration, the scattering coefficients at three wavelengths and the concentrations of elemental and organic carbon are shown in Fig. 1. The average number concentration of particles having diameter from 10 to 487 nm ranged from ca. 500 to 12.5×10^4 particles/cm^{-3} with an average value of around 2093×10^3 particles/cm^{-3} (Fig. 1a). The concentrations observed where at similar levels with those observed at Finokalia station at the South Aegean (Pikridas et al. 2010). The peaks of average number concentration observed on 29/08 and 30/08 were correlated with air masses originating from Eastern Europe, while on 9/9 from Northern Europe as indicated by back-trajectory analysis (HYSPLIT model; Eleftheriadis et al. 2006). The average values of ambient aerosol scattering coefficients measured at three wavelengths (λ = 450, 550 and 700 nm) were 27.5±19.5, 15.7±12.9, and 6.7±7.2 Mm^{-1}, respectively (Fig. 1b). The mean values were in average two times lower than other studies at coastal sites (Bryant et al., 2006).

The chemical analysis of organic and elemental carbon (OC and EC) shows that the ratio OC/EC ranged from 5.9 to 21.94 with an average value of 11.6±4.8 during the total sampling period (Fig. 1c). The mean concentrations of organic and elemental carbon were 1.53±0.92 and 0.17±0.15 μg/m^3, respectively. The mean concentration of OC was on average 9 times higher than EC, indicating the dominant contribution of secondary organic matter.

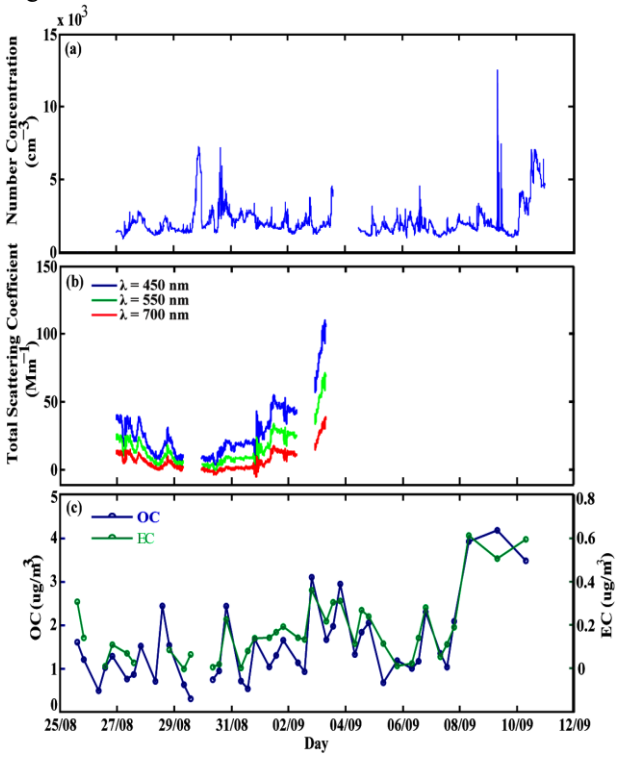

Figure 1. Time series of (a) the total number concentrations of particles having diameter from 10 to 487 nm, (b) the total scattering coefficient 450nm (blue), 550nm (green) and 700 nm (red), and (c) the concentrations of organic (blue line) and elemental carbon (green line) from 25/08/11 to 10/09/11.

Humic-Like Substances (HULIS) have been proven to comprise a significant fraction of the aerosol particle organics in various environments. HULIS have attracted a lot of attention because of their ability to efficiently lower surface tension of water solutions and thereby influence hygroscopic growth and cloud condensation nuclei (CCN) activity (Graber and Rudich, 2006).

We have previously presented CCN-activity and growth factors of HULIS from three different environments. Our results from the three sites were almost identical and similar to what has been observed for Suwannee River Fulvic Acid (SRFA) (Kristensen *et al*, 2011). Filter samples from the rural continental background site Melpitz ($PM_{2.5}$), from a street canyon in Copenhagen (PM_{10}) and from Storm Peak Laboratory (SPL) located 3.2 km a.s.l. in Colorado ($PM_{2.5}$) were used. In this study SRFA and the three HULIS samples were characterized by use of HPLC-QTRAP-MS, Fourier transform infrared (FTIR), ultraviolet-visible (UV/Vis) and Raman spectroscopy. It is to our knowledge the first time Raman spectroscopy has been used for characterization of atmospheric HULIS samples.

The extraction of HULIS was carried out by applying the one-step protocol described by Varga *et al* (2001) with minor modifications. A VERTEX 70 (Bruker) FTIR spectrometer was used to measure the absorbance of HULIS samples with 1.0 cm^{-1} resolution. The samples were prepared on a CaF_2-window by drying the HULIS-methanol-solution in a gentle stream of N_2. The spectrometer was purged with N_2 to minimize the interference by H_2O and CO_2 during measurements. The Raman spectra of the dried samples were measured using a Bruker RFS 100 FT-Raman spectrometer. The exciting laser is a Nd:YAG laser with a wavelength of 1064 nm, and spectra were measured at a resolution of 1 cm^{-1}.

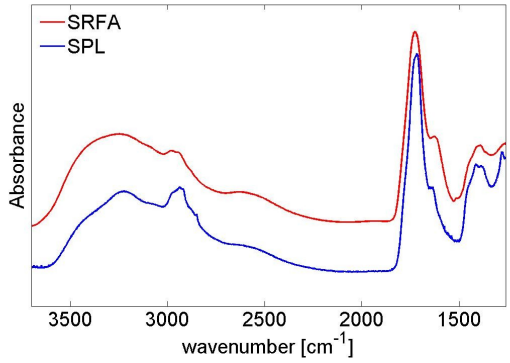

Figure 1. FTIR spectra of SRFA and HULIS from SPL

The UV/Vis spectra were measured with a PerkinElmer Lambda 1050 UV/Vis/NIR spectrometer. The spectrometer was operated with a reference sample in a double beam mode and the resolution was 0.4 nm. The HPLC-QTRAP-MS consisted of a liquid chromatograph (Agilent 1200) interfaced to a ion trap mass spectrometer (AB Sciex QTrap 5500, AB Applied Biosystem - MDS Analytical Technologies) that employed Turbo Ionspray (TIS) ionization.

The FTIR and Raman spectra of HULIS from SPL and SRFA are depicted in Figure 1 and 2 respectively. Many spectral features of the two samples are similar, implying similarities of functional groups. However, distinct differences in spectra obtained by the different techniques indicate characteristic differences of the three HULIS samples.

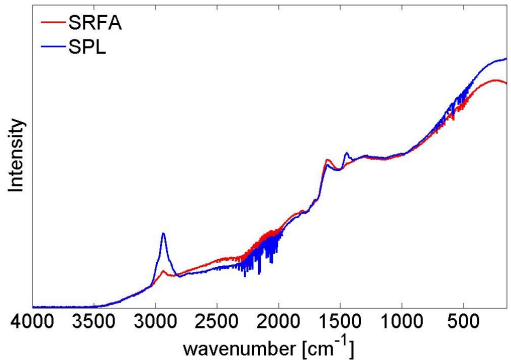

Figure 2. Raman spectra of SRFA and HULIS from SPL.

Photophoresis of soot aerosols in the atmospheric radiation field

L.B. Kochneva* and S.A. Beresnev

Aerosol Physics Laboratory, Ural Federal University, Ekaterinburg, 620083, Russia
Keywords: fundamental aerosol physics, stratospheric aerosols, photophoresis, soot aerosol
Presenting author email*: louisa.letfulova@usu.ru

This report continues and summarizes analysis and estimations of the photophoretic effects for soot aerosols in stratosphere. One of possible mechanisms of aerosol transport in the thermally and mechanically stable stratosphere can be well-known radiometric photophoresis as the regular factor of aerosol vertical motion on the synoptic and global temporal scales. It can lead, for example, to the uncontrollable accumulation of soot particles at the certain altitudes in stratosphere from aircraft engines and biomass burning.

At the first stage of studies the estimations of transport opportunities of negative "solar" (motion of particles in the field of short-wave solar radiation against gravity) and positive "thermal" (motion in the field of thermal outgoing radiation) photophoresis of soot particles have been given at the assumptions of the highest possible intensities of atmospheric radiation fluxes (Beresnev *et al,* 2003). In this report we present updated and expanded calculations of the photophoretic motion characteristics according to the advanced radiation block of the model. Firstly, the results for "solar" photophoretic motion are calculated in the framework of advanced model for short-wave solar radiation (Beresnev *et al*, 2012). Secondly, the characteristics for "thermal" photophoresis are specified taking into account the downward flux of the long-wave thermal radiation (Beresnev *et al.*, 2011).

The results of theoretical analysis of photophoretic motion of soot particles in the short-wave solar radiation field for stationary atmosphere are presented. The integrated fluxes of solar radiation were calculated by the Monte Carlo method with approximation of a plane-parallel, horizontal-homogeneous molecular-aerosol atmosphere. The analysis confirms again an opportunity essential photophoretic effects for soot aerosol particles in stratosphere: the "sun" photophoresis can be considered as the effective mechanism of vertical transport of well-absorbing sub-micrometer particles up to heights of the middle stratosphere. The forces of "sun" photophoresis can compete to gravities up to heights 30-35 km for particles of sub-micrometer and micrometer sizes. On other hand, the estimations have shown again the small efficiency of radiometric photophoresis for weakly-absorbing, dense and high-conducting particles of atmospheric aerosol. The results for photophoretic motion of soot particles in the field of the Earth' thermal radiation in a stationary atmosphere are also presented. In calculations the up- and down-fluxes of thermal radiation are taken into account. It is shown that positive "thermal" photophoresis potentially can be the effective mechanism of vertical transport for micron-sized soot particles at stratospheric altitudes.

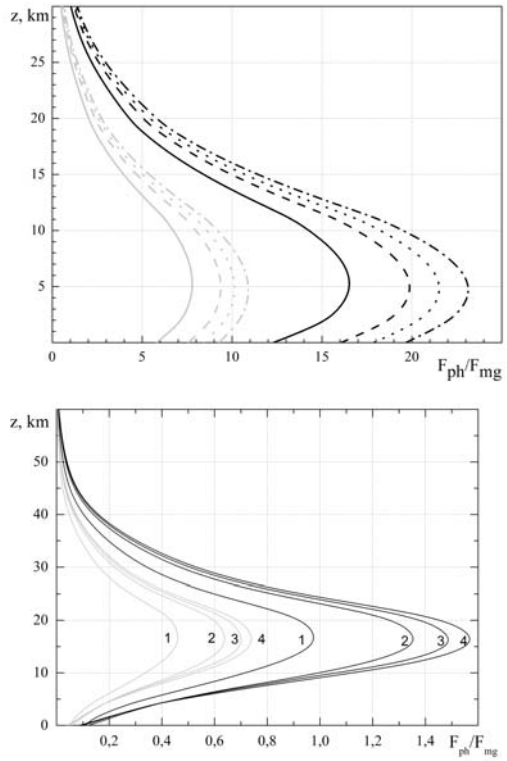

Figure 1. Ratio F_{ph}/F_{mg} as function of altitude z for soot particles in stratosphere. The top panel: the negative "sun" photophoresis; $R_p = 0{,}2$ μm; $m = 1{,}95 + 0{,}1i$; $\Lambda = \lambda_p / \lambda_g = 5$, middle latitudes – summer, solar angle 30^0, surface albedo 0.0(solid), 0.1(dash), 0.2(dot), 0.4(dash-dot); black lines $\rho_p = 165$ kg/m^3; grey lines $\rho_p = 350$ kg/m^3. The bottom panel: the positive "thermal" photophoresis; $R_p = 1{,}5$ μm; $m = 2{,}42 + 1{,}02i$; black lines $\rho_p = 165$ kg/m^3; grey lines $\rho_p = 350$ kg/m^3; 1 – subarctic–summer; 2 – USA standard atmosphere; 3 – middle latitudes – summer; 4 – tropical atmosphere.

Chemistry of Size Separated Aerosols over the Indian Arctic Station, Himadri

M.P. Raju, S. M. Sonbawne, P.D. Safai, P.S.P. Rao and P.C.S. Devara

Indian Institute of Tropical Meteorology, Pune, Maharastra, 411 008, India
Keywords: Size seperation, Arctic region, Chemical composition, fine and coarse mode particles
Presenting author email: mpraju@tropmet.res.in

Abstract:

During the 20th Indian Scientific Expedition to Arctic a detailed study of aerosol mass size distribution was made during July 2010. In order to establish the sources of aerosols, it is necessary to monitor their physical and chemical properties. Low volume aerosol air sampler (Andersen 2000 Inc., USA) was installed at the Indian Arctic site, Himadri. The sampler is operated at a constant flow rate 30 LPM for about one week period to get sufficient aerosol load. Two set of samples were collected. Size distribution of aerosols showed bimodal distribution during both the periods. The coarse mode particles during 13-19 July 2010 period (Set 1) and 24-29 July 2010 period (Set 2) contributed 78.8% and 79.8%, respectively as compared to the fine size aerosol which contributed 21.2% and 20.2%, respectively. The residence time of aerosols in the atmosphere mainly depends upon the size of the particles. Percentage contribution of aerosol for set 1 in nucleation, accumulation and coarse mode was 2.8%, 18.3% and 78.8%, respectively where as in set 2 it was 1.5%, 18.6% and 79.8%, respectively.

Chemical composition of aerosols have also shown a peak each in fine and coarse size for all the components with maximum concentration observed in the coarse mode. Concentration of Na, Cl and Ca was found to be higher indicating dominence of the marine source, but the concentration of F, NO_3, SO_4, NH_4, K and Mg were comparatively less during the study period. Marine source contributed about 48.5% to total measured composition of aerosols where as crustal and anthropogenic sources contributed about 30.0% and 33.6%, respectively. Similarly, in set 2 maximum contribution was from marine (17.8 $\mu g/m^3$), followed by crustal (1.0 $\mu g/m^3$) and anthropogenic (5.2 $\mu g/m^3$). Thus, the site at Indian Arctic station, Himadri is not highly enfluenced by anthropogenic activities.

Two years of measurements of atmospheric aerosols at a remote mountain site in NE Spain

A.Ripoll[1], M.C. Minguillón[1], J. Pey[1], X. Querol[1], A. Alastuey[1],

Investigation of atmospheric aerosols at mountain sites permits to perform ground measurements in the free troposphere without the interference of local pollution, and consequently to better characterize background aerosols, source origins and atmospheric processes. This paper summarizes preliminary results on the interpretation of the time variation of levels of physico-chemical parameters of tropospheric aerosols measured at the Montsec (MSC, 1570 masl) remote background station located in NE of Spain, since November 2009.

PM_{10}, $PM_{2.5}$ and PM_1 concentrations were recorded on a semi-hourly basis by an optical counter (Grimm Labortechnik GmbH & Co. KG, model 1107). Aerosol absorption coefficients at 637 nm (from which black carbon (BC) concentrations were calculated) and particle number (N) concentrations were measured on a 1-5 minutes basis by means of a Multi Angle Absorption Photometer (MAAP, model 5012, Thermo) and a Condensation Particle Counter (CPC, Model TSI 3776, 3-1000nm), respectively. PM_{10} and PM_1 24h samples were collected on quartz fibre filters at a ratio of 1 sample out of 4 days by means of sequential high-volume samplers (MCV CAV-A/MSb), equipped with PM_{10} and PM_1 cut-off inlets. Filters were treated and analysed following the methodology described by Querol et al. (2008), for the determination of the concentrations of major PM components (Al, Ca, Fe, K, Mg, Na, NO_3^-, NH_4^+, SO_4^{2-}, Cl^-, OC and EC) and trace elements (V, Ni, Ti, Cu, Zn, As, among others). In addition to the routine measurements, an intensive field campaign was performed during summer 2011, focused on the investigation of the summer regional recirculation episodes and Saharan dust outbreaks. To this end additional parameters were monitored: size distribution of submicron particles by using a SMPS 3080TSI; NH_3 hourly concentrations by AIRRMONIA; particles scattering (σ_{sp}) and hemispheric backscattering (σ_{bsp}) coefficients by means of a LED-based integrating nephelometer (model Aurora 3000, ECOTECH Pty, Ltd, Knoxfield, Australia); hourly concentrations of non refractory compounds (SO_4^{2-}, NO_3^-, NH_4^+, Cl^- and organics) by means of an Aerosol Chemical Speciation Monitor (ACSM, Aerodyne Research).

Local meteorology was studied by using the data from the Montsec d'Ares station (Catalan Autonomous Meteorological Service). The calculation of back-trajectories ending at MSC at 1500 and 2500 m a.s.l were made in order to classify the origin of the air masses reaching this site. Furthermore, the interpretation of aerosol maps for the identification of long range transport of atmospheric aerosols, including African dust, biomass burning and anthropogenic pollution plumes, were made by using BSC/DREAM8b, SKIRON and NAAPS models.

Low average concentrations of particle matter (PM) and BC were recorded for 2010-2011 (11.5 µg m^{-3}, 8.5 µg m^{-3}, 5.9 µg m^{-3} and 192 ng m^{-3} for PM_{10}, $PM_{2.5}$, PM_1, and BC, respectively), which is typical of the continental background sites,. On the contrary, the mean level of N for the same period (3588 # cm^{-3}) can be considered as relatively high for remote sites.

Concentrations of PM, BC, N, and PM components varied markedly according to the origin of the air masses. Lowest levels for most pollutants were recorded during winter stagnating conditions and the Atlantic advections, when the MSC site is located above the boundary layer. High absorption coefficients and levels of PM_{10} and mineral matter were obtained during Saharan dust outbreaks. Summer regional recirculation episodes (Rodriguez et al., 2003) are characterized by high levels of PM_1, SO_4^{2-}, OC, EC, absorption coefficients (BC) and N. The European episodes, occurring typically in winter, showed high concentrations of NO_3^- and EC. The maximum N was usually recorded in summer at midday, associated to winds from the SWS sector, and are interpreted as the new formation of particles by photochemistry nucleation episodes (Figure 1).

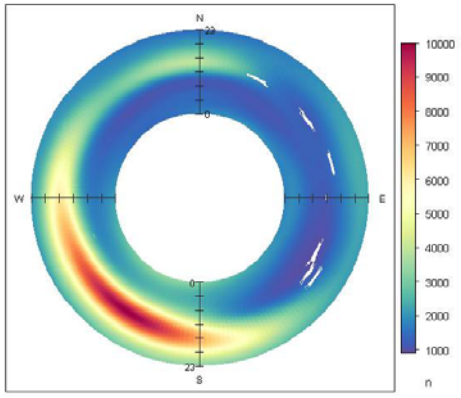

Figure 1. Daily variation of particle number concentration as a function of the wind direction

Investigating physicochemical properties of marine aerosol over the Atlantic Ocean

S. Huang, L. Poulain , Z. Wu, F. Höpner, H. Herrmann, A. Wiedensohler

Leibniz Institute for Tropospheric Research, Leipzig, 04318, Germany

Keywords: Atlantic aerosol, Marine sulphate, Methane sulfonic acid, Hygroscopicity, Polarstern.
Presenting author email: huang@tropos.de

Marine aerosol plays an important role in global climate regulation and marine biogenic system. For a better understanding of its importance, much research was performed to investigate its physical and chemical properties by ship campaigns, but mostly focused on coastal regions or part of ocean areas. In our study the physicochemical properties of marine boundary layer aerosol were measured on board of the research vessel Polarstern during a series of cruises from North Atlantic to South Atlantic.

The primary results of chemical composition and hygroscopic properties of Atlantic aerosols for the first cruise, Polarstern Expedition ANT-XXVII/4 from Cape Town (South Africa) to Bremerhaven (Germany) in April and May of 2011 were presented. During this cruise, a large suite of on-line instrumentation including a High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS), a Scanning Mobility Particle Sizer (SMPS), a Cloud Condensation Nuclei counter (CCNc), a Hygroscopicity Tandem Differential Mobility Analyzer (H-TDMA), an Integrating Nephelometer, and a Multi Angle Absorption Photometer (MAAP) were deployed, as well as 24-hour DIGITEL filter samples (PM_1).

HR-ToF-AMS provided high time resolution and size-resolved chemical compositions for marine aerosol. Since Methane sulfonic acid (MSA) is considered as an important tracer for marine aerosol and sulphur cycle, but mainly contained in sulphate and organic compositions when detected by AMS, we extracted MSA from the standard AMS compositions by the method described by Zorn *et al* (2008).

AMS Unit Mass Resolution (UMR) results showed that sulphate is the dominant species of non-refractory submicron marine aerosol in marine boundary layer(-9 ng/ m^3 - 11.95µg/m^3), averagely taking 61% of total measured mass fraction during the whole measuring period (excluding periods with ship exhausts contamination). Figure 1 provided a full picture of the sulphate mass concentration along the ship track. The outflow from Gibraltar and continents seems have strong influence when ship passed by. However, a clearer understanding could be achieved after detailed back trajectory analysis.

The organic is the second important species accounting for 22% in average over the whole period. Ammonium shows an obvious concentration (-5 ng/ m^3 - 2.13µg/m^3) in most measurement period. But the mass concentrations of nitrate and chloride are very low all over the cruise. The same situation happened to the marine aerosol tracer MSA. However, it presented a visibly similar trend with sulphate.

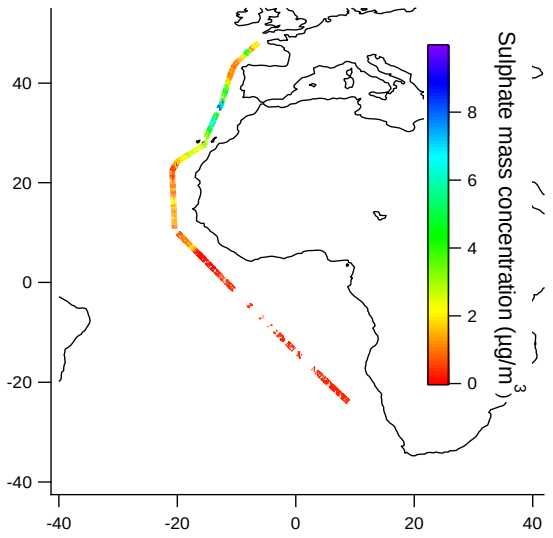

Figure 1. Sulphate concentration along the ship track

In addition, we performed a closure study of hygroscopicity of the size-resolved particles using the Zdanovskii–Stokes–Robinson (ZSR) method based on H-TDMA measurements and AMS data. The theoretically predicted GFs, which were calculated from chemical compositions, showed a good consistence with the measured GFs derived from HTDMA measurements. The high time resolution and size-resolved particle chemical composition provided a significant insight into the influence of the aerosol chemical composition on the aerosol hygroscopicity.

Evaluation of aerosols properties using ground based instruments in Magurele, Romania

J. Vasilescu[1], L. Marmureanu[1], A. Nemuc[1] and L. Belegante[1]

[1]National Institute of Research and Development for Optoelectronics, Magurele, RO 77125, Romania
Keywords: organic aerosols, refractive index, aerosol size distribution
Presenting author email: jeni@inoe.inoe.ro

The aim of this study is to characterize local and biomass burning long-range transported aerosols influences at Magurele site (44.35 N, 26.03 E), using collocated ground based instruments. Chemical composition and size distribution of submicronic aerosols at ground level have been studied using an Aerodyne C-TOF aerosol mass spectrometer (AMS) (Allan et al, 2003). Inversion products (Angstrom exponent, single scattering albedo, refractive indexes and integrated aerosol size distributions) from an eight wavelengths CIMEL Electronique spectral sun photometer, part of AERONET-Aerosol Robotic Network (Holben et al, 2001), have been also used. Long range transported aerosols cases have been confirmed by Hysplit-Hybrid Single Particle Lagrangian Integrated Trajectory Model (Draxler et al, 2012) and MODIS (Moderate Resolution Imaging Spectroradiometer) global fire maps.

In order to assess the influence of local organic aerosols we have been chosen measurements data in cases of nearby fires (spring 2010) and local heating (winter 2011, 2012). Two cases of long range transported biomass burning aerosols (summer 2010) are taken into consideration as well. The age of organic aerosols was assessed from mass spectrum values of m/z 57, 43 and respectively 44 (Hildenbrandt et al, 2010) and from percentage of the *m/z* 44 fraction from the total organics (Adler et al, 2011). Even though the instruments measured different air samples, AMS at the ground level and sunphotometer on integrated column, some correlations between optical and chemical retrieved parameters were observed.

According to AMS measurements, main species at ground level are organics, nitrate, sulphate, and ammonium. Organics concentrations five times higher than other species in some particular cases have been noticed. Small values of the percentage of the m/z 44 from the total organics indicate less oxygenated organic aerosols. The spring cases with percentage around 0.02±0.001 are fresh organics, in contrast with summer cases, with higher percentage (0.18 ±0.003) considered aged aerosols transported from Ukraine region.

The aerosols refractive indexes, real (mR) and imaginary (mI) part, are related to the particles chemical composition and to the internal mixture of species. As it was expected in the cases with local aerosols influence the sunphotometer retrieved refractive indexes values are different from those measured nearby sources indicated by literature (mR: 1.49-1.53; mI 0.01-0.02) (Adler et al, 2011). The local ground aerosols don't influence too much the data sensed by instruments which measure an integrated column. In Figure 1 real and imaginary part of refractive indexes from sunphotometer are plotted versus normalized organics concentration from AMS to show the correlations of these parameters for nearby fires (green), house heating related organics (white) and long range transported biomass burning (grey). The mR values sensed by sunphotometer are not influenced by local aerosols, but the mI is more sensitive to these events. Size distributions of submicronic aerosols during heating period presented in general two peaks (at 200 and 500 nm diameter) and during biomass burning influence only one peak (at 400 nm diameter). The AMS and sunphotometer data are in good agreement regarding the size distribution of aerosols.

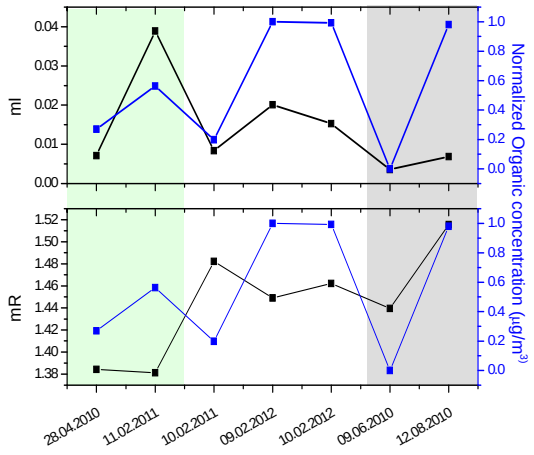

Figure 1 Comparison between sunphotometer refractive indexes (imaginary and real) and normalized organic aerosols concentration derived from AMS measurements

Size-segregated inorganic aerosol compounds during different meteorological scenarios

M. A. Revuelta, F. J. Gómez-Moreno, L. Núñez, M. Pujadas, B. Artíñano

Department of Environment, Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), Madrid, 28045, Spain
Keywords: sulfate, particulate nitrate, hygroscopic growth, size distribution
Presenting author email: b.artinano@ciemat.es

Secondary inorganic compounds (SIC) represent a significant fraction of particulate matter in urban environments. They are formed from precursor gases through different processes that define the chemical and physical state of the particulate compound. Photochemical oxidation through the OH radical and aqueous-phase reactions – and thus meteorological conditions - play a key role in these processes. SIC generation produces acidic nitrate and sulfate that in the urban atmosphere are usually neutralized mainly by ammonium (Bari et al, 2003).

In an urban background site in the Madrid Metropolitan Area measurements have been taken for three different meteorological scenarios during winter 2011. A severe fog episode (E1) was compared to a typical intense winter accumulation situation (E2). E3 was intermediate between E1 and E2.

During the three events, size-distributed particle ion composition was obtained by a micro-orifice deposit impactor (MOUDI) and a nano-MOUDI attached. This impactor collected fourteen size fractions that were chemically analyzed for soluble ions (sulfate, nitrate, ammonium, calcium and others). Total size distribution spanned from 18 µm to particles smaller than 0.01 µm. Samples were taken on a 24 h time basis. Near real-time measurements of particulate sulfate, nitrate and precursor gases concentrations were continuously monitored, as well as meteorological variables. In addition, for E2 the particle size distribution from 20 to 0.015 µm was measured by the combined use of an optical particle counter GRIMM1108 and a Scanning Mobility Particle Sizer.

During E1, ion analysis showed a very pronounced accumulation mode of 1-1.8 µm of both sulfate and nitrate. Aerosol was acidic below 0.18 µm. Time series shows production of these compounds during day and night and relative humidities always above 85%.

During E2 the prevailing aerosol mode was also in the accumulation range, but the highest concentrations were found in smaller sizes. A minor nitrate coarse mode was found. Aerosol was acidic in the range 0.32-1.8 µm and also below 0.18 µm. Total concentrations were one order of magnitude lower than in E1. Time series shows daily SIC generation correlating with solar radiation and related to precursor gases. A comparison between the ion size distributions and the aerosol volume distribution was performed.

During E3, ion distributions and time evolution parameters show intermediate characteristics between E1 and E2. However, ion concentrations are only slightly higher than in E2, and very far from those found in E1. (See Fig. 1). This indicates that aqueous-phase is more efficient than photochemical-dominated SIC production.

This study was conducted in Madrid as an extension of Plaza et al (2011). In that case the efficiency of sulfate formation by aqueous phase oxidation and further ammonia uptake was stated. In the present work this efficiency is evaluated for a severe fog event and also for nitrate.

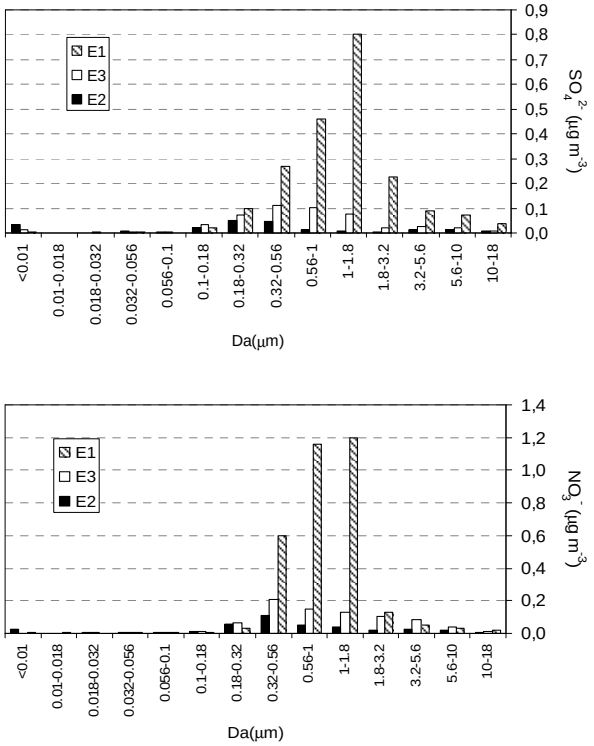

Figure 1. Sulfate (top) and nitrate (bottom) size distribution for E1, E2 and E3.

Ionization of the atmosphere induced by cosmic rays: Full model and practical applications

I.G. Usoskin[1]
[1]Sodankylä Geophysical Observatory and Dept. of Physics, University of Oulu, Finland
Keywords: atmosphere, ionization, cosmic rays
Presenting author email: ilya.usoskin@oulu.fi

An important physical characteristic of the atmosphere is its degree of ionization. Although it is usually very low, viz. the atmosphere is essentially neutral, the small amount of mobile ions can play an important role in atmospheric chemistry. Ionization in the atmosphere is grossly defined by the cosmic ray energetic particles either of galactic or solar origin. A direct effect of atmospheric ionization on aerosol formation and growing is not confirmed by field experiments (Kulmala et al., 2010) and is shown to be small by laboratory experiments (e.g., Kirkby et al., 2012). On the other hand, a case study of an extreme solar energetic particle event of January 20, 2005 suggest that barely noticeable effect in polar stratospheric aerosols may exist (Mironova et al., 2008, 2011), probably via indirect way.

In order to study the role of ionization, one needs a reliable numerical model. Here we present a full 3D numerical model of cosmic ray induced ionization in the atmosphere which can be applied in all conditions. The model CRAC:CRII (Cosmic Ray induced Atmospheric Cascade: application for Cosmic Ray Induced Ionization) is a full 3D physical model based on a full Monte-Carlo simulation of the cosmic ray induced atmospheric cascade (Usoskin and Kovaltsov, 2006; Usoskin et al., 2010). We note that most of earlier models (including semi-empirical) do not consider the full atmospheric cascade and/or limited in energy of incoming energetic particles and thus have strict limitation to be valid only in the upper polar atmosphere. The CRAC:CRII model is applicable in the entire neutral atmosphere, from poles to equator and from ground level to the mesosphere. It has been tested versus fragmentary measurements to show agreement within 10%. The model output is given either as a pre-calculated look-up tables or a simple parametrization, and is easy to apply in practice. The CRAC:CRII model is used to evaluate the ionization background in many atmospheric models, and also in the CLOUD experiment.

We present the physical background of the ionization processes, and discuss practical implications.

Presenting author email: thomas.hamburger@itm.su.se

The tropics comprise an important source region of aerosol particles, most notably desert dust, biomass burning and biogenic aerosols. However, long-term measurements of aerosol properties in the tropical free troposphere are sparse. Aerosol measurements were conducted between March 2007 and May 2009 at the Pico Espejo Atmospheric Research Station Alexander von Humboldt (Schmeissner *et al*, 2011). The Pico Espejo (8.51° N, 71.05° W, 4765 m a.s.l.) is located on the top of the Sierra Nevada mountain ridge close to the city of Mérida, Venezuela.

Particle number concentration, size distribution, volatility and light absorption were observed at the high altitude research station. The aerosol instrumentation contained a Particle Soot Absorption Photometer (PSAP) and two Differential Mobility Particle Sizer (DMPS). Particle number concentrations were measured using Condensation Particle Counters (CPC). A thermodenuder was used to heat the sampled aerosol to 300°C. It was combined with one DMPS to retrieve information on volatile particle number and volume. Case studies using different thermodenuder settings were performed to analyse the temperature dependency of volatile and semi-volatile particle compounds.

The location of the Pico Espejo allows for observations of air masses within the lower free troposphere as well as air masses from the planetary boundary layer reaching the high altitude station through shallow convection. Observed air masses frequently originate from the Amazon Basin. The Amazon is a rich source of biomass burning aerosol during the dry season from December till April (Guyon *et al*, 2003). In addition to the influence from regional and continental aerosol sources episodes of long-range intercontinental transport were observed. Results retrieved from the Lagrangian Particle Dispersion Model FLEXPART (Stohl *et al*, 2005) show that air masses originating in Africa are a very likely source of aged biomass burning plumes observed at Pico Espejo station.

The seasonal cycles of particle absorption and ambient and heated (300°C) particle concentrations follow a well-defined pattern reaching their maxima in the end of the dry season around March and April. Besides the seasonal cycle, there is also a distinct diurnal cycle at Pico Espejo. Free tropospheric air dominates during night time until midday. Air influenced by the planetary boundary layer often reaches the station from midday until evening hours due to increased surface heating and shallow convection induced by the orography.

Fig. 1 shows diurnal cycles of the absorption coefficient (a) and heated (300°C) particle volume concentration (b). Both diurnal cycles are divided into dry (red) and wet (blue) seasons. Median values (lines) and Quartiles (shades) are shown in both panels. The median values of both parameters increase during the wet season by a factor 2-3 from night time to daytime. An increase by a factor of 10 was observed for both parameters during the dry season. The third quartile of the absorption coefficient reaches 1.3 Mm^{-1} during the dry season. However, single events of absorption coefficients up to 8 Mm^{-1} were observed.

Further, aerosol light absorption and aerosol volatility seasonal cycles in the tropical free troposphere will be discussed with respect to meteorological conditions, transport, general circulation and source regions.

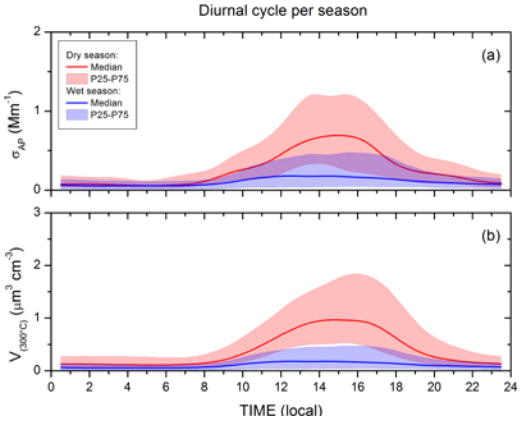

Figure 1. Diurnal cycle of the absorption coefficient (a) and non-volatile (300°C) particle volume concentration (b) for dry (red) and wet (blue) season.

Climate and health effects of atmospheric aerosols are determined by their properties such as their chemical composition. Aerosol chemical composition can be studied indirectly by measuring volatility of the aerosol particles. The volatility of submicron aerosol particles (15-500 nm) was studied in a boreal forest site at SMEAR II (Station for Measuring Ecosystem-Atmosphere Relations II) station (Vesala *et al.*, 1998) in Hyytiälä, Finland, during 01/2008-05/2010. The instrument used for the measurements was a VDMPS (Volatility Differential Mobility Particle Sizer), which consists of two separate instruments: a DMPS (Differential Mobility Particle Sizer, Aalto *et al.*, 2001) and a TD (Thermodenuder, Wehner *et al.*, 2002).

Aerosol evaporation was examined by heating aerosol and comparing the total aerosol mass before and after heating. In the VDMPS system ambient aerosol sample was heated to temperatures ranging from 80 ºC to 280 ºC. The higher the heating temperature was the more aerosol material was evaporated. There was a non-volatile residual present in aerosol particles when heated to 280 ºC. This residual explained on average 19% of the total aerosol mass. The aerosol non-volatile mass fraction had a clear negative correlation with ambient temperature: aerosol mass fraction remaining was the highest during winter and the smallest during the summer months.

The role of black carbon in the observed non-volatile residual was determined. Black carbon explained on average 55 to 90% of the non-volatile mass. However, especially during colder months noticeable fraction of non-volatile material, something else than black carbon, was observed. According to Kalberer *et al.* (2004) some atmospheric organic species can form polymers that have high evaporation temperatures. Also low-volatile organic salts may contribute to the non-volatile aerosol (Smith *et al.*, 2010).

Aerosol mass composition measured directly with AMS (Aerosol Mass Spectrometer, Jayne *et al.*, 2000) was analyzed in order to examine the properties of the non-volatile material (other than black carbon). The AMS measurements were performed during spring and autumn 2008. Results from the aerosol mass spectrometry indicate that some nitrate and organic compounds may be found in the non-volatile aerosol residual, especially during autumn. During the winter and spring months the non-volatile core (black carbon removed) correlated markedly with carbon monoxide and sulfur dioxide, which are tracers of anthropogenic emissions. Due to this, the non-volatile residual may also contain other pollutants in addition to black carbon. Thus, it seems that the volatility of submicron aerosol particles is affected by both anthropogenic and biogenic factors as well as by the meteorological conditions.

Keywords: Aerosol, water soluble organic matter, surface active substances, electrochemical method
Author email: kozarac@irb.hr

The composition of the organic part of the atmospheric aerosol and the respective source contributions are far less known than those of the inorganic part. Significant proportion (30-80%) of the organic carbon is water-soluble (WSOC) and made up of polymer-type substances of higher molecular weight. Surface active substances (SAS) are the most reactive part of organic matter in natural environmental systems which accumulate at the interfaces and are present in aerosols and atmospheric precipitations. They form the surface film at the rain drop/air interface in which persistent organic pollutants accumulate, making long distance transmission possible. Surface active organic constituents can influence the surface tension of nucleating cloud droplets and thereby modify the critical supersaturation necessary to activate aerosol particles. The electrochemical methods offer an elegant way of SAS qualitative and quantitative characterization based on the measuring of electrode double layer capacity changes at mercury electrode surface. The method is applicable for the analysis of SAS in different aquatic systems, both freshwater and marine, which is very convenient for comparative studies.

Aerosol samples (PM 2.5) were daily collected at Middle Adriatic station influenced by marine, regional and continental air masses inputs as well as from urban (Zagreb, Croatia) and rural (K-puszta, Hungary) areas during late spring-early autumn period and SAS were analysed by the electrochemical method.

The highest SAS concentrations, expressed in equivalents of Triton-X-100, ranging from 0.34-0.91µg m^{-3} (mean 0.55± 0.21µg $m^{-3,}$ n=10) were detected in urban samples. The surfactant activities of marine, regional and continental samples were in the narrow ranges from 0.14-0.31µg m^{-3}(mean 0.25±0.06µg m^{-3},n=10), 0.18-0.42µg m^{-3} (mean 0.27±0.07 µg $m^{-3,}$ n=18) and 0.07-0.28µg m^{-3} (mean 0.17±0.075 µg m^{-3}, n=10), respectively. The SAS concentrations in K-puszta aerosol samples ranged from 0.13-0.46 µg m^{-3} (mean 0.29±0.11 µg m^{-3}, n=6). Investigation of isolated humic-like substances (HULIS) confirmed that HULIS material exhibit strong surface activity. On the basis of the normalized surface activity we recommend that the surface activity of non-urban samples can be modeled by C9 fatty acid.

This work was funded by the bilateral Croatian –Hungarian research project "Complex investigation of organic aerosols in rural, urban and marine environment" and by the grant from the Croatian Ministry of Science, Education and Sports project "Nature of organic matter, interaction with traces and surfaces in environment" (098-0982934-2717).

Hygroscopic Properties of Ultrafine Aerosol Particles over the Aegean Sea

Ultrafine aerosol particles in the atmosphere can absorb and scatter radiation, thereby affecting the climate of the Earth at a local and a global scale (IPCC 2007). The scattering and absorption efficiency of these particles strongly depends, among other factors, on their water content. It is therefore important to have information on their ability to take up water (i.e., particle hygroscopicity) when exposed to conditions of different relative humidity (RH) in order to understand their impacts on climate.

In this work we report in situ measurements of the hygroscopicity of the particles observed in the atmosphere over the Aegean Sea during the end of summer (from 25 August to 10 September 2011) when the composition of the atmosphere in the region is affected by northern winds (Etesians). For the measurements we employed a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA; Rader & McMurry, 1986) located at Vigla station on the island of Lemnos, and high time-resolution particle composition measurements obtained by an Aerosol Mass Spectrometer (AMS; Jayne et al. 2000) that was onboard the BAe146-FAAM aircraft that was also operational in the region during the measuring period. The hygroscopic growth of the particles over the Aegean Sea was then estimated using the k-Köhler theory (Petters & Kreidenweis, 2007) in combination with the AMS measurements

Fig. 1 shows the HTDMA measurements of particles having dry diameter from 50 to 170 nm at Vigla station. The hygroscopic growth factors ranged from 1.0 to 1.8 with an average value of ca. 1.2 when the operating RH within the HTDMA was set to 85%. The relatively low hygroscopic growth factors indicate that the particles had a substantial amount of organic species. This conclusion is corroborated by the airborne AMS measurements when the aircraft flew over Lemnos at a height ± 300 meters higher/lower from the station. Using the k-Köhler theory and the AMS measurements when the aircraft was flying close to the station the predicted hygroscopic growth factors showed good agreement with those measured by HTDMA (cf. inset in Fig. 1).

Fig. 2 shows the particle growth factors calculated using k-Köhler theory using as input the AMS measurements during flight from Crete to Lemnos of 1 September. The predicted growth factors ranged from 1.0 to 1.8 with an average value ca. 1.3. Similar behaviour was observed for all the flights of the aircraft indicating that particles of low hygroscopicity due to a high fraction of organic species is characteristic for that period over the Aegean Sea.

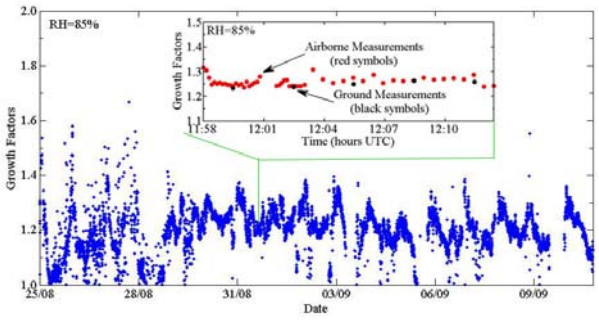

Figure 1. Hygroscopic growth factors of aerosol particles having dry diameter between 50 and 170 nm when exposed to 85% RH at Vigla station from 25/8/2011 to 11/9/2011. Inset: comparison between growth factors measured by the HTDMA (black symbols) and predicted by k-Köhler theory using the chemical composition measurements from the airborne AMS (red symbols) when the aircraft was flying over the station on 1/9/2011.

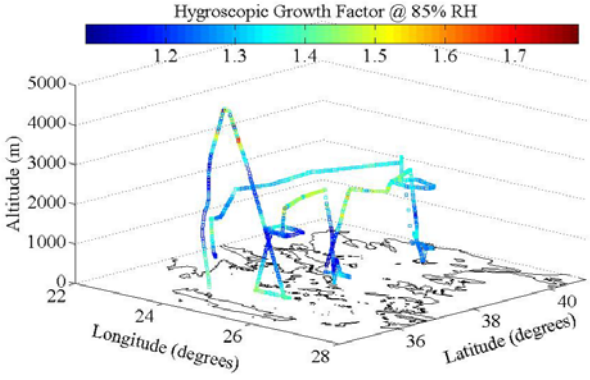

Figure 2. Hygroscopic growth factors of aerosol particles at 85% RH over the Aegean Sea on 1/9/2011. The GFs are calculated by the k-Köhler theory using the chemical composition measurements from the airborne AMS.

In planetary scale, fine and ultrafine aerosol particles contribute to the planet's global radiative balance through direct and indirect effects (IPCC 2007). In regional scale, the same particles affect human health by infiltrating the lower respiratory system (Brunekreef & Holgate, 2002), and visibility (Cababa et. al., 2004). Quantitative measurement of particle hygroscopicity can help us understand the ability of the particles to act as Cloud Condensation Nuclei (CCN) and their efficiency to infiltrate the respiratory system, thereby providing valuable information for estimating their potential impacts on global climate and human health.

In situ measurements of particle hygroscopicity were conducted at the NCSR Demokritos Global Atmosphere Watch (GAW) urban background site in Athens from 13 October to 6 November 2011 using a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA; Rader & McMurry, 1986). HTDMA scans over a period of 180 s each were processed by a curve fitting algorithm that was designed to fit up to three lognormal distributions depending on the spread of the selected monodisperse size distributions. By doing that we were able to identify different particle hygroscopic behaviour and the aerosol mixing state. Fig. 1 shows a characteristic example where two distinct modes are identified when dry monodisperse particles having 100 nm mobility diameter are exposed to 85% relative humidity (RH), indicating that the sampled aerosol is externally mixed.

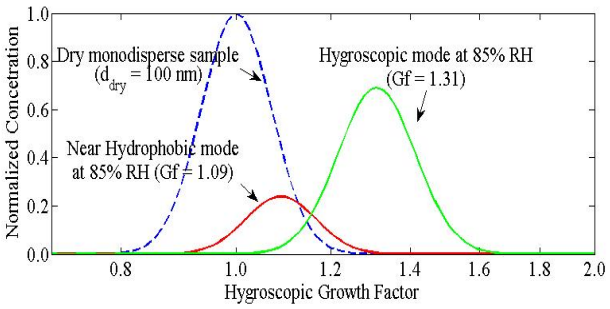

Figure 1. HTDMA measurements of particles having dry mobility diameter of 100 nm when exposed to < 10% RH (blue line) and 85% RH. Two modes are revealed when the particles are exposed to 85% RH indicating that the aerosol is externally mixed. The first population is almost hydrophobic having a hygroscopic growth factor of ca. 1.10 (red line) and the second is more hydrophilic having a hygroscopic growth factor of ca. 1.31 (green line).

Table 1 shows aggregate statistical results of particle hygroscopicity observed in the Demokritos site during the period of our study. Monodisperse particles having dry mobility diameters from 60 to 170 nm were selected using the first DMA of the system. More than half of the measurements (58.1%) indicated internally mixed aerosols, with an average growth factor ca. 1.2. More than one third of the measurements indicated externally mixed particles with one hydrophobic mode having a growth factor of ca. 1.1, and one more hydrophilic of ca. 1.3. Less than 5% of the measurements indicated externally mixed particles, with three distinct hygroscopicity modes: one hydrophobic mode with an average growth factor of ca. 1.1, one less hygroscopic with an average growth factor ca. 1.3, and one more hygroscopic with an average growth factor ca. 1.6. The variability of growth factors and modes observed was statistically evaluated against other important aerosol parameters (e.g., scattering coefficients, concentration of organic and elemental carbon, etc.).

Table 1: Aggregate statistical results of particles hygroscopicity in Athens from 13 Oct. to 6 Nov. 2011. Key: N is the number of modes of each sample, P is the relative frequency of occurrence for unimodal (1), bimodal (2) and trimodal (3) samples, Gf 1, 2, and 3 are the average growth factor ± one standard deviation of mode 1, mode 2, and mode 3, respectively, whereas C1, 2, and 3 are the ratios of particle number concentration of each mode with respect to the total particle number concentration of the selected dry fraction

N	P (%)	Gf 1	C1 (%)	Gf 2	C2 (%)	Gf 3	C3 (%)
1	58.1	1.23 ±0.12	100				
2	37.0	1.10 ±0.09	47.4	1.34 ±0.13	52.6

Method of the heterogeneous nucleation investigation in the laminar flow chamber is developed. This method give the relationships between the main process parameters: the critical nucleus size *d*, size of the seed particle *D*, supersaturation ratio, temperature and contact angle. The efficiency of this approach is demonstrated for the heterogeneous nucleation of sulfur vapor on tungsten oxide nanoparticles.

The experimental setup is shown in Fig. 1. The installation consists of three main parts: the generator of seed aerosol particles of tungsten oxide, the laminar flow chamber and the diffusion spectrometer of aerosol (DSA). The sulfur vapor was generated inside the chamber with the concentration below of the homogeneous nucleation limit. Clean air was used as a carrier gas. Number concentration and size distribution of aerosol particles at the outlet of reactor were measured by DSA.

Fig. 2 shows the size distributions of the incoming seed particles and the particles at the exit of chamber after the heterogeneous nucleation. During the experiments we varied the vapor pressure of sulfur without changing the size distribution seed nanoparticles. At low vapor pressure the size distribution of the particles before and after the chamber is identical (Fig. 2*a*), i.e. the size of the particles that were filed into the chamber lie below the minimal size to start the heterogeneous nucleation. When the pressure is high enough (Fig. 2*b*), the bimodal size distribution at the output is recorded. Left peak is a part of the spectrum of original particles which is smaller than the size required for the start of heterogeneous nucleation. The right peak corresponds to the particles on which critically nucleus were generated followed by condensation growth. The comparison of the outlet and inlet spectra gives the threshold diameter from which heterogeneous nucleation was started.

The approximate location of the heterogeneous nucleation region was determined experimentally using the "supersaturation cut-off" method. For this purpose round metallic grid with diameter equal to the inner diameter of the tube was inserted into the chamber perpendicularly to the flow (Fig. 1). Sulfur vapor and small seed particles of tungsten oxide were partially deposited on the grid. Particles on which nucleation and condensation growth occurred are large enough for penetration through the grid.

The temperature radial and axial profiles inside the chamber were measured by a chromel-alumel thermocouple. The rate of sulfur evaporation in the saturation zone and the axial profile of wall vapor deposition rate were measured experimentally. The difference between these two quantities gave the vapor concentration *n* averaged over the tube cross section vs the axial coordinate *Z*. Based on function *n(Z)* the radial profiles of sulfur vapor concentration were determined solving the mass transfer equation. The supersaturation profiles were calculated from the concentration and temperature profiles.

Based on these experimental data and theoretical approaches [1-3] it were determined the parameters of sulfur critical nucleus (size, contact angle) which formed on the surface of the seed particle, Fig. 3. Contact angle of sulfur critical nucleus on the surface of tungsten oxide seed particle is $\Theta \approx 41$ °.

Presenting author email: norazannoni@gmail.com

Sugars and sugar alcohols constitute an important component of the organic fraction in atmospheric particles. They have been detected in high concentrations in ambient aerosols during field campaigns (Graham et al., 2003; Facchini et al., 2000). They are found to be mainly in the coarse mode fraction of ambient particles, with a diurnal variation associated to the class of compounds. Biogenic sources are: pollen, fern spores and insects for sugars, yeasts and small fungal spores for sugar alcohols. The hydroxyl groups on these compounds make them particularly interesting for their behaviour in aqueous droplets, e.g. they can alter the water activity and surface tension of the aqueous solution. In order to clarify their behaviour in the particle phase and hence their effect on climate, the volatility and physical state of laboratory generated particles was investigated through a Tandem Differential Mobility Analyzer (TDMA) coupled with a laminar flow tube.

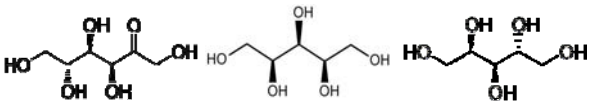

Figure 1. Chemical structures of Fructose, Xylitol and Arabitol.

Methods

A modified TDMA set up combined to a laminar flow reactor was used to measure the size distributions of laboratory generated particles (Bilde et al., 2003; Koponen et al., 2007, Zardini et al., 2010) of three compounds: Fructose, Xylitol and Arabitol. Aqueous solutions of ~$1*10^{-4}$ M of Fructose, Xylitol and Arabitol were prepared and atomized to obtain a polydisperse aerosol flow. The flows were then dried, and size selected with a Differential Mobility Analyzer coupled with a neutralizer. Particles entered a laminar flow reactor 3.5 m long, with four sampling ports along its length. A sheath flow of dry air was used to assure laminar conditions along the tube, and a water recirculating bath was used to control the temperature during each experiment. The particles initial and final diameter was sampled with a Scanning Mobility Particle Sizer (SMPS) at different sites along the set up. A lognormal function was used to fit the measured size distributions and from mass transfer theory we could infer a value of the vapour pressures for the three investigated compounds.

To obtain deeper information about the particles physical state, we repeated the experiments by varying the relative humidity at the last step of the set up.
The growth factors of the particles of a given compound were used to assess if the particles were either solids or liquids.

Results

The estimated growth factors obtained from the wet particles experiments suggest that the particles of Fructose, Xylitol and Arabitol were in the metastable liquid phase also when dried low to RH~2%, as in these experiments (Table1).
The obtained values of vapour pressure in the order of 10^{-6}-10^{-5} Pa, indicate that the compounds in the investigated conditions are semivolatile, hence they can continuously partition between the particle and the gas phase.

Table 1. Particles diameter in nm at the DMA and at Port 2 of the reactor, at different values of the SMPS RH and corresponding growth factors.

Compound	Dp RH=2%	Dp RH=45%	Dp RH=76%	Gf 45%	Gf 76%
Fructose	107.2	110.7	113.0	1.03	1.05
	108.1	109.0	112.8	1.01	1.04
Xylitol	105.4	109.7	114.6	1.04	1.09
	107.0	110.1	113.0	1.03	1.06
Arabitol	98.7	101.4	104.7	1.03	1.06
	97.8	101.2	103.9	1.03	1.06

Conclusions

The experiment on wet particles showed that under the investigated conditions particles were liquid. The results of vapour pressures indicate that studies on the effects of these compounds on the atmosphere are needed.

Aerosols are fundamental for understanding climate change (IPCC, 2007). The knowledge on size, distribution, chemical composition (especially Black Carbon, BC) and the vertical distribution of aerosols is vital to explain the effect of aerosols on climate (Corrigan et al., 2008). In the Arctic aerosol properties are typically obtained at ground while they are scarce along the vertical profile. Thus, systematic aerosol vertical profile measurements over Svalbard (Ny-Ålesund) were performed in the frame of the CICCI (Cooperative Investigation of Climate-Cryosphere Interaction) program (http://ny-niflheim.nilu.no/cicci//).
Vertical profiles (up to 1 km height) were carried out in the periods 30 March – 30 April and 30 June – 15 July 2011 at the Gruvebadet station (Ny-Ålesund).
A tethered balloon was fitted with an instrumentation package consisting of: 1) an Optical Particle Counter (OPC)-tandem system (2 OPCs GRIMM *1.107*; 31 size classes between 0.25 to 32 µm); the first OPC measured aerosol number size distribution at ambient relative humidity (RH), the second one used a drier; 2) a miniaturized electrical nanoparticle detector (miniDiSC); 3) a novel micro-Aethalometer (AE51 and AE52 prototype, Magee Scientific) to measure BC aerosol and the absorption coefficient; 4) a miniaturized cascade impactor (Sioutas SKC with 2 impaction stages: <1 µm, >1 µm) to collect samples of particulate matter; 5) a meteorological station (Vaisala Tethersonde TTS 111).
During the spring and summer we measured 84 and 18 aerosol profiles respectively to study the vertical structure of aerosol over Ny-Ålesund (Fig. 1a). Multilayered structures, homogeneous profiles and transport events were observed. The Multilayered structures were detected in ~75% of profiles. Each aerosol stratification was characterized by a change in aerosol concentration. Balloon profiles measured a concentration drop with increasing height in 80% of cases. The frequency distributions of the 1st and the 2nd aerosol stratifications with height are shown (Fig. 1b). The ratio between the aerosol concentrations measured across each aerosol stratification for three broadsize ranges (d_p<250 nm, 250 nm<d_p<1000 nm, d_p>1000 nm) are resumed in Tab. 1. Finest particles (d_p<250 nm) experienced a higher concentration decrease at the first aerosol stratification than larger particles (Tab. 1). This behavior, found essentially in the nanoparticle size, was accompanied by a decrease of BC concentration (Fig. 1a). Thus it may be related to early nucleation events close to the ground level.

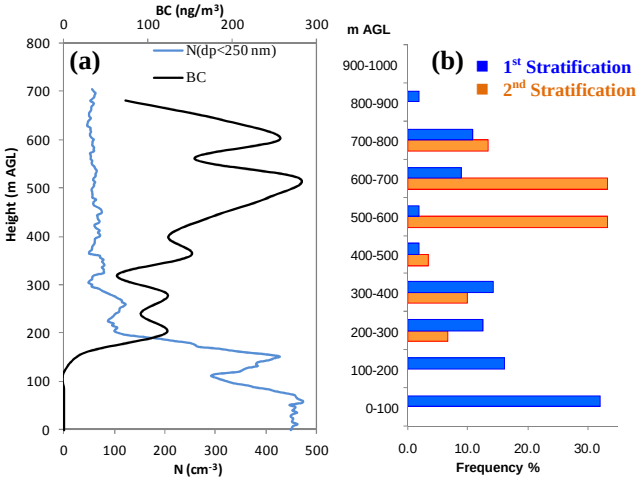

Figure 1. (a) Vertical profiles of N(d_p<250 nm) and BC on 6th April 2011 19.00 UTC (b) Frequency distributions of the 1st and the 2nd aerosol stratifications with height.

Aerosol ratio	N(dp<250 nm)	N(250 nm<dp<1000 nm)	N(dp>1000 nm)
1° Stratification	0.63(±0.27)	0.82(±0.16)	0.69(±0.21)
2° Stratification	0.81(±0.16)	0.67(±0.19)	0.43(±0.15)

Table 1. The ratio between the aerosol concentrations measured across each aerosol stratification.

In summer, vertical profiles allowed to study the impact of ships anchoring in Ny-Ålesund harbour.
Particularly on 6th July 2011 the ship plume affected the whole Ny-Ålesund. As a result the aerosol concentration reached values up to $2*10^4$ cm^{-3}, and BC up to 2000 ng/m^3. In the same day vertical profiles of both parameters were measured and were not affected by the ship plume. They were 534 cm^{-3} and 81 ng/m^3 respectively, underling the immense impact of ship emissions in the Arctic.

Surface-active organic compounds influence water uptake on atmospheric aerosol and cloud particles. The efficiency of water uptake by such particles contributes to cloud development and growth in the atmosphere with implications for the Earth's water cycle and climate.

Here, we investigate the influence of organic coatings on ice's water uptake. Methanol and *n*-butanol are used as alcohol surfactants with different carbon numbers and miscibilities in water. Water interactions with ice are probed using a recently developed environmental molecular beam (EMB) technique that allows for experiments at vapour pressures up to 10^{-2} mbar (Kong *et al.* 2011; Thomson *et al.* 2011). When probing alcohol-coated ice, a micrometer thick water ice layer is first condensed onto a graphite substrate, upon which an alcohol monolayer is subsequently grown (Kong *et al.* 2012). The application of a large range of alcohol partial pressures confirms the stability of the adsorbed monolayer. A pulsed molecular beam consisting of D_2O and helium is directed at the ice surface over a range of temperatures (165-200 K). A quantitative analysis of time-of-flight distributions of the scattered and desorbed D_2O illuminates molecular kinetics (Figure 1), including water uptake efficiency. No HDO is detected above the noise threshold, eliminating it as a sink of D_2O.

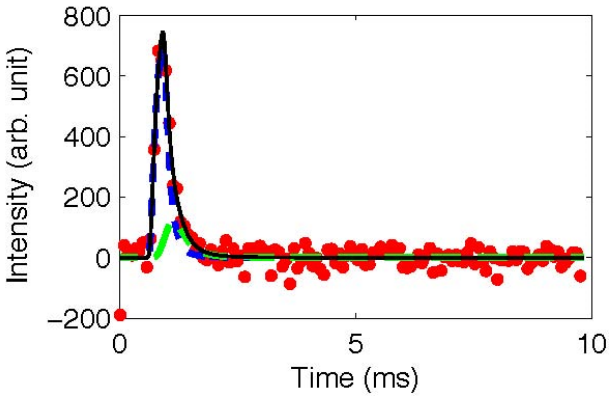

Figure 1. Time-of-flight distribution for D_2O scattering from butanol-covered ice at 180 K: Experimental data (red points), and fit to the data (black line) including indirect scattering (blue line) and trapping-desorption (green line) components. The incident angle and kinetic energy were 45° and 30 kJ/mol.

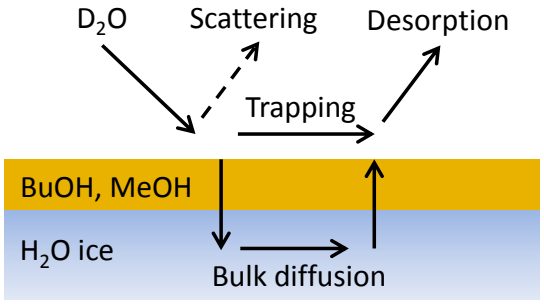

Figure 2. Pathways for heavy water molecules colliding with water ice covered with a surfactant monolayer of either methanol or *n*-butanol. In case of *n*-butanol, the surface layer provides a barrier that partially blocks incorporation of molecules into the ice structure and desorption of bulk water.

The results illustrate that on pure ice surfaces uptake of impinging D_2O molecules is almost unity. However, the presence of alcohol surfactants attenuates sticking in a manner that depends on the carbon chain length. Molecules colliding with the butanol-coated ice scatter and thermally desorb (Figure 2) more efficiently than from ice coated by methanol. The butanol layer is concluded to provide a substantial barrier for water desorption and for water adsorption and incorporation into the water ice structure. The temperature dependence of water uptake is also investigated.

These results provide a quantitatively constrained demonstration that adsorbed volatile organic compounds fundamentally alter ice surfaces and thus have the potential to be important in cloud processes ranging from formation to gas-phase scavenging.

Since 2005, a continuous, all-year-round aerosol sampling has been carried out at Dome C (Central East Antarctica, 3233 m a.s.l., about 1100 km far from the coastline), in the framework of "Station Concordia", an Italian PNRA – French IPEV joint program.

Size-segregated aerosol samples were collected in summer and winter periods by low- and medium-volume systems, including pre-selected cut-off samplers and multi-stage impactors.

Here we report the first multi-year record (2005-2008) of nitrate content in the atmospheric aerosol collected at Dome C, which can be considered as representative of the Antarctic background aerosol in the high central plateau.

A preliminary data analysis of nitrate concentration in PM10 aerosol shows a characteristic pattern for all the annual sampling campaigns with relatively low and constant background values throughout the year and some marked concentration maxima in early summer, namely November and, to a lesser extent, December (Fig. 1).

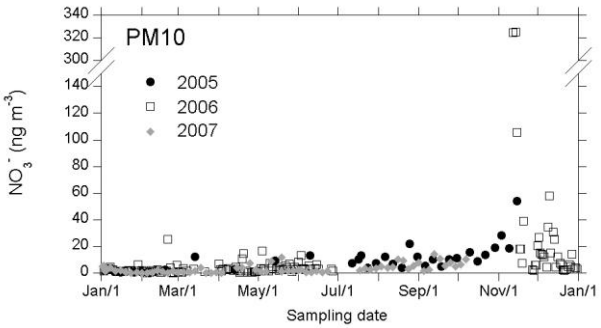

Figure 1. Nitrate concentration in PM10 aerosol collected at Dome C in the 2005-2007 period.

As shown in Fig .2, such maxima are related to both super-micrometric and sub-micrometric fractions but are particularly evident in the aerosol size classes ranging from 0.4 to 2.1 μm, with concentration up to 80 ng m^{-3} in the 1.1-2.1 μm size class (stage 5).

The availability of a complete aerosol chemical composition will allow establishing if nitrate concentration spikes (accounting for a significant part of total nitrate budget) are linked to common transport processes or neutralization reactions with sea spray or crustal aerosol components or rather due to nitric acid deposition. Considering the results reported by Frey *et al* (2009), we suppose the early summer nitrate peak is of stratospheric origin.

Such a result is particularly relevant in order to help in the assessment of the relative contribution and seasonal behaviour of nitrate sources in central Antarctica, not yet fully understood. In fact, nitrate deposition onto the Antarctic ice sheet has been attributed to various sources (stratospheric N_2O oxidation, low latitude lightning activity, polar stratospheric cloud precipitation and solar activity) but their extent and temporal evolution have not been disentangled so far.

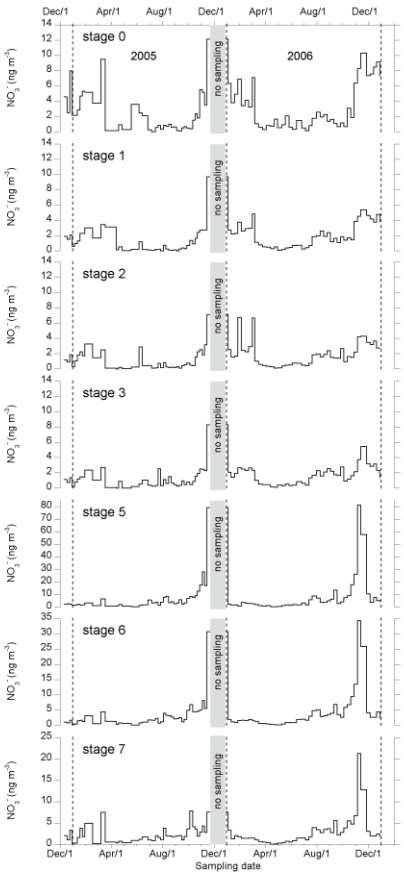

Figure 2. Nitrate distribution in 8 aerosol size classes collected at Dome C in 2005-2006.

This work benefited of Concordia Station logistic and personnel facilities.

Volume-based κ-interaction model, hygroscopicity parameters and solute interaction coefficients

E. Mikhailov[1,2], S. Vlasenko[2], D. Rose[1] and U.Pöschl[1]

[1]Max Planck Institute for Chemistry, Biogeochemistry Department, 55128 Mainz, Germany
[2]St. Petersburg State University, Atmospheric Physics Department, Institute of Physics, 198504 St. Petersburg, Russia

Keywords: aerosol hygroscopicity, volume-based theory, interaction parameters.
Presenting author e-mail: Eugene.Mikhailov@paloma.spbu.ru

In this study we have presented an volume-based version of κ -interaction model (KIM) (Mikhailov et al.,2011) to describe hygroscopic properties by pure and mixed aerosol particles. Likewise mass-based model the volume-based analogue (KIM_v) describes the particles hygroscopic behavior including early stage of particles growth where all solutes are in solid state and final stage where all solutes are completely dissolved. Non-ideal behavior of the concentrated particle solution is accounted for cross-($i \neq j$) and self ($i=j$) – interaction coefficients ($\chi_{i,j}$) in hygroscopicity parameter, κ_v:

$$\kappa_v = \sum_i \kappa_{v,i,\infty} \varepsilon_i + \sum_{i,j} \chi_{i,j} c_i c_j \ , \qquad (1)$$

where εi is the dry volume fraction of the solute i and and ci its volume concentration in solution. In Eq.(1) first term is based on additive ZSR relation, and second term accounting for interaction effects. In contrast to rigorous thermodynamic models the interaction coefficient consider only binary interactions between all forms of the solutes. For example, for dissociated salt, MX and nondissociated organic, O, these pair interactions are M-O, X-O, M-X, and only one coefficient $\chi_{MX,O}$ responsible for all of them. As a result the final expression for hygroscopicity κ_v is simpler than for osmotic coefficient (Clegg et al., 2001).

In this work the experimental growth factors, g_b obtained from humidified tandem differential hygroscopicity analyzer (HTDMA) (Mikhailov et al. 2004) were used to test the theory approach. As an example Fig. 1 shows experimental data (a) and fit results based on KIM_v model (b) for mixed particle containing ammonium sulfate and levoglucosan with 1:3 mass ratio. By application of KIM_v to the measurement data we can distinguish two different regimes of hygroscopicity: gradual deliquescence at low relative humidity (RH<78%, blue model curve), where solute undergo gradual dissolution in aqueous phase, and a dilute regime, where solutes are fully dissolved including high concentrated metastable solution (gray model curve). The observed gradual deliquescence of the mixed particles can be attributed to an amorphous (semi-solid) state of organic species (Mikhailov et al., 2009).

The volume-based KIM_v theory model provides a good fit on the all stages of mixed particle evolution. We suggest that κ_v-model may be useful in describing particle hygroscopicity both in under- and in super-saturated water vapor.

If the chemical composition, interaction parameters and solubilities of the multicomponent aerosol particles are known the hygroscopicity κ_v can be determined over the all water activity range. In the absence of information on these characteristics, experimental data for complex particles can be fitted to obtain the volume hygroscopicity parameter.

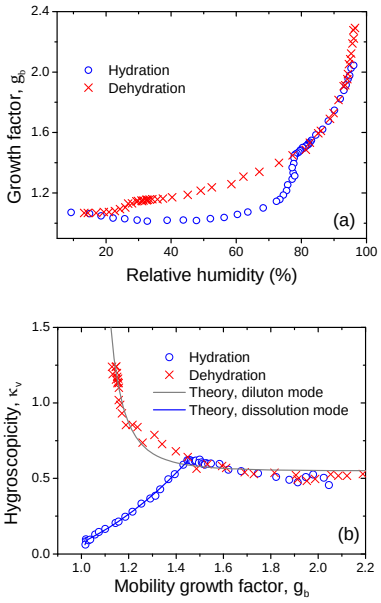

Figure 1. Hygroscopic properties of ammonium sulphate and levoglucasan mixed particles with 1:3 mass ratio: **(a)** - HTDMA derived growth factors ; **(b)** – a comparison between KIM_v theory predicted particle hygroscopicity and experimental data.

Keywords: atmospheric aerosol, African dust, optical properties, size distribution.
Presenting author email: cerqueira@ua.pt

Huge amounts of mineral dust are emitted every year from the Sahara desert and the Sahel to the atmosphere. A significant amount of this mineral dust is exported towards the Caribbean, North America and Europe under the prevalent synoptic scale air mass circulations. Optical parameters of mineral aerosols, e.g. scattering and absorption coefficients, the particle size distribution and spatial distribution of mineral aerosols determine the direct interaction of solar and terrestrial radiation in the atmosphere through scattering and absorption. Mineral dust also has a great impact on cloud formation leading to additional indirect radiation effects. The dense haze from dust events is also known to affect visibility.

The Cape Verde islands are ideally located to study mineral dust properties since they are under the pathway of trade winds, which transport dust from sources in North Africa to the northern tropical Atlantic Ocean. Aerosol measurements were performed at the outskirts of Praia, Santiago Island, Cape Verde (14º55'N, 23º29'W, 98 m above sea level), between January 2011 and January 2012, within the framework of CV-Dust project (Atmospheric aerosol in Cape Verde region: seasonal evaluation of composition, sources and transport). Aerosol size distribution was measured with a GRIMM EDM164 optical dust monitor from 0.25 um to 32 µm in 31 channels. The aerosol light absorption was measured with a Magee Scientific AE31 Aethalometer at seven wavelengthts (370, 470, 520, 590, 660, 880 and 950 nm).

The time variation of daily average $PM_{2.5}$, PM_{10} and TSP concentrations is presented in Fig. 1. The highest aerosol mass concentrations were observed in January and February 2011, during periods of air mass transport from northern Africa, and the lowest during November 2011, under the influence of marine air masses.

The aerosol size distribution measurements revealed three modes (fine, coarse and giant). An increase of the aerosol mass concentration was observed for the three modes during dust advection from Africa, but much more significantly in the coarse mode (around an aerodynamic diameter of 2 µm).

The seven wavelength spectra of equivalent black carbon concentration generated with the aethalometer during dust event periods revealed similar profiles but with different amplitudes of variation. These results suggest that mineral constituents in aerosol particles transported from the African continent may give a significant contribution to aerosol absorption properties. Iron oxides, mainly in the form of hematite, are known to explain this effect (Fialho et al., 2006) and high concentrations of iron were already observed after the chemical analyses of aerosol samples collected in Santiago Island during dust events, also as part of CV-Dust project research activities.

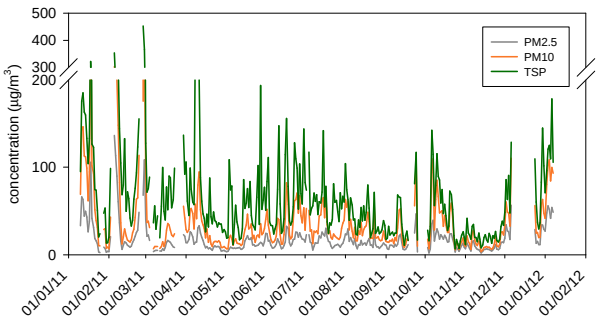

Figure 1. Daily average $PM_{2.5}$, PM_{10} and TSP concentrations at Santiago island.

Mass scattering efficiency and chemical composition of different aerosol types at a coastal area of the Gulf of Cadiz (SW Spain)

J.F. López[1], V.E Cachorro[1], Y. González-Castanedo[2], J.D. de la Rosa[2] and A.M. de Frutos[1]

Keywords: aerosol, scattering, nephelometer, chemistry.
Presenting author email: juanfran@goa.uva.es

Atmospheric light extinction, scattering and absorption by aerosol depend on the particle load, size and chemical composition. The latter in particular determines the particle refractive index which is the most important optical property in the interaction processes of radiation and particles. Since the nineties the sensitivity of radiative forcing to the nature of aerosol has been discussed (Charlson, et al., 1992). Therefore, aerosol studies require the measurement and analysis of scattering and absorption coefficients together with chemical analysis of particle composition in a wide and multidisciplinary task.

Simultaneous measurements of the aerosol scattering coefficients σ_{sp} (López, 2011) and daily sampling of PM10 and PM2.5 were carried out during 2006 and 2007 at El Arenosillo-ESAT station belonging to INTA (Spanish Aerospace National Institute). These measurements allow the determination of the mass scattering efficiency α_{sp}, through the slope of the linear correlation between both magnitudes σ_{sp} and PMx. In addition, the PMx chemical analysis is also used to calculate the specific scattering efficiency for the main particle aerosol components. The σ_{sp} was measured using a 3-λ integrating nephelometer of TSI Company, and the aerosol samples were collected on quartz fiber filters with two high-volume sampling system (MCV). The filter weight and its chemical analysis were carried out in CIQSO of the University of Huelva.

A total of 30 and 34 days for PM2.5 and PM10 respectively under dry σ_{sp} measurements conditions have been selected for this study. The mass scattering efficiency α_{sp} at 550 nm ranges from 1.33 to 5.20 m^2g^{-1} with an average of 3.02±0.09 m^2g^{-1} and a correlation coefficient of R=0.82 (see Figure 1).

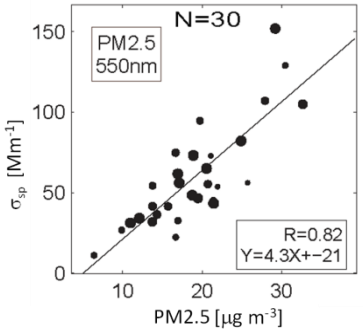

Figure 1 Correlation between daily scattering coefficient and PM2.5 value.

The composition of the dominant particulate matter obtained in the chemical analysis as $(SO_4)^{-2}$, $(NH_4)^+$, $(NO_3)^-$, C, and other minor species were grouped in anthropogenic, marine, desert types and a class representing "not-determinated" mass components. The best agreement was found for $(NH_4)^+$ component with a correlation coefficient of R=0.92 for PM10 and 0.88 for PM2.5 taking σ_{sp} at 450 nm. Using a least square fit multivariable regression:

$$\sigma_{sp} = \alpha_0 + \alpha_i M_i$$

the specific mass scattering efficiency α_i of the mainly aerosols components were obtained which are summarized in Table 1.

Despite the high relative efficiency of anthropogenic contribution , the presence of low efficiency scatters as marine and mineral aerosol, is in agreement with the average mass efficiency close to 3 m^2g^{-1} obtained at this rural-coastal site.

Aerosol Component	Mass scattering efficiency (m^2g^{-1})
Anthropogenic	4.86 (*)
Sulphate	3-7 (McMurry, et al., 1996)
Marine	0.05 (*)
Mineral	0.30 (*)

Introduction

Atmospheric aerosol particles play an important role in climate and air quality. In Portugal, long time series on the chemistry and morphology of atmospheric aerosol particles as well as on their seasonal dependency are still relatively scarce and mostly confined to the North of the country. To assess the relative contribution of several aerosol particle sources, a 1 year quasi continuous aerosol sampling is currently under way, which started on 10 August 2011 at a sampling site in Evora, Southern Portugal. In the first month an intensive field measurement campaign was carried out, providing additional data for summer (Wagner et al. 2012).

Experimental

Particulate matter was collected using a modified version of the aerosol passive sampler Type A "flat plates" by Ott and Peters (2008). This collector consists of 2 brass plates at a distance of about 1.6 cm and it was modified by the introduction of a liquid trap. The air could freely flow and particles deposited by gravitation. Aluminium stubs coated with carbon adhesives were used as deposition substrates. The sampler was placed at the top of a university building about 15m above ground level. As the gravitational settling of particles is slow the sampling was run on a weekly basis. Single particle automated analysis was performed using an HITACHI VP-SEM interfaced with a Bruker EDS QUANTAX automatic ESPRIT software. Analytical conditions were as follows: 20 kV accelerating voltage; 10 mm working distance; 120 mA emission current; 70 mA probe current. The particles were classified according to their chemical composition into eight classes and into 3 classes according to their size.

Results

First results (Fig. 1) of the SEM automated particle analysis on a selected sample of 1000 particles collected during a dust episode in August (whose provenance could be ascribed to Northern Africa as deduced from trajectory calculations (HYSPLIT/GDAS) show that the relative abundance of dust-related aerosols (oxides+quartz+silicates) increases with particle size reaching a maximum in the > 10 µm class. Within this size range, larger particles commonly are formed by agglomeration of heterogeneous particles. Sulphate containing particles are mainly concentrated in the smaller particles.

It is interesting to note the presence of significant amounts of phosphorus-bearing particles whose origin is currently under investigation but could perhaps be due to the semi-rural location of the sampling site and its nearby agricultural activities.

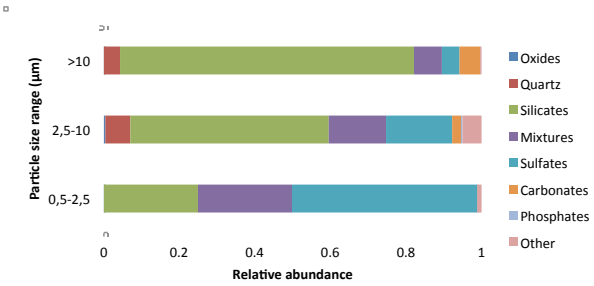

Figure 1. Classification according to chemical composition and particle size. Sampling period: 18-21 August 2011.

Summary and Conclusions

For the first time a fully automated VP-SEM+EDS single particle characterization was performed in Portugal. By the time of the conference the collection of aerosol particles by gravitational settling will have completed its first year. The annual cycle of particle sizes, morphology and elemental chemical composition will be shown.

Arctic aerosol sampled at Ny Ålesund: results from size-segregated samples

Presenting author email: calzolai@fi.infn.it

The chemical characterization of size-segregated aerosol samples can help in the identification of the main aerosol sources and can give information on the atmospheric processes occurring during atmospheric transportation and modifying the aerosol properties. Moreover, both size distribution and chemical composition play a crucial role in the interaction aerosol-solar radiation, in the aerosol ability to induce cloud and fog formation and to modify the microphysical cloud properties (thus affecting the Earth's radiation budget), in the long-range transport processes and in the deposition patterns of anthropogenic pollutants over the polar areas.

In this work, we report the results on size distribution and bulk chemical composition of the Arctic aerosol sampled at Ny Ålesund (78.6°N, 11.6°E, Svalbard Islands, Norway) in March – September 2010, at the recently installed Gruvebadet station.

Svalbard Islands are an ideal site for the study of the interaction between the climate changes and the atmosphere, ocean and land variations, since they are located in the northernmost point influenced by the warm West Spitsbergen Current. Furthermore, in Ny Ålesund, the international cooperation ensures the continuous study and monitoring of a large number of physical and chemical parameters characterizing the Arctic ecosystem.

The sampling site is located sufficiently far from the village (about 800 m) and in a sector usually not affected by winds coming from the village direction, in order to minimize contamination. Anyway, a meteo-trigger system turns off the long-term samplers if wind direction or too low wind velocity make possible the transport or the diffusion of pollutants from the village.

The presented data regard the samples collected with a PM10 sampler (24-h resolution), with Teflon filters, and a 12-stages impactor (4-days resolution, Dekati Small Deposit area Impactor (SDI) [1], stages with cut points in the range from 45 nm to 8.5 μm), with polycarbonate filters.

PM10 samples were analyzed for cations, inorganic anions and selected organic anions (acetate, formate, oxalate and methanesulphonate) composition in the clean room at the Department of Chemistry of Florence by means of Ion Chromatography (IC), taking care to avoid any contamination during filters handling and analysis.

Size segregated samples were analyzed for elemental characterization by means of Particle Induced X-ray Emission – Particle Induced γ -ray Emission (PIXE-PIGE) measurements at INFN-LABEC laboratory in Florence. PIXE is unrivalled for the direct measurement of the mineral dust fraction in the aerosol, as it is highly sensitive to all the crustal elements except oxygen and carbon. PIGE was coupled to PIXE in order to get a more accurate estimate of light elements. Moreover, both the techniques do not need any sample pre-treatment, thus minimizing contaminations.

Results on the chemical compositions of the daily PM10 samples will be shown (Figure 1). Such results were also used to identify interesting and representative events to be deeply characterized by means of the analysis performed on the multi-stage impactor samples.

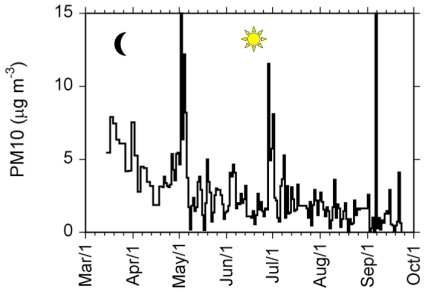

Figure 1. Daily PM10 concentrations.

The measurements on size-segregated samples have demonstrated to be an important tool for aerosol source identification, as they give information on the elemental mass size distributions. In particular, they allowed the identification of both local and long-range transport episodes, evidencing contributions from dust, sea spray and anthropogenic aerosol (Figure 2).

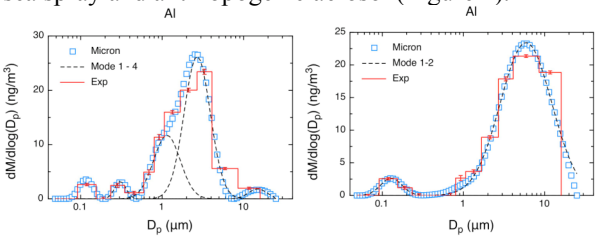

Figure 2. Mass size distributions for Al during a long-range transport (left) and a local dust event (right).

Some preliminary results on seasonal trends were also assessed, showing, as an example, that coarse modes are more important during summer.

Keywords: ultrafine aerosol, carbonaceous aerosol, urban areas
Presenting author email: pavese@imaa.cnr.it

The UPUPA project (Ultrafine Particles in Urban Piacenza Area) is currently running in Piacenza (45.03 °N, 9.41 °E, 67 m a.s.l), a medium-sized city (about 100.000 inhabitants) located in the middle of the river Po Valley in Northern Italy.

In the framework of the UPUPA project an integrated measurements campaign was devoted to the investigation of the presence of carbonaceous particulate species in the urban atmosphere. In particular, the campaign was intended to collate information on different parameters tracing the carbonaceous aerosols.

A large set of instruments were concurrently employed during the monitoring campaign, including filter-based instruments measuring the optical absorption coefficient of the aerosol at different wavelengths, a radiometer in the visible spectra, a single-particle laser photometer, particulate matter impactors, condensation particle counters and spectrometers, and gravimetric samplers for PM1 samples speciation.

Measurements started on September 20th 2011 and lasted ten days at the LEAP laboratory site in Piacenza, located between the river Po bank and the main railway station, close to a flyover connecting two heavy traffic motorways.

Preliminary data analyses focused on aethalometer data: Black Carbon (BC) concentration have been derived from the Magee AE31 aethalometer (7 wavelenghts) data collected with a 5-minute time resolution. The resulting estimated BC time pattern over the entire monitoring campaign is presented in Figure 1.

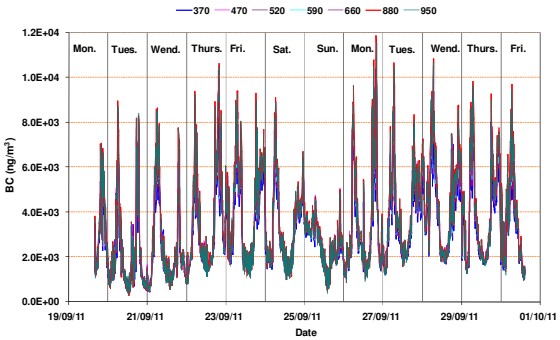

Figure 1. Time pattern of BC content in PM2.5 in Piacenza as estimated based on the 7-wavelenght aethalometer data. September 19th-30th 2011.

According to the regular daily pattern of BC content (two peaks per day on morning and evening rush hours) vehicular traffic can be considered as the main source of carbonaceous particles at the site. Due to the anthropogenic activities fine particles contribution is expected to be prevailing over the coarse one. This is confirmed by the information on the particle size distribution derived from radiometric measurements: Figure 2 displays the daily mean volume size distributions for three days during the campaign. Despite the different PM levels measured on these days all the size distributions display a bi-modal structure essentially dominated by submicron particles.

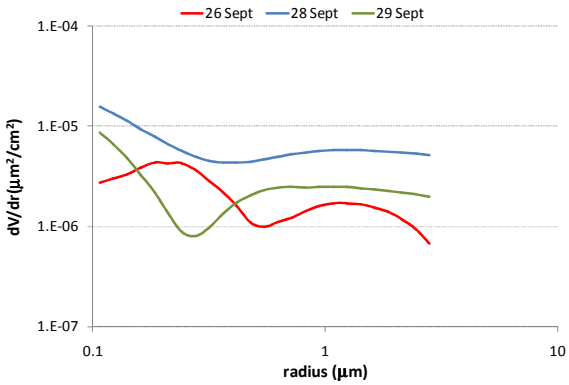

Figure 2. Daily mean volume size distributions as retrieved from radiometric measurements on September 26th, 28th and 29th.

These preliminary findings are to be further analysed concurrently with the piece of information provided by the other instruments for carbonaceous species monitoring and with the concurrent particle number concentration and related size distribution data.

Saharan vs. local influence on atmospheric aerosol deposition in the southern Iberian Peninsula: significance for N and P inputs

R. Morales-Baquero[1], C. Pérez-Martínez[1]

[1]Departmento de Ecología and Instituto del Agua, Universidad de Granada, 18071 Granada, Spain
Keywords: Saharan dust, nutrients, ecosystems, aerosol chemistry.
Presenting author email: rmorales@ugr.es

Atmospheric deposition is recognized as a significant input of both gaseous (e.g. nitrogen) and soil-derived (e.g. phosphorus) elements to ecosystems. Nitrogen deposition in the Northern hemisphere has increased due to anthropogenic activity and its impact on diverse ecosystems has intensely been studied. In particular, a considerable scientific effort has been made to assess its impact on lake chemistry and lake recovery after emission reduction. On the other hand, atmospheric inputs of phosphorus derived from Saharan dust deposition and its impact on ecosystems are receiving growing attention.

The southern Iberian Peninsula is an area strongly influenced by Saharan dust deposition. Previous results indicate that atmospheric contribution of P and Ca is essential to explain the functioning of oligotrophic lakes (Morales-Baquero et al, 2006; Pulido-Villena et al, 2006), and that atmospheric input of organic matter partially supports the pelagic food web of these ecosystems (Pulido-Villena et al, 2005). Nevertheless, the importance of Saharan dust contribution to atmospheric deposition in relation to local sources it is not well established. The goal of this work was to assess the relative importance of the Saharan dust vs. local sources in the atmospheric aerosol deposition in the southern Iberian Peninsula. Moreover, we studied its relevance to atmospheric inputs of N and P in this area.

To achieve this goal, during spring and summer of the years 2004 and 2005, we obtained simultaneous weekly series of wet and dry atmospheric deposition of particulate matter, total nitrogen (TN) and total phosphorus (TP), at three locations in the province of Granada, spaced apart by up to 40 Km. Common variability between sites tens of kilometers distant, it is recognized to be caused by a factor as climate that affects them equally.

Figure 1 shows the time series of total atmospheric deposition of particulate matter. As can be seen the series presents simultaneous maximum depositions at the three sites, which coincide with the weeks in which there was significant Saharan intrusions over Iberian Peninsula. As a result, the three series show significant positive correlations with each other and, through a principal component analysis, we obtain that 75% of the variability in the deposition of the three sites is common. The deposition of TN and TP is also studied in relation with the particulate matter deposition and Saharan dust intrusions

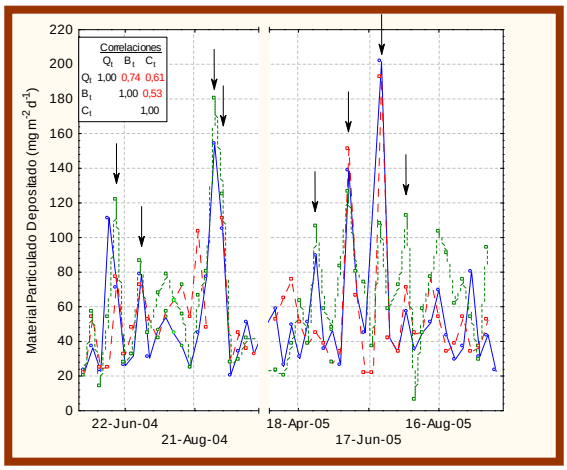

Figure 1.- Deposition of particulate matter (dry + wet) during spring and summer at three locations: (Qt), (Bt) and (Ct,) during the two years studied. Arrows indicate weeks in which the Saharan intrusions were more important. Box shows the correlations, all significant, between the corresponding series.

Now a network of stratospheric lidar stations operates in Siberia and Far East: in Institute of Atmosphere Optics, Tomsk, in U.G. Shafer Institute of Cosmophysical Iinvestigations and Aeronomy, Yakutsk, and in Institute of Cosmophysical Researches and Radio Wave Propagation, Kamchatka. Monitoring of vertical aerosol structure in the upper troposphere, in the stratosphere, and in the mesosphere is one of the main goals of these stations.

In this work we present systematization of lidar observations of aerosol layers in the middle atmosphere registered by this network. To a great extent, identification of different types of aerosols results from analysis of air masses transfer by backward trajectories method. Trajectory calculations were carried on the basis of software package which we have developed. We used UK MetOffice assimilated data on wind velocities and temperature. Results of our calculations were complemented by calculations using GDAS data and HYSPLIT software package available on NOAA site.

Such combined data of local lidar observations of the atmosphere and global satellite data enables to identify certain correlations of aerosol formation with structure of dynamic, thermal and chemical processes in the atmosphere.

For explanation of some types of aerosol layers in the stratosphere and mesosphere we employed gravito-photophoresis theory. This is the result of our investigation on photophoretic phenomenon.

Photophoresis can be responsible for aerosol layer formation at altitudes of 20, 30, 50, 70 and 85 km. The layers form in specific geographic regions and at certain seasons (Cheremisin et al., 2011a). The equality of the average gravito-photophotetic force and gravity force has been taken as the main condition of layer formation. This requirement has been supplemented by the condition of mechanical stability, that ensures return of the particle to the equilibrium position when an accidental shift in altitude occurs. Laboratory observations of photophoresis are available in the literature, obviously for the laboratory conditions.

Several types of aerosol layers were detected.

1. Appreciable aerosol content of the upper troposphere and the stratosphere at altitudes of up to 30 km was observed in winter-spring period.

2. Several cases of polar stratospheric clouds (PSC) were registered in winter time. The facts of PSC observations were confirmed by backward trajectory analysis.

3. Aerosol scattering peaks were observed in the stratosphere episodically at altitudes about 20 km in summer time. Aerosol at these altitudes has been associated with its transport from tropical aerosol reservoir described by Hitchman.

4. Volcanic activity in the northern hemisphere has increased over the last few years. After various powerful eruptions aerosol layers of volcanic origin were observed in Tomsk. Volcanic origin of aerosol was confirmed by backward trajectory calculations (Cheremisin *et al*., 2011b).

5. Lidar observations of the upper stratosphere and the mesosphere above Kamchatka were started in 2007, and aerosol layers at altitudes 35-50 km and 60-75 km were found (Bychkov *et al.*, 2011). Noctilucent clouds were registered above Kamchatka and Tomsk as well.

Keywords: $PM_{2.5}$, aircraft measurements, long-range transport, Northeast Asia.

Presenting author email: yjkim@gist.ac.kr

Asian mineral dust and anthropogenic pollutants (long-range transported pollutants, LTP) are usually transported long distance in the lower troposphere. Results from ground based measurements in Deokjeok island (Cayetano, *et al.*, 2011) and aircraft measurements (A-FORCE Campaign) were used for direct observations of LTP aerosols. In order to identify the air mass origin, HYSPLIT (Draxler and Rolph, 2011) air parcel back trajectory model was used. An algorithm (Lee, *et al.*, 2006) to retrieve aerosol optical depth (AOD) using the NASA moderate resolution imaging spectroradiometer (MODIS) data was used to map the transport of LTP aerosols during the Spring of 2009. A three-dimensional aerosol transport model (CMAQ 4.5) was also used to simulate the transport of aerosols over the region of interest. Level flights to measure fine mode SO_4^{2-} and NO_3^- have been conducted over Deokjeok Island on clean (April 2-4) and LTP days (April 5).

Table 1. Comparison between ground and airborne measurements in Deokjeok island on April 4-5, 2009.

Date	$PM_{2.5}$ ($\mu g/m^3$)	NO_3^-($\mu g/m^3$)	SO_4^{2-}($\mu g/m^3$)
April 2G	23.0 ± 2.9	1.1 ± 0.5	2.2 ± 0.4
April 3G	14.9 ± 3.0	0.5 ± 0.2	2.1 ± 0.5
April 4G	24.6 ± 1.4	1. 3 ± 0.2	4.3 ± 0.1
A		2.7 ± 2.0	8.9 ± 1.9
April 5G	83.5 ± 5.1	5.7 ± 0.2	15.9 ± 0.6
A		0.1 ± 0.1	2.5 ± 2.0

Airborne measurement on April 4 showed that elevated layer SO_4^{2-} was observed around 2km altitude. It was found that transported fine mode SO_4^{2-} aerosols reached the ground on April 5 resulting in three-fold increase in SO_4^{2-} concentration (Figure 1) compared to previous day (Table 1). CMAQ model predicted relatively well the column integrated SO_4^{2-} concentration for both days. Evidence of aerosol transport was confirmed by satellite retrieved AOD data showing plume of thick aerosol (AOD>2.0) observed near the Shandong area of China on April 4, and moved over the Korean peninsula the next day, passing over Deokjeok island on April 5 (Figure 2).

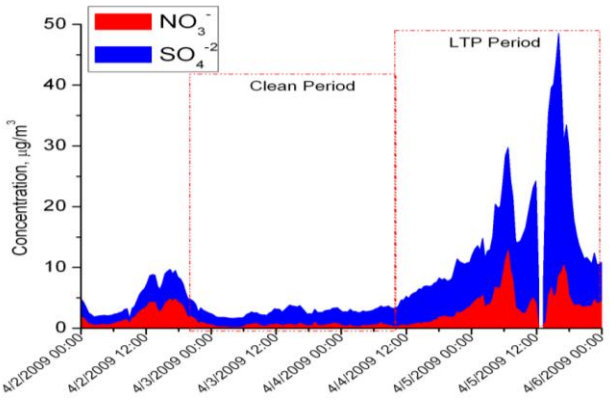

Figure1. Temporal plot of SO_4^{2-} and NO_3^- concentrations at the surface

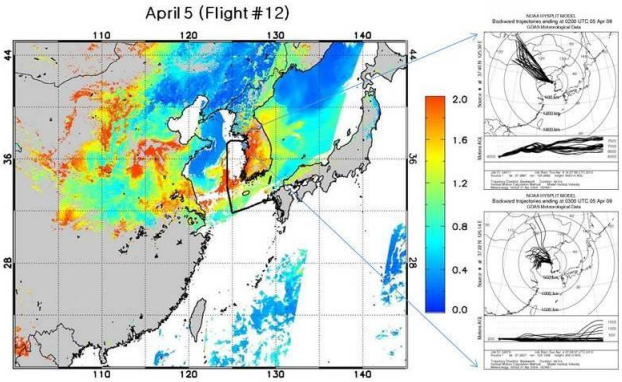

Figure2. Satellite retrieved AOD and Hysplit back trajectory plots at ground and aircraft levels on April 5.

Analysis of particle size distribution on urban and rural sites with connection to meteorological conditions

B. Kotlík[1], J. Keder[2], L. Černikovský[2]

[1]Department of Environmental Hygiene, National Institute of Public Health, Prague, Czech Republic
[2]Czech hydrometeorological Institute, Prague, Czech Republic
Keywords: aerosol, size spectra, temperature, source identification
Presenting author email: b.kotlik@szu.cz

Continuous weekly particle counts from four selected stationary AIM stations in the North Moravia region were conducted during 2. 2. to 9. 2. 2011.

The aim of this study was to identify the spectra of those particle distribution counts that would enable description of effects caused by sources and meteorological conditions. Four measuring stations were selected - 2 urban-industrial (Ostrava-Fifejdy and Karvina) and 2 rural (Studenka and Vernovice) all of which are suitable for representing measured fractions from local sources during the heating season and particularly during prevailing south-westerly winds.

The monitoring periods characterize favorable dispersion conditions associated with prevailing south-westerly zonal winds over the targeted areas. The mean wind speed during 1 hour in the urban collection sites was 1 - 4 m/s on 8. 2 - 9. 2. 2011 (except at night) and 2 - 7 m/s at the rural stations.

Thanks to favorable dispersion conditions the 1 hour PM_{10} concentrations were very low, largely far below 50 ug/m^3.

This abstract presents preliminary analysis results from the rural station in Studenka.

Particle counts within the separate size bins were normalized by the bin width and assigned to the bin centre size (fig. 1).

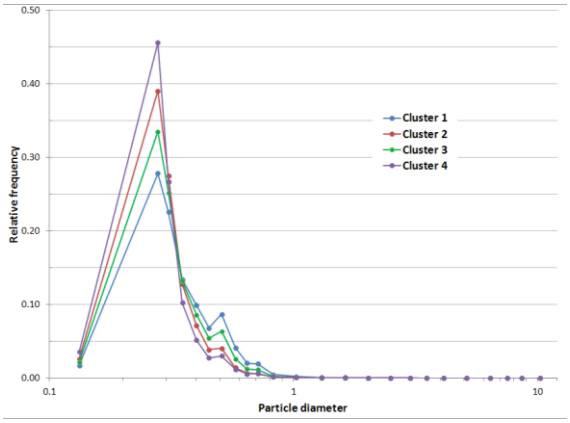

Figure 1. The typical distributions are presented in rural station (in µm).

For each measuring time period a particle size distribution has been obtained by this procedure. With the aim to find some typical structures among the particle size distributions a cluster analysis has been applied. Using hierarchical clustering approach a number of four distinct clusters has been estimated in the size distribution data. Applying the K-means clustering method the particular size distributions were sorted into 4 clusters. For each cluster a typical size distribution has been obtained as a mean of all distribution within the particular cluster.

An analysis of the link to the meteorological conditions prevailing during the measuring period has been provided. With this goal air temperature histograms categorized by the particle size distribution clusters were constructed (fig. 2). This made apparent that temperature values distribution differs significantly among particular clusters.

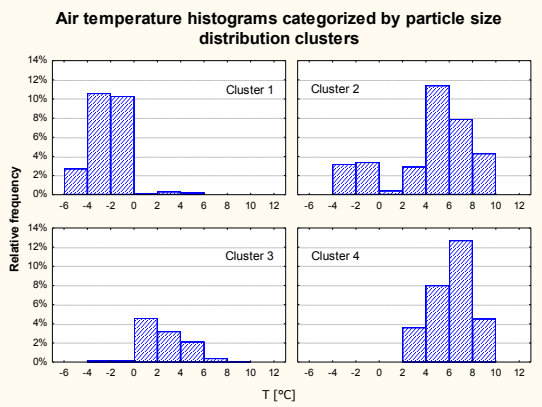

Figure 2. Air temperature histograms categorized by particle size distribution clusters

The expected dependence on wind speed in excess of 4 m/s was not proven.

The most significant difference between the clusters 1 and 4 might be observed: for cluster 4 with prevailing small-sized particles air temperatures above 2^{0}C were typical whilst cluster 1 in which the small particle share decreases in favour of coarser ones is mainly connected with negative air temperatures.

The detected clusters have a characteristic distribution pattern and their incidence corresponds to recorded temperatures. The reason for this is the probable influence of various ratios of local sources such as traffic and domestic heating.

The reason for this will be a subject of further analysis.

Temperature influence on the natural aerosol budget over boreal forests

L. Liao[1], H. Junninen[1], M. Kulmala[1] and M. D. Maso[1]

[1] Division of Atmospheric Sciences, Department of Physics, University of Helsinki, P.O.Box 48, 00014, Helsinki, Finland

Keywords: aerosol, temperature, VOCs

Presenting author email: li.liao@helsinki.fi

Atmospheric aerosol has climatic influence, and affects air quality and human health. The source of atmospheric aerosols includes both natural and anthropogenic origins. Secondary aerosol formed via the oxidation of biogenic volatile organic compounds accounts for the most significant fraction among the global aerosol budget. The boreal forest emitted VOCs, in particular terpenes, have shown to be one of the important aerosol precursor sources linking to the secondary aerosol production in northern hemisphere (Tunved et al., 2006). The emission of biogenic VOCs is temperature dependent, thus it may influence the secondary aerosol production as well as the CCN loading (Tunved et al., 2008), which further forms the vegetation, aerosol and climate interaction system (Kulmala et al., 2004).

In this work, we investigate the potential and the order of magnitude of the temperature influence to the natural aerosol budgets; we discuss the natural aerosol growth at different size ranges in different temperature bins from back trajectory analysis.

The research and data analysis were based on the observations at the SMEAR II station (61º51'N, 24º17'E, 170 m asl, Figure 1), Hyytiälä, Finland. 15 year dataset from 1996 to 2010 has been used, including continuously DMPS measurements, temperature and backward trajectory data. The DMPS particle size spectrums were divided into three size modes: the nucleation mode in the particle size range of 3--25 nm, Aitken mode (25--100 nm), and accumulation mode (100--1000 nm). Particle number concentrations at each mode were calculated every one hour. Hourly particle volume concentrations were integrated from the DMPS size distribution assuming spherical particles. The hourly 96 hour backward trajectories arriving at 100 m a.g.l over the Hyytiälä station were calculated from the HYSPLIT4 model (Draxler et al., 1997).

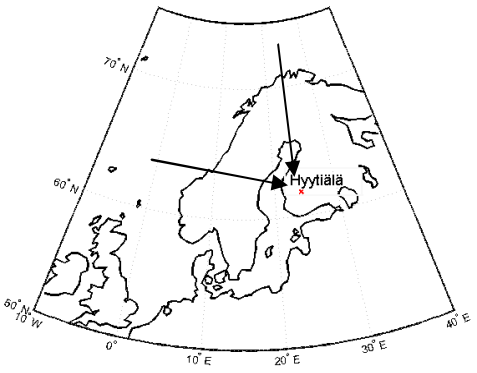

Figure1. The transport zone of the back trajectories.

Trajectories transporting 90% of time in an 80° North-West sector over land were extracted from the whole dataset. The travelling time over land for each trajectory was estimated from topographical data. The temperature along each trajectory was equally separated to 6 bins from 0 to 30 Celsius degrees.

Figure 2 depicts the integrated aerosol volume concentrations against time over land at the SMEAR II station. The colours indicate the range of temperatures. It is visible that the fitting slopes of the particle volume concentrations in relation to time over land increased when the temperature range elevated.

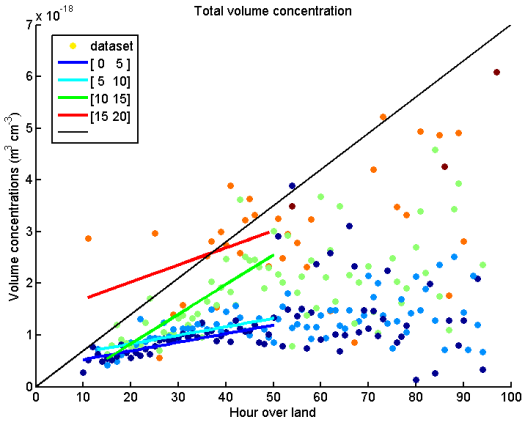

Figure 2. The integrated aerosol volume vs. time over land at four temperature bins.

The preliminary results suggest that temperature plays a strong role on controlling the growth of aerosol particles. In other word, temperature controls the precursor emissions of secondary aerosols, which will directly link to the volume (and mass) growth of aerosol particles. However, temperature has various influences on aerosol particles at different modes.

Large particle climatology in Finland – Estimating the effect of aerosols in extinction of infrared radiation

Automatic measurements of visibility are often based on the scattering or extinction of infrared radiation in ambient air. Infrared radiation can also be used passively to detect signals caused by motors or electrical devices. In these applications it is crucial to know the rate of extinction of the signal in air to be able to estimate the distance to the signal source.

Shettle and Fenn (1979) have developed a model for estimating the extinction of radiation in atmosphere due to aerosols. The model was developed in military use. In their model there are four different shapes for the aerosol particle size distribution: Urban, rural, marine with continental origin, marine with oceanic origin and tropospheric. The logarithmic mean diameter of the mode depends on both distribution type and ambient relative humidity. Finally the number concentration of aerosol particles is parameterized by the distribution type and the ambient visibility.

In some cases this model greatly underestimates the aerosol effect on extinction in Scandinavian conditions (Kaurila et al., 2006; Mielonen et al., 2008). The work presented here aims to improve the estimation by taking a prescribed source region dependent shape of the dry aerosol size distribution and then scaling it by PM10 aerosol concentration and relative humidity.

We have analysed continuous dry aerosol size distribution data from three stations in Finland: Hyytiälä (61º 51' N, 24º 17' E), Puijo (62º 54' N, 27º 31' E) and Pallas (67º 58' N, 24º 07' E) from years 2007-2011. The data was measured from dried flow of ambient air using DMPS and APS, giving the aerosol size range 0.01 – 15 µm. The number size distributions were converted to volume size distributions and normalized by the total volume concentration. The aerosol data was combined with FLEXTRA air mass back trajectories (Stohl et al., 1995).

Different combinations of marine and continental source areas were studied, but the differences between different continental areas as well as those between different marine areas were so small that in the end two simple source areas were used: marine and continental. The size distributions for these areas were somewhat different than those by Shettle and Fenn (1979) for the corresponding maritime and rural areas. For both size distributions extinction was calculated using Mie theory and assuming spherical $(NH_3)_2SO_4$ particles. There were significant differences in extinction between the new and S&F size distributions, especially in the case of continental air, where the new extinction was much larger due to larger fraction of large particles (fig 1).

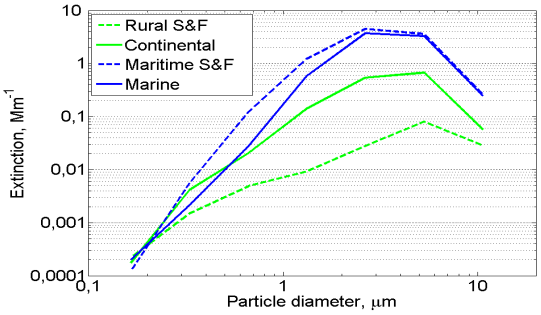

Figure 1. Extinction of 1 µm radiation caused by 1000cm^{-3} aerosol concentration in Shettle and Fenn (S&F) 1979 and in this work

For each trajectory the normalized aerosol size distribution was parameterized by taking a weighted average of the continental and marine size distributions based on the weighted fraction of time the air had spent over land or ocean, respectively.

The accuracy of this method was tested by scaling each parameterized aerosol size distribution by the measured total volume concentration (representing PM10). These were compared to real measured number-size distributions. Extinction in infrared wavelengths was calculated to both type of distributions, and these were compared to each other. The parameterized and "real" extinction values agree on average, but in individual cases the values can be significantly different.

In future the values will be compared to measured extinction values to see if the new size distributions improve the accuracy of the estimation. Also aerosol chemical properties will be included.

New particle formation (NPF) events and growth of the new particles has been observed frequently in different locations globally (Kulmala et al., 2004). Since the growth of the new particles can last from hours up to a couple of days, regional airmasses need to be considered atop of more local processes, when studying this phenomenon.

We examined the new particle formation in three measurement sites at Northern Scandinavia, and also analyzed how particle size distribution evolves when airmasses travel hundreds of kilometers.

Two of the measurement sites, Värriö SMEAR I station and Pallas GAW stations are situated in Finland and the last one, Abisko in Sweden near the border of Norway. The sites are located roughly along a straight line from west to east on latitudes 67-68 °N. The distance from Abisko to Värriö is 440 km. The Abisko area is dominated by subarctic mires surrounded by birch woodland and mountain tundra, whereas Pallas and Värriö are surrounded by boreal forest. The Pallas itself is situated above the tree line.

Our aerosol size distribution data were collected between Aug-2005 - Dec-2007. The data was measured using Differential Mobility Particle Sizers (DMPS) with a cutoff sizes of 3 and 7 nm in Värriö and Pallas, respectively, and using a Scanning Mobility Particle Sizer (SMPS) with a cutoff size of 10 nm in Abisko. The measurements at Pallas and Värriö are continuous, whereas the Abisko data were collected during campaigns of several months.

We analyzed and compared NPF events from each site according to the schema created by Dal Maso et al. (2005). The days are classified as events, non-events and undefined days. For event days we fitted the particle number-size distribution data to sum up to three lognormal distributions, and calculated the growth and formation rates of the nucleating particles.

Tunved et al. (2006) have shown that boreal forests are a source of secondary organic aerosols via emission of biogenic volatile organic compound precursors. Here we repeated and broadened their analysis to cover also Abisko, and compared the growth of particles as a function of time the corresponding airmass has spend over land for all three measurement station. We used the HYSPLIT trajectory model (Draxler and Hess, 1998) was used to calculate the passing-times over-lands. In Fig. 1 is shown the growth of the particle diameter when the airmasses arrive from sea to over land. As a comparison, during the NPF events the observed growing rate is about 3-4 times larger than these rates, which includes all data, not only the data from NPF days.

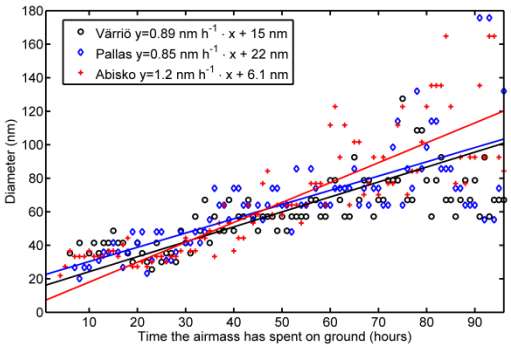

Figure 1: Particle diameters as a function of time the corresponding airmass has spent on-land. Coefficients calculated from time values of <80 h.

Three measurement sites located in a row enabled us to use a pseudo-Lagrangian approach to examine the dynamics of the aerosol during transport. Among other features, we discuss shifts in the modes of the particle size distributions, when the airmasses are drifting between a measurement site pair.

This research was supported by the Academy of Finland Center of Excellence program (project number 1118615).

The Impact of Meteorological Conditions on PM air pollution in Tartu, Estonia

E.-S. Kerner[1], M. Eller[1]

[1]Institute of Physics, University of Tartu, Tartu, 51007, Estonia
Keywords: air quality, meteorological conditions
Presenting author email: stinkin@ut.ee

We study in the meteorological phenomena which impact the presence and accumulation of PM in the near-ground air and thus worsening air quality. Our study is based on the EAS and NAIS measurements in the city of Tartu. Most influentially, these unfavourable conditions appear to be (i) in case of the smallest PM fractions but also in case of new particle formation – the presence and prevailing of high air pressure systems (Fig. 1) on one hand, but the strength of turbulent motion in the air on the other hand (Fig. 2) – the two phenomena which generally work against each other. (ii)Thermal stratification – in terms of PM NC fractions around 100 nm (Fig. 3).

The role of turbulence in new particle formation has not been under thorough investigaion up to now. The role of thermal stratification and inversions in PM accumulation is interesting in terms of local climate and topography.

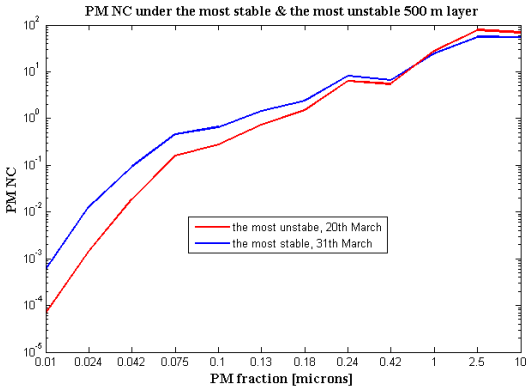

Figure 1. Examples of the number of particles in the air on days with very stable/unstable stratification.

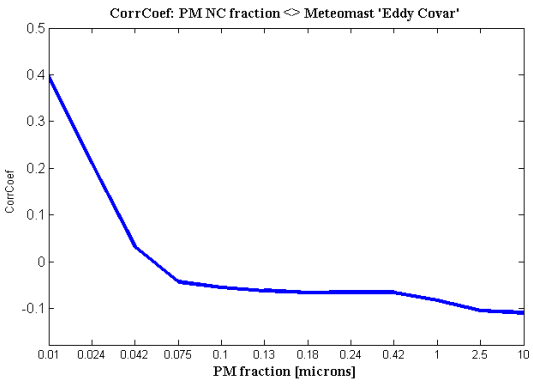

Figure 2. The correlation of EAS PM fractions [NC] with wind speed eddy covariance.

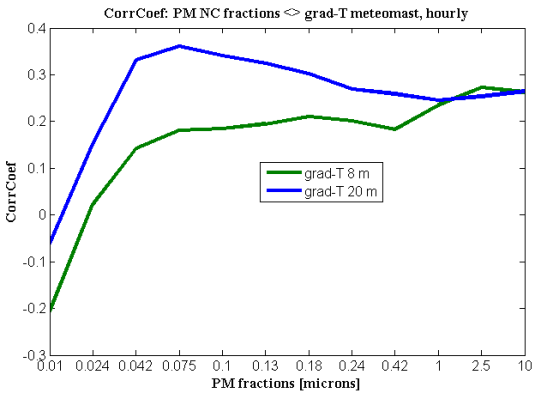

Figure 3. The correlation of PM fractions [NC] with the stratification of near-ground air.

Data

We use the measurements of NAIS and EAS in Tartu during the spring 2011 and since October 2011 till now, in comparison with measurements of night-time radiosondings and a 24 m high meteomast for vertical profiles of meteorological variables near Tartu.

We have observed the accumulation of particles measured with EAS under strong and shallow surface-based inversion rather than under high and long-lasting high air pressure systems. On the other hand, we have found dependence of the formation of new particles on the strength of turbulent motion present in the air as based on the measurements of NAIS.

This work was supported by the Estonian Research Fouocation under grant ETF8523.

Volcanic activities posed certain thread to the aviation in Europe during the last two years. European airspace was closed throughout most part of Europe because of the eruption of Eyjafjallajökull 2010. Moreover in 2011 airspace was temporarily closed in different parts of Europe because of the Grimsvötn eruption. Several paroxysms of Etna in 2011 resulted in a closure of the international airport of Catania (Sicily). During the eruption periods of all these volcanoes the Duesseldorf University of Applied Sciences performed a large number of research flights with light aircraft in close cooperation with the University of Iceland. The light aircraft were equipped with optical particle counters (OPCs) and, dependent on the flight mission, with additional instrumentation for ultrafine particles and volcanic gases.

Whereas the results of the research flights during the Eyjafjallajökull eruption are published elsewhere [1], this presentation will focus on the investigations during the Grimsvötn and Etna volcanic activities.
During the Grimsvötn eruption in May 2011 the airport of Keflavik in Iceland as well as airports in England, Scotland and Scandinavia were closed for some time, because of ash plume forecasts of the VAAC London. Even in Germany the airports of Bremen, Hamburg and Berlin were closed for several hours on 25 May 2011.

During this eruption period of Grimsvötn a team of the Duesseldorf University of Applied Sciences, the University of Iceland, the University of Reykjavik and the IMO has performed airborne in-situ measurements over Iceland and Germany as well as ground-based measurements in the south of Iceland.

The research flights on Iceland were started already one day after the beginning of the eruption (twelve in-situ measurement flights) and investigated the spatial and temporal spread of volcanic ash in the atmosphere. During all the flights TSP (total suspended particles) was recorded. These flights focused on the western part of Iceland in the region of Reykjavik and Keflavik and were mostly coordinated by ISAVIA. The measurement flights helped to keep Keflavik International Airport open for many additional hours despite of adverse predictions by the London VAAC model, because it was possible to observe the particle concentration on-line during the flights.
In Germany a research flight was performed on 25 May 2012 over the northern part of Germany where the volcanic ash cloud was forecasted from the dispersion model of the London VAAC. This flight was performed on the behalf of the German Weather Service (DWD).

Over western Iceland the research flights revealed most time relative low airborne ash concentrations, although the ground-based measured ash concentrations in the south of Iceland nearer to the Grimsvötn were very high.

In Germany the measured concentrations during the flight were low enough to be consistent with the re-opening of the airports Bremen, Hamburg and Berlin, which were closed by the authorities for several hours on 25 May 2011 because of high concentration predictions by the VAAC-model. During the research flight in Germany TSP, PM10, PM2.5, PM1 and aerosol size distributions were measured.

Whereas the airborne measurements during the Grimsvötn eruption were focused on the question, if the airspace was safe, the research flights at Etna concerned the investigation of the aerosol formation, change and dispersion within the volcanic plume. These investigations comprised the measurement of ultrafine aerosols as well as the full variety of aerosols in a size distribution between 250 nm and 32 µm. Moreover, volcanic gases as SO2 and gas fluxes were measured.

This work was supported in parts by the German Weather Service DWD, AIRBUS and German Federal Ministry of Transport, Building and Urban Environment. The support is greatly acknowledged

The focus of this paper is on the measured particle number concentrations (PNC) as well as elemental and organic carbon in 17 primary schools. This study is part of the "Ultrafine Particles from Traffic Emissions and Children's Health (UPTECH)", which aims to determine the relationship between exposure to traffic related ultrafine (UF) particles and children's health (http://www.ilaqh.qut.edu.au/Misc/UPTECH%20Home.htm). To achieve this, air quality and health data are being collected at 25 schools within Brisbane Metropolitan Area in Australia over two years. This paper presents the general aspects of UF particles data and preliminary results from the first 17 schools (S01 to S17), tested from Oct 2010 to Dec 2011.

Air quality data are being collected continuously at 5 sampling locations (3 outdoor and 2 indoor sites) within the school grounds for two weeks at each school. Particle number concentration (PNC) is measured at all sites. At one of the outdoor sites, which is in a central location within the school grounds, a range of particle and gaseous parameters are measured, including UF particle size distribution (10 - 400 nm); particle surface area; elemental and organic carbon (EC/OC) components in particle emissions; particle elemental composition; volatile organic compounds (VOC); polycyclic aromatic hydrocarbons (PAH); carbonyls; particle mass (including PM_{10}, $PM_{2.5}$ and PM_1); NO_x; CO; SO_2; ions; airborne pollen grains; culturable moulds; and meteorological conditions (wind speed and direction, relative humidity and temperature). Indoor sites (2 classrooms) are also sampled for particle chemical composition (carbonyls, VOC); CO_2; culturable moulds; endotoxins; total bacteria and exposure to persistent organic pollutants (POPs).

Figure 1 demonstrates the 25th, 50th (Median), and 75th percentile of the PNC at the central location for the first 17 schools during the weekdays. The whiskers illustrate the 10th and 90th percentiles. The variations in PNC at each school can be seen in this graph, showing the outdoor PNC is highest in S03 and lowest in S01.

Figure 2 shows the daily average indoor to outdoor (central location) PNC ratios (I/O) at schools. The I/O ratios of PNC greater than 1 show presence of an indoor source and this is more pronounced in S01, S10, S12 and S17.

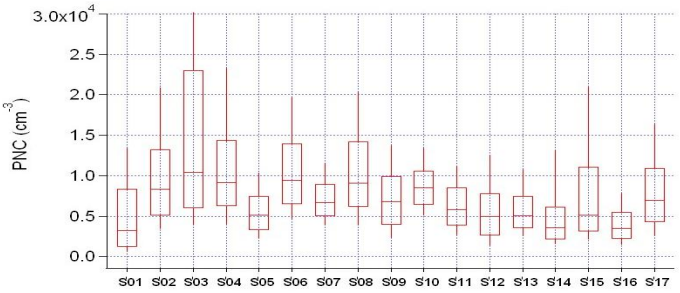

Figure 1: PNC in the central site at 17 schools.

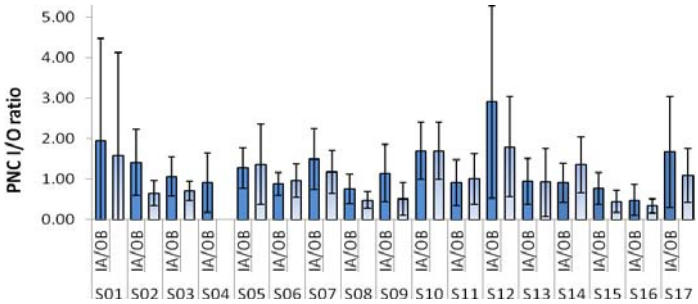

Figure 2: Daily I/O PNC ratios in 17 schools.

Figure 3 shows the average OC/EC ratio at each school, which was above 2, indicating the presence of secondary organic aerosols (SOA) (Chow et al. 1996) in addition to organic aerosols emitted from primary sources. The schools with the highest ratio had higher proportion of SOA while the schools with lower ratio showed more influence from primary sources (likely vehicle emissions).

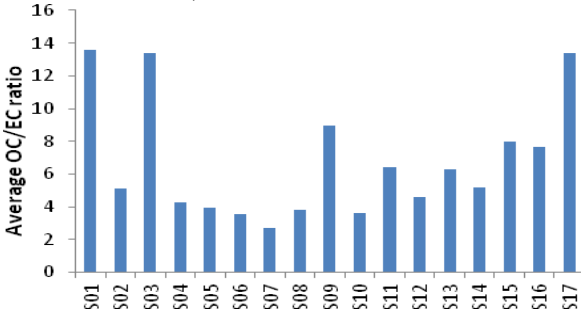

Figure 3: Average OC/EC ratio in the first 17 schools.

Carbonaceous aerosols in Barcelona during the SAPUSS campaign

A. Karanasiou[1,2], M. Dall'Osto[1], M. Viana[1], A. Alastuey[1], X. Querol[1]

Presenting author email: angeliki.karanasiou@idaea.csic.es

Organic carbon (OC) and elemental carbon (EC) constitute an important component of the atmospheric aerosol forming typically 10 to 50% of the total PM_{10} mass (Jimenez et al., 2009). EC is exclusively of primary origin (mainly traffic in urban agglomerates) while OC can be of both primary and secondary origin, associated to particulate organic compounds emitted directly into the atmosphere or formed by the condensation of compounds produced by the atmospheric photo-oxidation of volatile organic species.

The contribution of primary and secondary organic aerosol sources is rather difficult to quantify. This is due to the vast number of organic compounds with a variety of chemical and physical properties. However, it is possible to use an indirect method for the quantitative assessment of secondary organic aerosols (SOA), as the EC trace method (Pio et al., 2001). Nevertheless some limitations exist related to the capability of this method to represent the primary ratio between the OC and EC, $(OC/EC)_p$ resulting from fossil fuel combustion (Pio et al., 2011).

OC and EC concentrations were determined during the SAPUSS (Solving Aerosol Problems by Using Synergistic Strategies) campaign on September 2010 in Barcelona, Spain. Five monitoring sites were used: Road Site (RS), Urban Background (UB), Tower Mapfre (TM), site Tower Collserola (TC) and Regional Background (RB). The sites TM and TC were 154 and 445 m a.s.l respectively. Here we present the results of PM_{10} collected simultaneously with high volume samplers (MCV) using 12h intervals.

The concentrations of OC and EC were determined by a thermal analysis method using the Sunset Laboratory OCEC Analyzer and the EUSAAR-2 thermal protocol. As it was expected EC concentrations in RS were higher than those determined at all sites attributed to the considerable amount of primary emissions by traffic. OC concentrations had a similar behavior, Figure 1. The ratio of the ambient concentrations of OC to EC includes information about the extent of secondary OC formation. The fact that the average OC/EC ratio (~4.5) during SAPUSS exceeded significantly the $(OC/EC)_p$ measured at typical traffic sites (0.3-0.4) (Pio et al., 2011) shows significant contribution of secondary organic aerosol that is rapidly formed. Consequently the EC tracer method could not accurately assess the input of the secondary organic aerosol.

Figure 2 shows the regression of OC to EC concentrations in PM_{10} at the sampling sites. The intercept of the regression represents the non combustion OC. The intercept was similar for all sampling sites at ground level: RS, UB, RB and also for the two towers TC and TM at 154 and 445 m a.s.l respectively, suggesting a uniform horizontal and vertical distribution of this non combustion OC. Significant differences were observed in the intercept only during days with intense regional air mass recirculation. During normal conditions non combustion OC accounted for 48% of OC while during regional episodes reached 68% of total organic aerosol mass. This fact implies that the non combustion OC is mainly emitted by regional and not local sources, consistent with its relatively homogeneous spatial distribution.

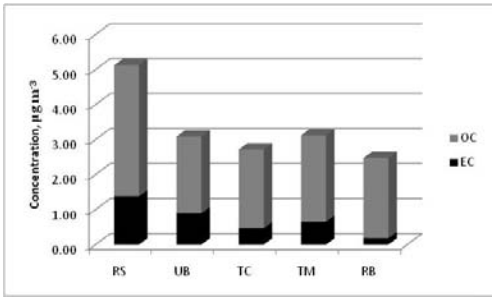

Figure 1. EC and OC concentrations during SAPUSS in the five sampling sites

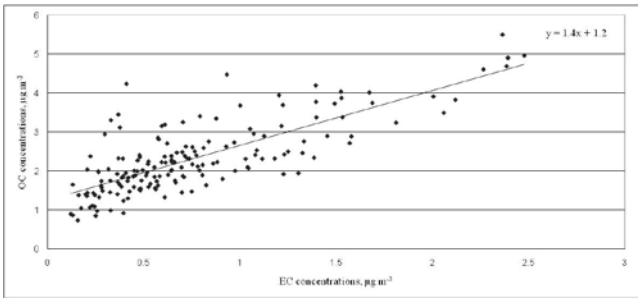

Figure 2. Regression of OC to EC concentrations during SAPUSS

Thessaloniki (40°62´E, 22°95´N) is a densely populated Greek city suffering from high concentrations of airborne particulate matter (PM), particularly in the city center. Several studies have been carried out to determine the chemical composition of ambient PM at various sites within the Thessaloniki Major Area. However, the organic and elemental carbon content of PM_{10} (OC and EC) has only recently started to be studied (Flarountzou *et al*., 2008; Chrysikou *et al*., 2009; Terzi *et al*., 2010). In a PM_{10} mass closure (Terzi *et al*., 2010), at an urban-industrial and an urban-traffic site, organic matter constituted a significant fraction of PM_{10} (18% and 23%, respectively), while EC had a lower contribution at both sites (3.6 % and 6.3%).

The aim of the present study was to investigate the OC and EC content of PM_{10} and $PM_{2.5}$ at two sites within the Thessaloniki Major Area (TMA), UT (urban-traffic) and UB (urban-background) (Figure 1). At both sites, PM_{10} and $PM_{2.5}$ samples were concurrently collected during the warm season of 2011 according to EN-12341 and EN14907, respectively. Low Volume Samplers (Ingenieur Derenda, Berlin) equipped with PM_{10} and $PM_{2.5}$ inlets were employed operating at constant flow rate 2.3 m^3/h. PM_{10} and $PM_{2.5}$ fractions were collected on Φ 47 mm high purity quartz filters (Tissuquartz^{TM}, Pall) prefired at 500 ^oC for 4 hours. Each sampling had a 24-h duration starting at 00:00. Organic carbon (OC) and elemental carbon (EC) were determined by the Thermal Optical Transmission method in a Sunset Laboratory OCEC Analyzer.

Summary statistics for OC and EC concentrations associated with $PM_{2.5}$ and PM_{10} are given in Table 1. These values are in general agreement with those previously found in Thessaloniki during the warm period (Flarountzou *et al*., 2008; Chrysikou *et al*., 2009; Terzi *et al*., 2010). As seen, both PM fractions were higher in the UT site, which exhibited lower $PM_{2.5}/PM_{10}$ ratio (Table 2) suggesting stronger impact of traffic induced resuspension of road dust.

Table 1. Mean±SD for mass concentrations of PM_{10}, $PM_{2.5}$ and associated OC and EC (μg/m^3)

	PM_{10}	OC_{10}	EC_{10}	$PM_{2.5}$	$OC_{2.5}$	$EC_{2.5}$
UT	48±10	8.4±2.9	7.7±1.4	26±6	6.2±2.3	6.0±1.3
UB	28±9	4.1±1.7	0.7±0.2	17±6	3.2±1.3	0.5±0.2

Daily concentrations of OC and EC associated with the PM_{10} and $PM_{2.5}$ particle fractions are illustrated in Fig. 2.

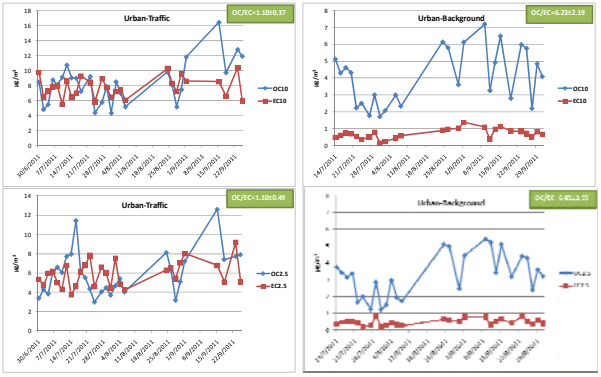

Figure 2. Daily variation of OC and EC concentrations associated with the PM_{10} and $PM_{2.5}$ particle fractions

EC, considered as a tracer of primary emissions mostly derived from traffic, was higher at the UT site, while both sites exhibited similar $EC_{2.5}/EC_{10}$ ratios averaging 0.81, indicative of EC distribution mainly in fine particles (Table 2). OC, that may originate from secondary aerosol formation processes as well, was also higher at the UT site**.** The relatively lower $OC_{2.5}/OC_{10}$ ratio at UT (0.77) suggests inputs of organic matter in the coarse fraction, whereas the high value of this ratio at UB (0.92) implies secondary organic aerosol formation.

Table 2. $PM_{2.5}/PM_{10}$ ratios for PM mass, OC and EC

	$PM_{2.5}/PM_{10}$	$OC_{2.5}/OC_{10}$	$EC_{2.5}/EC_{10}$
UT	0.54±0.10	0.77±0.26	0.81±0.26
UB	0.64±0.10	0.92±0.46	0.81±0.41

As seen in Fig. 2, the OC/EC ratio at the UT site was 1.1 in both particle fractions, in contrast to the significantly higher values observed at the UB site (6.23 in PM_{10}, 6.85 in $PM_{2.5}$), which reveal increased secondary organic particle formation (Duan et al., 2005).

In Europe, the carbonaceous aerosol is a major fraction of atmospheric aerosol even at rural background sites (Yttri *et al*., 2007) with possible exceptions at coastal sites and at sites located in the Mediterranean area where the contribution of Saharan dust can be high. The Mediterranean area is one of the most susceptible areas to climate changes, yet with large uncertainties regarding the fine-scale climate processes associated to the complex physiography of the region (Diffenbaugh *et al*., 2007).

This work shows the OC and EC concentrations at coastal rural site in the in the South of Italy (ENEA-Trisaia Research Centre (44°30'N, 11°21'E)) during a two months (May and June 2010) field campaign. The measurements were performed with a semi-continuous OC/EC analyzer (Model-4 Field analyzer, Sunset Lab.) using the EUSAAR_2 thermal optical transmittance protocol (Cavalli *et al*., 2010).

In order to better understand the OC/EC aerosol mass concentration in relation to number concentration of particles with different sizes, real-time particle concentration measurements performed with a dust monitoring system (Mobile Enviro Check GRIMM EDM107) are shown.

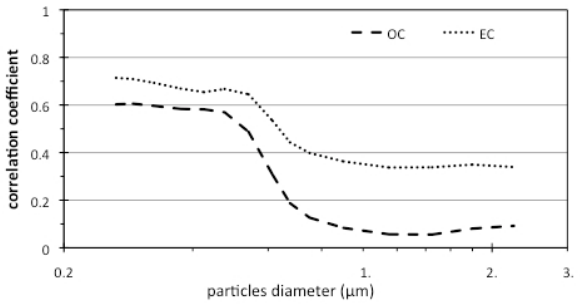

Fig. 1 Correlation coefficient between the OC and EC mass concentrations and the number concentration of aerosol particles with diameters contained in the following ranges: 0.25- 0.28- 0.3- 0.35- 0.4- 0.45- 0.5- 0.58- 0.65-0.7- 0.8- 1- 1.3- 1.6- 2.0-2.5 µm.

Temporal variations of carbonaceous aerosols, gaseous pollutants such as carbon monoxide (CO) and nitrogen dioxide (NO_2), and meteorological variables over the days of the week are also examined.

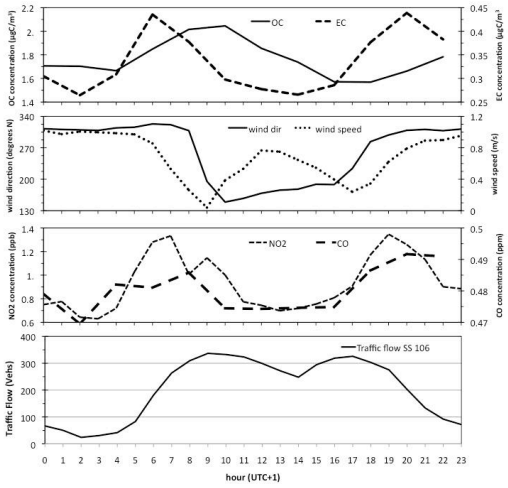

Fig. 8 Daily cycle of wind speed and direction, OC and EC concentrations, NO_2 and CO concentrations, and traffic flow on SS106 freeway.

Black carbon is the second biggest contributor to current global warming, second only to carbon dioxide in global radiative forcing (Ramanathan and Carmichael, 2008). Optical absorption is commonly modelled using Mie theory, assuming a concentric sphere core-shell configuration, however this is sensitive to the physical size and complex refractive index of the particles(Bond and Bergstrom, 2006). As nonrefractory species condense to form a thicker coating, the amount of light absorbed per unit mass of black carbon is increased, analogous to a lensing effect focusing light onto the core.

This effect has been studied in detail theoretically (Lack and Cappa, 2010) and has been seen in numerous laboratory studies (e.g. Schnaiter *et al.*, 2005; Shiraiwa *et al.*, 2010). Many ambient measurements of mass absorption cross-section (MAC) are available, though most used filter-based methods, which are subject to artefacts when nonrefractory material is present. Several measurements of core-shell diameters have also recently been published since the introduction of the single-particle soot photometer (SP2). Ambient studies of this effect are however extremely limited, and no study has compared SP2 core-shell measurements to changes in measured absorption.

We present results from the CalNex study, which took place in Pasadena, Los Angeles in summer 2010 in an attempt to provide a real-world assessment of the validity of models and parameters used to represent black carbon optical properties. The BC at this site was believed to be dominated by diesel emissions. An SP2 was deployed alongside a 3-wavelength photoacoustic soot spectrometer (PASS) measuring absorption. Combining both measurements yields the MAC in high time-resolution, free from filter-based artefacts.

We compare measured MAC to that calculated from SP2 core-shell measurements using Mie theory under a range of different atmospheric conditions, to test the applicability of the core-shell model in an urban environment. A thermal denuder (Huffman *et al.*, 2005) was also used to assess the optical properties and model performance of the BC cores in isolation, allowing the effect of the coatings to be quantified.

This work was supported by UK Natural Environment Research Council (NERC) under grant NE/H008136/1 and a NERC doctoral training grant.

We thank Jim Smith for loan of the thermal denuder.

FTIR-ATR spectroscopy of water-soluble organic matter from atmospheric aerosols

S.M.S. Freire, R.M.B.O Duarte and A.C. Duarte

Department of Chemistry &CESAM, University of Aveiro, Aveiro, 3800-193, Portugal
Keywords: Atmospheric aerosols; Water-soluble organic matter; FTIR-ATR spectroscopy.
Presenting author email: sandra.freire@ua.pt

Water-soluble organic matter (WSOM) in fine aerosols (i.e., aerosols particles with aerodynamic diameter <2.5 µm, and also called $PM_{2.5}$ fraction) is in the forefront of atmospheric research. Aerosol WSOM play an important role in the physical and chemical properties of atmospheric aerosols and therefore on climate effects (Facchini *et al* 1999; Gysel *et al* 2004). However, a sensitive methodology for the detailed characterization of such component of atmospheric aerosols is lacking on the current literature. Such lack may be due to the complex nature of WSOM.

In this work, $PM_{2.5}$ samples were collected during four different seasons (autumn, spring, summer, and spring/winter) in an urban North Western European coastal region (40°38'N, 8°39'W). Aqueous extracts of the $PM_{2.5}$ samples were fractionated through a DAX-8 resin resulting into two different fractions: a) a more hydrophobic fraction, and b) a more hydrophilic fraction. Figure 1 show typical images of the isolated hydrophobic fraction of WSOM from fine aerosols obtained at autumn and winter/spring seasons. Since the hydrophobic fraction represents more than 60% of the WSOM, this study began by the characterization of its structural features using Fourier transform infrared - attenuated total reflectance (FTIR-ATR) spectroscopy.

The results obtained show the presence of various functional groups in the different aerosols samples, which were collected at different environmental conditions. The hydrophobic acids fraction from autumn and winter/spring aerosols seems to contain lignin derived structures. The winter/spring samples also reveal signals typical of carbohydrate structures. All these structures are commonly found in biomass burning emissions (Duarte *et al* 2005; Duarte *et al* 2007).

Furthermore, this work can contribute to the comprehension of the influence of different seasonal events on the chemical nature of WSOM, as well as to assess the usefulness of a sensitive analytical technique such as FTIR-ATR for the characterization of WSOM.

Figure 1. Isolated hydrophobic fraction of WSOM obtained from fine aerosols collected at: a) autumn, and b) winter/spring seasons.

Black carbon (BC) in atmospheric particulate is composed of amorphous carbon, which is a by-product of incomplete combustion (Bond and Bergstrom, 2006). Emissions from natural sources such as forest fires are localized and incidental in China (Bai and Wang, 2005), whereas anthropogenic emissions are widespread and continuous (Liu et al., 2010). The increasing demand for energy in the past century has led to a great increase in the rate of BC emissions resulting from fossil fuel combustion. Black carbon particles have received increased interests. Nanjing is one of the mega cities in China. The high population density and rapid industrialization lead to an increase of primary emission of pollutants. Combination of primary and secondary pollutants results in high concentrations of fine particles.

The experiment presented in this paper was conducted at north suburb of Nanjing which is located in the center of the Yangtze River Delta of China during November 2008 to April 2010. Twelve-hour integrated samples of $PM_{2.5}$ were collected on quartz filters. These samples were analyzed for elemental carbon (EC) using a Thermo/Optical Reflectance (TOR) method. Aerosol black carbon (BC) was determined using an Aethalometer, a continuous optical absorption method. Twelve-hour average concentrations were calculated from the continuous BC measurements to temporally match the EC/OC integrated quartz filter samples. BC and EC concentrations are highly correlated over the study period (R^2=0.9492). In this paper, the seasonal and diurnal variation characteristics of black carbon (BC) in $PM_{2.5}$ and the effects of heterogeneous reactions of traces gases within BC were studied. The results showed that daily averaged concentrations of BC ranged from 1114 to 19408 ng · m^{-3}. The diurnal variabity in BC mass was characterized by a double peak, which can be attributed to local anthropogenic emission and atmospheric boundary layer diurnal changes. The background concentration of black carbon in $PM_{2.5}$ is 2920ng/m^3 during observation period, which was higher than that of most cities in China. Observations of SO_2, NO_2, HNO_2 and O_3 by differential optical absorption spectroscopy were used to investigate the relationships between trace gases and BC. During very hazy days, there were positive correlations between BC and SO_2, NO_2 and HNO_2, with correlation coefficients of 0.290, 0.615 and 0.676, respectively. In contrast, negative correlation was found between BC and O_3, with the correlation coefficient of -0.455.

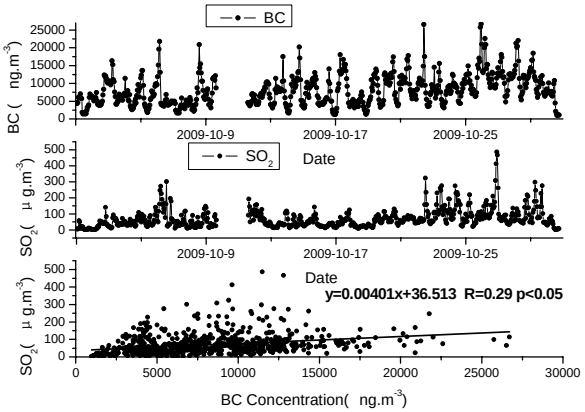

Fig. 1 Hourly mean variation series of SO_2 concentration in the north suburb of Nanjing during Oct.2009 and correlation character between SO_2 and BC

Size-segregated aerosol measurements were carried out at the Finokalia measuring site of the University of Crete during a three-year period using a 12-stage Small-Deposit-area low-volume-Impactor for particles with aerodynamic diameters between 0.01 and 13.6 μm. 111 samples were collected in total and were subsequently analyzed in order to determine, for the first time in the area, the size distribution of organic, elemental, and water-soluble organic carbon.

All three carbonaceous constituents exhibit a unimodal distribution with a prominent maximum in the Accumulation mode particles (D_a ~0.45 μm) which sometimes exhibits a second, less pronounced peak in the Coarse fraction (D_a 1.66-4.08 μm). OC and EC occasionally show a minor, secondary peak in the lower particle range (D_a 0.04-0.06 μm), especially for anthropogenic emission-laden (traffic/heating) air masses coming from Central-Eastern Europe (Figure 1). Maximum concentrations for OC and WSOC occur during summer, while for EC during spring, summer and autumn. In general, it was found that almost 2/3 of OC and EC concentrations are found in the PM_1 fraction of the aerosol.

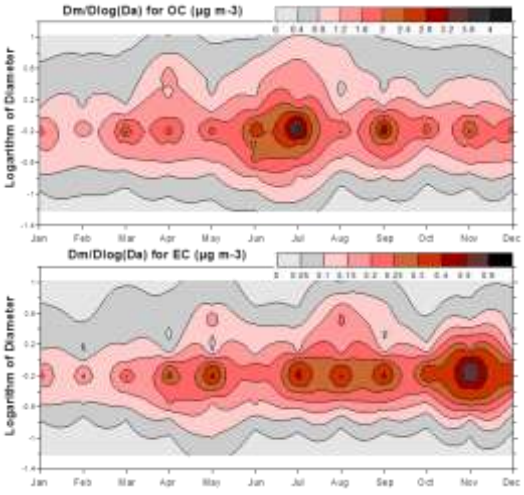

Figure 1. Contour plots of monthly averages for OC, EC.

Using the majority of samples for all 12 stages of the SDI, an OC/EC ratio of 5.13 is obtained, with this ratio being slightly higher for the PM_1 fraction. This ratio is similar to other ratios found for marine background sites (e.g. Aveiro-Portugal). Using the EC-tracer method, it was found that 64.6±17.6% of the PM_{10} organic carbon is secondary, with the percentage reaching ~70% for the PM_1 fraction. Having in mind that high secondary organic aerosol concentrations result principally via photochemical oxidation, adding oxidized functional hydrophilic groups and increasing the solubility of organic carbon in water, we studied the WSOC/OC relationship in the samples. It occurred that a grand majority (~70%) of the OC in the fine fraction is water-soluble, with the ratio increasing, as expected, during summer.

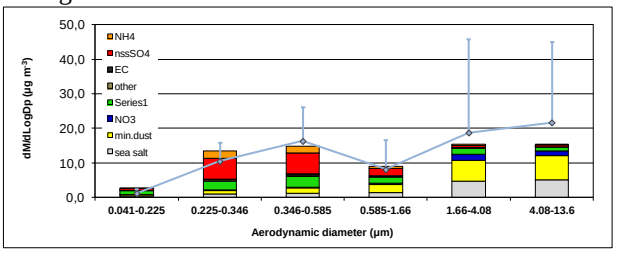

Figure 1. Mass closure of size-segregated aerosol.

Finally, we concurrently established the size distribution of major water-soluble inorganic aerosol components. SO_4^{2-} and NH_4^+ also exhibit a pronounced maximum in the fine fraction (0.45-0.67 μm), with ammonium sulphate accounting for 59.4±17.9% of the total inorganic mass fraction and 82.8±12.8% of the total sulphate being in the submicron mode. Together with ammonium and organic matter, they constitute the largest part of this aerosol faction. NO_3^-, Na^+ and Cl^-, on the other hand, show a maximum in the coarse fraction (aerodynamic diameters 3.31-5.85 μm). Using the median size segregated concentrations, a mass closure study was successfully performed (Figure 2). It was estimated that sea salt and mineral dust account for 32.9% and 44.5% of the coarse inorganic mass fraction, respectively. Our results represent a valuable long-term measurement dataset of size-segregated aerosol measurements in the area.

A yearly cycle of radiocarbon in organic and elemental carbon at a rural site in the Netherlands

U. Dusek[1], M. Monaco[1], S. Szidat[2], H. A. J. Meijer[3], J. van der Plicht[3], T. Röckmann[1]

Keywords: organic carbon, elemental carbon, 14C, fossil fuel.
Presenting author email: u.dusekt@uu.nl

Measurement of the radioactive carbon isotope ^{14}C in aerosols can provide a direct estimate of the contribution of fossil fuel sources to aerosol carbon. In aerosol science, measurements of $^{14}C/^{12}C$ ratios are usually reported as fraction modern (f_m). The radiocarbon signature gives a clear distinction between 'modern' carbon sources (f_m around 1.1-1.2 for biomass burning and around 1.05 for biogenic secondary organic aerosol) and 'fossil' carbon sources (f_m =0 for primary and secondary formation from fossil fuel combustion).

High volume filter samples have been collected since February 2011 at the Cabauw site, situated in a small rural area in the Netherlands, surrounded by some major urban centers. We report measurements of f_m for total carbon (TC), organic carbon (OC), water insoluble OC (WIOC) and thermally refractory carbon (RC) as a proxy for elemental carbon. The carbon fractions are isolated by combusting TC at 650 °C, OC and WIOC at 360 °C. Refractory carbon is defined as the carbon remaining on the filter after water extraction, combustion at 360 °C for 15 min and at 450 °C for 2 minutes. The method has been tested with test substances and real aerosol filters and indicates little charring for water-extracted filters.

First results of 7 filter samples taken from February – Mai 2011 show f_m(OC) generally larger than 0.86, except for one case, when a strongly polluted air mass originating in Eastern Europe reached the site. This indicates a strong contribution of natural sources to OC, even in the Netherlands, a very densely populated country with one of the highest levels of aerosol pollution in Western Europe. In particular, water soluble OC in the rural springtime aerosol seems to originate almost entirely from contemporary sources.

Refractory carbon also showed relatively high f_m, generally between 0.3-0.5, except in two cases, when marine air masses reached the site from the west and f_m(RC) dropped to around 0.1. This could mean that biomass combustion plays a significant role around the Netherlands even in springtime. It is also possible that there exists a biogenic, organic component of the aerosol that evolves at such high temperatures that it is virtually inseparable from elemental carbon.

Figure 1 shows a first estimate of the contribution of biomass burning sources to EC, under the assumption that all non-fossil EC comes from biomass burning and that biomass burning aerosol has f_m = 1.2. During our campaign, biomass burning sources account for 10 to 40% of EC. The contribution of biomass burning to EC in Cabauw is lower than the contribution measured in two winter campaigns at rural sites in Switzerland and Sweden (Szidat *et al.,* 2007; Szidat *et al.,* 2009). However, a significant part of our campaign was held in Spring and air pollution from fossil sources is likely higher in the densely populated Netherlands than in rural Switzerland or Sweden. Therefore, the significant contribution from biomass burning sources to EC was somewhat unexpected.

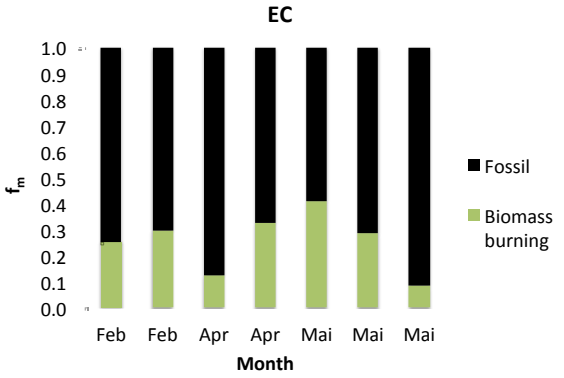

Figure 1. The fraction of EC from fossil and biomass burning sources, assuming no primary biological contribution to EC, and fm = 1.2 for biomass burning

Currently, filter samples from other seasons are prepared for radiocarbon analysis and a full yearly cycle of ^{14}C measurements in various fractions of the carbonaceous aerosol will be presented.

Characterisation of trace metals in airborne carbonaceous aerosols by single-particle EDX - Scanning Electron Microscopy

A. Pietrodangelo[1], S. Pareti[1] and C. Perrino[1]

[1]Institute for Atmospheric Pollution Research, National Research Council (C.N.R.), Monterotondo (Rome), 00016, Italy

Keywords: carbonaceous aerosol, trace metals, scanning electron microscopy, backscatter analysis.

Presenting author email: pietrodangelo@iia.cnr.it

Different types of carbonaceous aerosols have been identified in airborne particulate matter (PM) samples collected during a two years extended field campaign in Central Italy. Airborne PM to be investigated by scanning electron microscopy (SEM) was collected in parallel at three sites (two sub-urban and one regional background) by 8-stage cascade impactors (Moudi 100); 3 days and 24 h sampling was performed, respectively, for size fractions above and below 1 µm aerodynamic diameter (a.d.).

Identified carbonaceous formations include char particles, soot single-chains and aggregates, cenospheres, carbon-with-secondary sulphates combined aerosol and silicon-rich carbonate particles.

Aerosol aggregates and single particles were characterised by morphology and elemental microanalysis by energy dispersive X-ray spectroscopy (EDX). Backscatter analysis was employed to investigate the presence of metal particles included in each type of carbonaceous aerosol and X-rays mapping was also performed to gain information about the chemical species contributing to element composition.

Char and soot aggregates, cenospheres and Si-rich carbonate particles were mostly observed in the >1 µm (a.d.) fraction, while mixed carbon-sulphates materials mainly distribute in the finer fractions; moreover the latter type is hardly distinguishable as single particles or aggregates.

Metal particles observed were in the 1 – 0.05 µm physical size range, although the presence of smaller particles should be reasonably considered. Iron-rich particles were found in large number, showing rounded shape and average physical diameter ranging 0.8 - 1 µm. EDX spectra of smaller metal particles show Fe, Mn, Cu, Cr and Zn in different proportion, with either rounded or elongated shapes. All these particles were found associated mainly to char aggregates and Si-rich carbonate particles. The presence of Pb, in some cases combined with Zn, has been observed in a large number of nano-sized metal particles particularly identified in mixed carbon-sulphates materials, while these particles were not observed in char and Si-rich carbonate types. Moreover, EDX spectra put on evidence the presence on Ni, V and Ce in nano–sized particles included in cenospheres. Conversely, no evidence of metal particles was generally observed in soot; nevertheless, metal particles, mostly Fe-rich and in the 0.8 - 1 µm have been found included in the structure of large soot aggregates, mainly together with Si-rich particles (silicates and silica spheres) and inorganic salts.

Figure 1 show a cenosphere where metal nano-particles are evidenced by backscatter electron detector (BSE); the EDX spectrum of a Ni,V,Fe particle included in the cenosphere is showed in Figure 2..

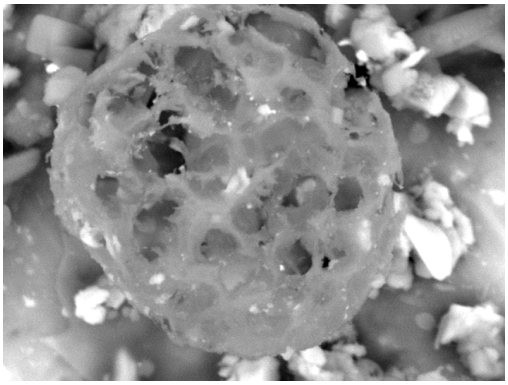

Figure 1. Cenosphere. Metal nano-particles are evidenced by backscatter electron detector (BSE).

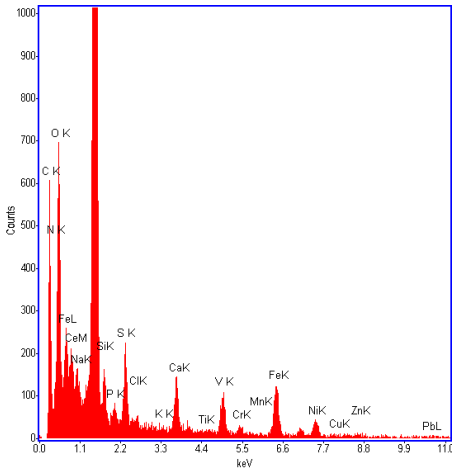

Figure 2. EDX spectrum of a Ni, V, Fe particle included in the cenosphere of Figure 1.

$\delta^{13}C$ values of TC, EC+CC and OC in size segregated aerosol particles

A. Garbaras, R. Bariseviciute, K. Kvietkus, R. Skipityte, I. Garbariene, A. Masalaite and V. Remeikis

[1]Institute of Physics, Centre for Physical Sciences and Technology, Vilnius, LT-02300, Lithuania
Keywords: Carbonaceous aerosol, Organic carbon, PM and source apportionment.
Presenting author email: garbaras@ar.fi.lt

Stable carbon isotopes have been used in source apportionment studies of atmospheric aerosols where two or more sources have a distinct isotopic composition. It has been shown that areal and temporal isotopic variabilities of aerosol samples are related to the diversity of the sources (Cahier, 1989). The stable C isotope signature of individual PAHs has been used to determine the contribution of different sources to the PAH content of soils and sediments. Glaser et al. (2005) concluded that compound-specific $\delta^{13}C$ analysis in PAHs failed for source apportionment, probably due to the low differences between their stable carbon isotope signature.

We think size spectrometry can help to follow aerosol transformation in the atmosphere, but there is a lack of studies of size segregated aerosol carbon isotope values (Garbaras et al., 2009).

We report $\delta^{13}C$ values of TC, EC+CC and OC in size segregated aerosol particles. Aerosol samples were collected at Preila (Baltic sea coast), Rugsteliskis (forested area) background stations and Vilnius city (0.5 mill inh.) during winter 2010, spring and summer 2011. MOUDI impactor had 11 size intervals, from 0.056 to 18 μm.

MOUDI foils were analyzed with EA-IRMS (FlashEA 1112 coupled to ThermoFinnigan Delta Plus Advantage). Half of the foil was measured directly (TC $\delta^{13}C$ values). The rest was baked in the oven (400 °C) to remove organic part and measured EC+CC δ13C values (carbonates were not removed with acid). OC $\delta^{13}C$ values were calculated using isotopic balance equation.

There is differences in $\delta^{13}C$ values and carbon concentration in each size interval in different locations and time of the year. In overall, in Aitken and in accumulation mode EC+CC had $\delta^{13}C$ values ranging from -25 to -28 ‰; OC from -25 to -32 ‰.

The variation of carbon isotopic ratio values clearly reflects the different sources of size segregated aerosol particles and ongoing processes in the atmosphere. Isotopic ratio mass spectrometry, when combining with other analysis methods, can be used not only in source apportionment, but also for aerosol evolution studies.

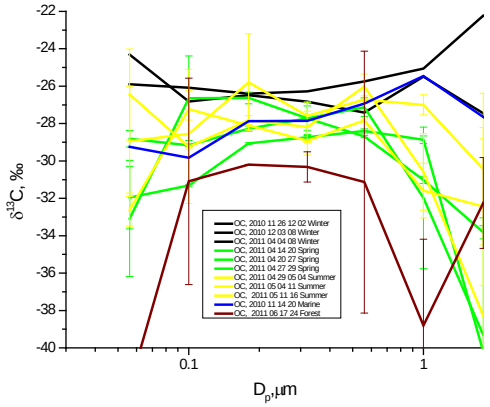

Figure 1. $\delta^{13}C$ values of OC in size segregated aerosol particles in spring, summer and winter.

Comparison of PM1 Organic and Elemental carbon between an urban and a regional background station

E. Yubero[1], J.F. Nicolás[1], Crespo J[1], M. Chiari[2], S. Nava[2], G. Calzolai[2], F. Lucarelli[2]

Presenting author email: eyubero@umh.es

The present study was performed in two locations. The first one is located in the city centre of Elche (235,000 inhabitants), approximately 12 km from the Spanish Mediterranean coast. The sampling point is placed in a busy canyon street with a lot of traffic. The device was located 3 m above ground level on the first floor of a City Hall building. The other one is located at the top of Aitana mountain range (38°38'56.50"N, 0°15'55.23"W, ▲1558 amsl.). It is located approximately 60km from the city of Elche and 20 km from the Mediterranean coast in an east westerly direction. Twenty-four hour PM1 samples were collected approximately every three days from February to October 2011 using a low volume sampler (2.3m/h). The set of samples (around 70 samples in each site) collected was analysed for EC and OC at INFN of Florence with a Sunset Laboratory Thermal-Optical Carbon Aerosol analyser using the NIOSH protocol.

Period mean and daily maximum values were compared at both sites during the study period (Table 1), for the PM1, OC, EC, TC (calculated as the sum OC+EC), OM (calculated as 1.4*OC) and the OC/EC ratio.

Table 1. Concentrations for PM1 related carbonaceous species measured in Elche and Aitana (µg/m^3)

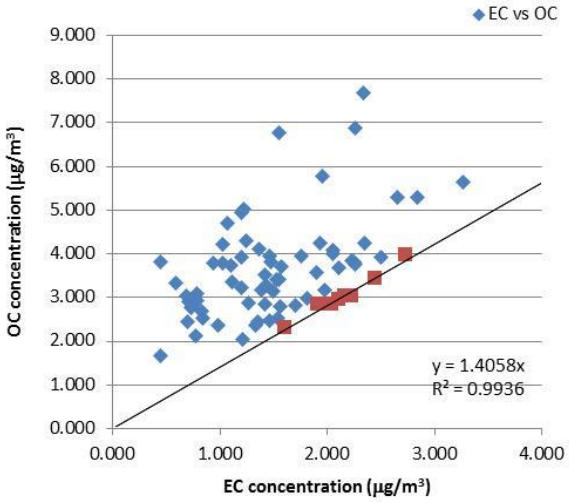
	Elche		Aitana	
	Mean	Max	Mean	Max
PM1	19.0	41.7	3.9	12.1
OC	3.6	7.7	1.6	6.3
EC	1.6	3.3	0.1	0.3
TC	5.2	10.0	1.7	6.6
OM	5.0	10.8	2.2	8.8
OC/EC	2.7	8.6	19.2	101

As can be seen, the difference between values in both stations is huge. The traffic station presents very high values for concentration of particles under 1µm. Organic matter and elemental carbon represent 26% and 8% of the bulk mass respectively. OC/EC ratio varies between 8.6 and 1.4, highlighting the presence of secondary aerosol. This secondary aerosol is not constant during the year and does not have any seasonal pattern. The PM1 concentrations measured in the Aitana station are remarkably low, despite being located close to important cities (Benidorm, a coastal city which is highly populated during summer months, is located less than 20km away). It is not observed that the urban aerosol reaches this urban background location during the entire year. That is confirmed with the EC data, with values close to the method detection limit in every sample. On the other hand, OC values are not negligible and represent more than 56% of the concentration PM1. In this case, either the organic aerosol has a secondary origin or it is bio-aerosol or biomass burning primary aerosol

A simple and low cost method for the indirect evaluation of secondary OC in atmospheric particles is based on the minimum values of OC/EC ratios, considering that those represent samples containing exclusively primary carbonaceous aerosol from fossil fuel combustion. In this approach the concentration of secondary OC was estimated from the following equation: $OC_{sec}=OC_{total}-(OC/EC)_{minimum}\times EC$.

The $(OC/EC)_{minimum}$ has been estimated for the traffic data by means of the ten values with a fewer ratio (squares in Figure 1). A lineal adjustment is shown in the graph. The slope of this straight line is our estimation of the primary carbon fossil fuel emission ratio. This value is $(OC/EC)_{ff}$.=1.4

Figure 1. OC and EC concentrations in PM1 aerosol samples collected in Elche (Traffic)



The concentration of primary fossil fuel OC is around 60%, with the remaining 40% being secondary. This secondary aerosol is due to the high photochemical activity in the city of Elche.

Organic matter and non-refractory aerosol over the remote Pacific: oceanic and combustion sources

L. M. Shank[1], S. Howell[1], A. D. Clarke[1], S. Freitag[1], V. Brekhovskikh[1], V. Kapustin[1], C. McNaughton[1], T. Campos[2], R. Wood[3]

Keywords: organic aerosol, black carbon, marine source
Presenting author email: tclarke@soest.hawaii.edu

Organic aerosol (Org) is now recognized as an important component of the atmospheric aerosol with both natural and anthropogenic sources. Recent studies have indicated oceanic emissions constitute an important natural source to the global atmosphere (O;Dowd et al, 2004; Spracklen et al., 2008). However, many studies have focussed upon the North Atlantic Ocean and most have had limited or uncertain criteria for exluding the influence of non-marine sources linked to combustion. Here we report on submicron aerosol physical and chemical properties in remote marine air measured from aircraft over the Southeast Pacific (SEP) during VOCALS-REx in 2008 and the North Pacific during IMPEX in 2006, and aboard a ship in the Equatorial Pacific in 2009. Black carbon (BC) measurements from a single particle soot photometer (SP2) and carbon monoxide (CO) concentrations over the Southeast Pacific provided sensitive indicators of combustion influence. As BC is in the particle phase and only derived from combustion it provides a direct indicator of the presence of combustion aerosol. In clean air over the Pacific we find lower organic mass fraction in the aerosol than most other studies and over the SEP we see little evidence of a significant marine source in air from South Pacific (Shank et al., 2012).

A High Resolution – Particle Time of Flight Aerosol Mass Spectrometer (HR-ToFAMS) measured non-refractory submicron aerosol composition during all campaigns. Sulfate (SO4) and Org measured during VOCALS off the coast of Chile and the TAO cruise in the equatorial Pacific show lower absolute values than those reported for previous "clean air" studies. In the marine boundary layer, average concentrations for SO4 were 0.52 μgm−3 for the VOCALS region and 0.85 μgm−3 for the equatorial region while average Org concentrations were 0.10 and 0.07 μgm−3, respectively. Campaign average Org/SO4 ratios were 0.19 (VOCALS) and 0.08 (equatorial Pacific).

CO and BC were used to identify the least polluted air, which had average concentrations of SO4 and Org of 0.14 and 0.01 μgm−3, respectively, with an average Org/SO4 of 0.08. Data from IMPEX was constrained to similar clean air criterion, and resulted in an average Org/SO4 ratio of 0.19. Under the cleanest MBL conditions during VOCALS, identified by CO below 61 ppbv, a robust linear relationship between Org and BC concentrations (Fig. 1) revealed that even at very low BC concentrations (< 10 ng m^{-3}) levels, combustion sources dominated organic aerosol, suggesting little to no marine source of submicrometer Org to the atmosphere over the eastern South Pacific.

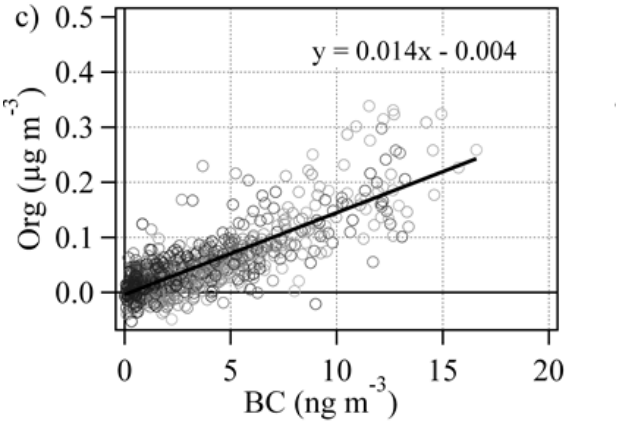

Figure 1. Organic aerosol mass (AMS) vs. BC from SP2 for clean MBL over SEP where CO is < 63ppb. Symbol shaded by CO ranging from 50ppb (black) to 61 ppb (light grey).

Note that all BC values plotted are generally much lower than BC criteria for "clean air" (often inferred BC from light absorption) in other studies. Many other studies use an arbitrary particle concentration or trajectory assessment over a few days to "screen" for pollution. Our observations imply that marine organics cannot be identified by merely setting a standard for background conditions below which anthropogenic influence can be disregarded. Other methods must be used to exclude non-marine sources.

We also examined the relation of sulphate concentrations to BC for CO<61ppb. Many values trended with BC even under this restriction. However, for CO restricted to <56ppb we found marked variation in sulphate to be independent of BC for BC< 1.8 ng m^{-3}. This SO4 is likely to be of marine origin, so any correlation of these data with Org may represent Org with a similar marine origin. A linear fit to the raw data between Org and SO4 mass, yielded a slope of 0.08±0.02, possibly indicative of an oceanic source for this Org. Our data argues for a weaker source of marine Org than currently used in many models.

Organic export from the ocean to the atmosphere - first investigations

M. v. Pinxteren[1], C. Müller[1], Y. Iinuma[1], C. Stolle[2] and H. Herrmann[1]

[1] Leibniz Institute for Tropospheric Research (IfT), Leipzig, D-04318, Germany

Keywords: sea surface microlayer, marine aerosol, chemical characterisation, organic compounds
e-mail: manuela@tropos.de

Marine aerosols contain, besides sea salt, a significant amount of organic material. As the composition of aerosols may influence their physiochemical properties, their chemical characterization and the identification of the source of the organic content is an important task [*Chan et al.*, 2005]. Recent investigations suggest that the organic content of marine aerosols, especially of particles in the sub-micron range, is strongly connected to the biological activities of the ocean [*Cavalli et al.*, 2004]. In this context, the sea surface microlayer (SML), i.e. the physical boundary layer between oceans and atmosphere plays an important role. The SML is operationally defined as the first 1000 micrometers of the ocean and often enriched with organic and inorganic matter. To study the interaction processes, a detailed chemical investigation in terms of organic material of the oceanic water and atmospheric phase above the mandatory.

Our first investigations dealt with the chemical analysis of the SML that is a challenging analytical task as seawater is quite a complex matrix and the high salt content is often problematic to analytical instruments. Moreover, the organic compounds are present in trace levels and some of them, like aliphatic amines, are very polar and reactive species and difficult to extract from the seawater. Therefore, appropriate sample preparation methods with the aim of enrichment of the target analytes and elimination of the matrix, especially the high salt content, in combination with hyphenated analytical techniques were developed [*van Pinxteren et al. submitted*].

Our results of sea water analysis (SML and bulk water) from the southern Baltic Sea suggest that different compound groups within the broad chemical class of nitrogen containing organic compounds and carbohydrates show very different behavior with respect to water concentrations and enrichment in the SML (Fig.1). Generally amines and amino acids tend to be enriched in the sea surface microlayer, whereas for dissolved carbohydrates a trend towards depletion was observed. The characteristics of the different compound classes were found to be in strong correlation to bacterial activity and meteorological conditions [*Stolle et al. 2010*; *van Pinxteren et al. submitted*].

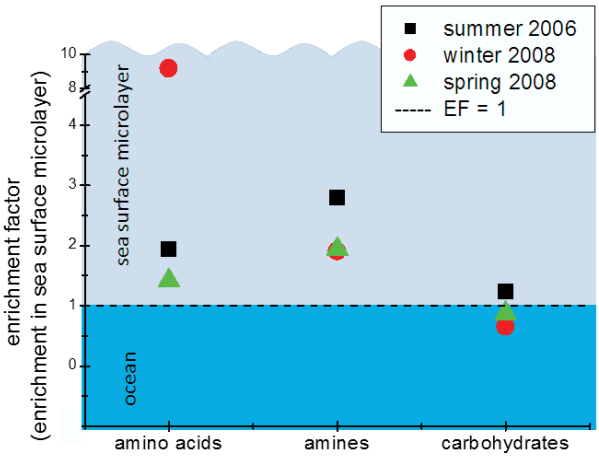

Figure 1. Enrichment factor of organic compound groups in the SML.

Our recent chemical analyses of seawater and the corresponding marine aerosol sampled in different field campaigns will help to reveal the connection of organic matter in these two compartments to address the question of net effluxes of organic matter between oceans and atmosphere.

Presenting author email: stephanie@chem.ku.dk

Sea spray particles ejected as a result of bubbles bursting from artificial seawater containing salt and organic matter in a stainless steel tank were sampled for size distribution, morphology, and cloud condensation nucleus (CCN) activity. The artificial seawater solution consisted of a salt (NaCl or sea salt) and one organic compound in deionized water. Bubbles were generated in the tank either by aeration through a diffuser or by water jet impingement on the seawater surface.

The ability of sea spray tanks to serve as proxies for aerosol generation from bubble bursting is addressed in this study. One concern is the effect of bubble residence time, which is much shorter in a tank than in the oceans. Bubble residence time was controlled by varying the depth of the diffuser in the water column of the tank. The effect of varying bubble residence time on particle size and CCN activity was found to be insignificant for the organic compounds studied. Moreover, at typical oceanic salinities, the CCN activity of particles from diffuser-generated bubbles is nearly indistinguishable from that of the salt component, which is not surprising since theoretical and experimental evidence show that small amounts of salt can dominate CCN activity (Bilde and Svenningsson, 2004).

Although sea salt consists largely of NaCl, and is therefore assumed to have similar properties, the minor constituents may alter its aerosol properties. Furthermore, the measurement of CCN activity of salt is complicated by the variations in its morphology as a function of size and rate at which it was processed from a droplet to a crystalline particle (Biskos *et al*, 2006; Wang *et al*, 2010). In this study, the CCN activity of solely inorganic artificial sea salt was measured and was found to differ from that of pure NaCl and from model predictions (Fig. 1). The possibility that the discrepancy could be explained by morphology was investigated by analyzing scanning and transmission electron microscopy images of salt particles for their aspect ratios (Table 1).

The effect of different bubble production methods (i.e., jet impingement and diffuser aeration) on particle physicochemical properties was also probed. CCN activities of particles produced from jet impingement on seawater containing sodium laurate, an organic surfactant, were much lower than those from diffuser aeration. Analyses indicate a considerable amount of organic enrichment in the jet-produced particles relative to the bulk seawater composition. The production of a thick foam layer during impingement may explain the difference in activation and supports hypotheses that particle production from the two methods of generating bubbles is not equal (King *et al*., submitted 2012).

Table 1. Mean aspect ratios of salt particles.

Sample description	Mean aspect ratio
Atomization	
60-nm PSL spheres	1.09 (SEM)
Polydisperse NaCl	1.20 (SEM) 1.28 (TEM)
100-nm NaCl	1.24 (SEM)
Artificial seasalt (SS)	1.21 (TEM)
Bubble-bursting from 35‰ seawater (SS)	1.28 (SEM)

The aim of this study was to analyse the potential circumstances controlling the variability of the aerosol number concentration over the south-eastern Baltic Sea with respect to the investigations of the Lithuanian coastal zone. In result of overview of several European campaign-type projects have provided information on the atmosphere submicron aerosol properties in Europe, showed that the measurement data of the Preila Environmental pollution research station, located in the south-eastern coast of the Baltic Sea, had partially similar characteristics to the Northern European region (Plauškaitė *et al*, 2010) with both aerosol concentration and size distributions showing influence from multiple source areas of particles and some similarities in concentration levels with Central European aerosol.

Measurements were performed during five cruises of r/v "Oceania" (Institute of Oceanology of Polish AS) in 2005 – 2010 mostly in southern and south-eastern parts of Baltic Sea. The data of the total aerosol particle concentration was compared with measurements at the Preila station during the same periods. The total aerosol particle concentration was measured by using CPC (size-cut 4.5 nm) at both investigation sites. Over the same period the measurements of the aerosol particle number concentration and size distribution were performed at the Preila station using DMPS (10 – 200 nm) in the year 2005 – 2008 and SMPS (9 – 840 nm) in 2009 – 2010. The series of HYSPLIT (NOAA) 72 hours air mass backward trajectories for the entire period at several altitudes above sea level which processed long-range transport of air mass at investigation sites (open sea or Preila station) were used for the analysis to determine source regions of atmospheric aerosols or precursor gases leadings to new particle formation (NPF) as well. The results indicated that the total aerosol particle concentrations over the open sea during all cruises despite different seasons (spring and autumn) or air mass transport directions was higher than at the Preila coastal station and showed influence both of cleaner (Atlantic ocean) and more polluted (continental outflow) air masses as well as the ship exhaust emissions, regional or lokal NPF and breaking waves during storm (Fig. 1). The analysis showed that the new particle formation (short-term "bump" type events; Figs. 1 and 2) both in marine boundary layer and coastal zone was observed during transport of air mass originating from the Atlantic Ocean and travelled upwind over Baltic Sea to Preila station. The change of air mass transport direction from western to eastern (from polluted continental regions) resulting the sharp increase of the total aerosol particle concentration in the coastal zone (8 – 9 April 2010). Especially high influence of ship emissions to increase of aerosol particle and chemical ingredients concentration (from 3 to 6 times) was determined in the marine boundary layer of harbours regions (Tallin, Tartu, Kaliningrad, Klaipėda, Gdansk Bay).

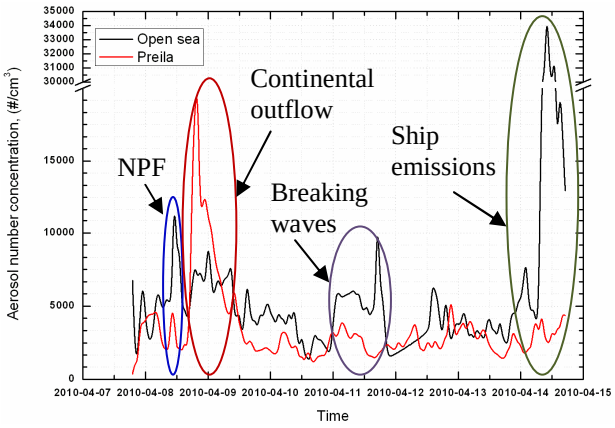

Figure 1. The CPC data as function of time in the marine boundary layer and at the Preila station during 7-14 April 2010.

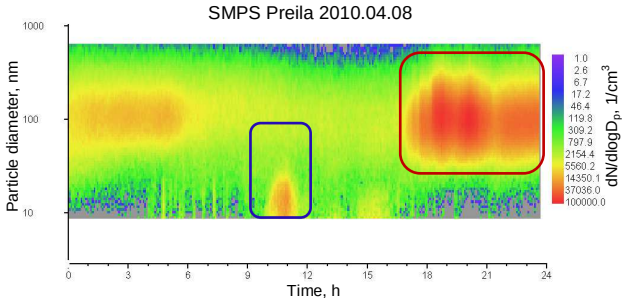

Figure 2. Aerosol size distribution during regional NPF and influence of polluted continental outflow.

Presenting author email: Julia.schmale@gmail.com

In recent years significant efforts have been made to investigate marine particles, principally through ship-based and stationary methods; however, many questions concerning their sources, chemical nature and evolution in the atmosphere remain. Indeed, there are even suggestions that not all drivers of marine aerosol production, especially of secondary nature, are fully understood yet (Lapina *et al* 2011). This is partly due to the low spatial and temporal data coverage and the seasonality of oceanic emissions associated with biological activity, among other factors (Decesari *et al* 2011). Here we present a preliminary detailed analysis of organic aerosol derived from stationary online mass spectrometric measurements in the Sub-Antarctic Atlantic Ocean during spring/summer 2010.

Eight weeks of measurements were performed at the remote Sub-Antarctic Bird Island (54°00'S, 38°03'W), which is approx. 4 km in length, 800 m wide, and lies about 1400 km east of the Falkland Islands. At Bird Island emissions are mainly influenced by the marine environment and local seabirds and seals. A set of instruments was used to characterize the ambient aerosol comprising among others a scanning mobility particle sizer (SMPS), and an Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS). The non-refractory chemical composition of submicron aerosol was determined with the AMS with a temporal resolution of 5 minutes and a collection efficiency of 50 %.

On average, the submicron particle concentration was 0.76 µg m^{-3}. Particulate sulphate, originating mainly from DMS emissions, contributed 40 %, while organics made up 34 % of the mass. The median particle number concentration was 377 cm^{-3}, ranging from around 180 to 1100 cm^{-3} between the 10^{th} and 90^{th} percentiles.

Based on the statistical method of positive matrix factorisation (PMF, Ulbrich *et al* 2009) applied to the organic aerosol (OA) data, five factors were determined (see Figure 1): (1) Methane sulfonic acid (MSA), a secondary marine aerosol component, was observed to contribute 25 % of the OA. (2) Organics associated with the sea salt primary marine aerosol (Sea Salt OA) were found to contribute 7 %, which correlated well with the local wind speed. It should be noted that quantifying this factor with the AMS is highly uncertain due to the refractory properties of sea salt. (3) In addition, a factor AA, strongly resembling the signatures of amino acids and amines (Schneider *et al* 2011, Hildebrandt *et al* 2011) was present and accounts for 18 % of the OA mass. The N:C ratio of 0.13 is very high compared with, e.g., 0.02 of the marine oxygenated OA (M-OOA). There are indications that the AA factor is of biogenic origin and not directly associated with marine emissions, as it is slightly anti-correlated to MSA. Thus, it may potentially originate from the local fauna (birds and seals). (4) A dominant fraction of 40 % was classified as M-OOA which is characterized by highly oxygenated ion fragments whose exact origins, however, are still under investigation. The last factor (5) is composed of hydrocarbon-like OA (HOA, 9 %) which originated from the local generator of the research station on the island.

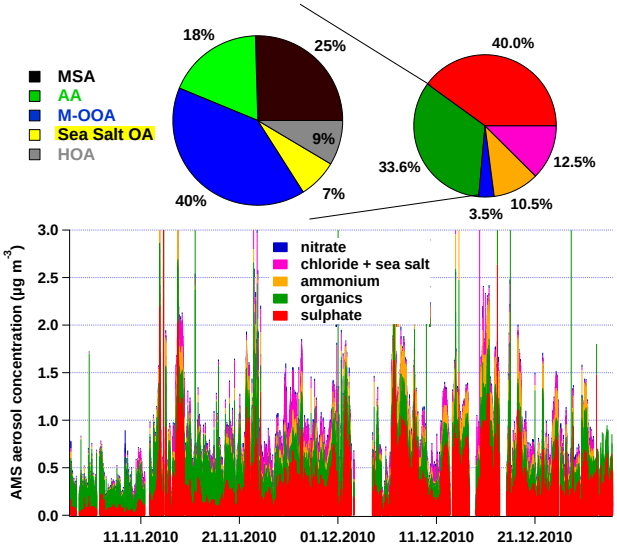

Figure 1. Time series of the submicron particle chemical composition, including the average composition (right pie chart), and the average contribution of 5 factors derived from positive matrix factorisation to the organic aerosol (left pie chart, see text for abbreviations).

Andrea Gambaro: gambaro@unive.it

Amino acids are ubiquitous compounds with an integral role in atmospheric aerosol compositions (Ge *et al.*, 2011). Despite their atmospheric abundance, the amino acids fate and properties are poorly understood; they could be involved in cloud formation or act as ice-forming nuclei due to their hygroscopicity (Szyrmer and Zawadzki, 1997), affect atmospheric radiation balance (Chan *et al*., 2005), lead to secondary aerosol formation (De Haan *et al*., 2009) and influence air pollutants scavenging (McGregor and Anastasio, 2001). As amino acids have a wide range of reactivities, they can help determine atmospheric transport of particles and drops (McGregor and Anastasio, 2001). Several sources affect atmospheric amino acids complicating the possibility of identifying their origin. Due to their distance from emission sources and their naturally low aerosol concentrations, Polar Regions are excellent natural laboratories to conduct source apportionment studies of such compounds.

In order to better understand the importance of amino acidic compounds for the global atmosphere, we analyzed twenty free amino acids (FAAs) in seventeen size-segregated aerosol samples collected in a polar station in the Svalbard Islands from April 19 until September 14, 2010. Samples were processed and analyzed using a previous developed method (Zangrando *et. al*, 2010); Total FAAs concentration ranged between 592 fmol m^{-3} and 4593 fmol m^{-3} with serine and glycine being the most abundant compounds in almost all samples and accounting for 45-60% of the total amino acid relative abundance. The other compounds had an average concentration between 0.3 and 98 fmol m^{-3}. The higher amino acids concentrations were found in the ultrafine aerosol fraction (<0.49 µm) which in most cases accounted for the major part of the total amino acid content. Some samples showed a more complex distribution in the different aerosol size fractions, evidencing the presence of local-derived aerosol. Local aerosol sources such as neighboring volcanic activity and human-induced fires influenced FAAs concentrations in the large (10-7.2 µm) and medium (3.0-1.5 µm) size distributions of samples collected during these events. Back trajectory analysis determine marine derived aerosol as the major amino acids source in the rest of samples.

A cluster analysis and a factor analysis identify possible aerosol and amino acids sources influencing the study site, demonstrating the contribution of both long-range aerosol transport and a local marine source.

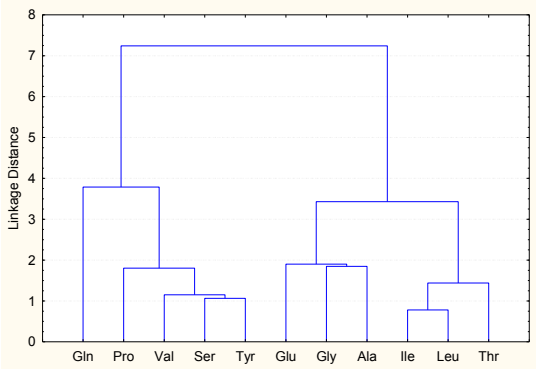

Figure 1: Cluster analysis results

Presenting author email: andrew@chem.ku.dk

Sea spray aerosols (SSA) represent large uncertainty in models of aerosols flux from the oceans. The physico-chemical processes producing these aerosols may play an important role in their emissions, size, and chemical composition.

SSA are generated from wind-steepened breaking waves. As the wave breaks the peak of the wave curls forming a plunging jet, entraining air which causes bubbles to form, rise and burst, releasing aerosols. SSA have been generated in the laboratory using different techniques including frits, diffusers, and plunging jets. Despite limitations of replicating an oceanic process in the laboratory, such that all variables can not be satisfied, plunging jets appear to reproduce sea-spray generation mechanics.

Despite the extensive literature on the subject of SSA, there is no consistent method to compare laboratory generated SSA and their production methods. This may contribute to the uncertainty in the flux parameterizations, particularly in the sub-micrometer size range (de Leeuw *et al*, 2011). In this work we attempt to determine key jet parameters that are essential for reproducing the physical system of air entrainment, bubble bursting, and subsequent aerosol production in the open ocean and across various experimental configurations.

The plunging jet used most commonly in laboratory experiments can be characterized in many ways, but only some parameters may be important for the production of aerosols. The jet flow rate, entrained air flow rate, and turbulence generated in the flow field of the jet appear to be relevant. These factors provide clues of the characteristics of the underwater bubble cloud as well as the bursting characteristics of bubbles that reach the surface.

D_{Jet}	Flow Rate ($L min^{-1}$)	E_{diss} (W/m^2)	$\#/cc$
4 mm	3.2	11	872
	4.8	37	6.39×10^3
	6.3	88	1.09×10^4
16 mm	14	4.5	382
	15.5	6.3	-

Table 1: Jet energy dissipation and aerosol concentration

The energy dissipation rate of wind generated breaking waves over the ocean scales with the square of the wind friction velocity, however the energy transfer from wind to wave diminishes depending on the age of the wave or fetch. Gemmrich *et al* (2008) indicate that the wave energy dissipation rate varies with the effective wave speed, C_{eff}, a function of wave age, over three orders of magnitude from 10^{-1} to 10^2 W/m^2.

Following the work of Garret *et al* (2000), we calculate the energy dissipation rate within a laboratory SSA tank using bubble spectra and compare this with the calculated energy dissipation rate from the kinetic energy of the jet, $E_J = \frac{1}{2}\rho_w V_{jet}^2 Q_w$. Assuming that all incoming energy from the jet is dissipated, the average energy dissipation rate of the system can be determined. It is found that the dissipation rate calculated from the bubble spectra are several orders of magnitude higher than the energy that is added to the system via the plunging jet. Due to the nature of the bubble spectra measurement, energy dissipation calculated from the bubble spectra may represent fluctuations in energy dissipation rate due to the turbulent flow field produced by the jet.

Ultrafine particles are generally recognized to have a severe impact on human health and an increasing focus is turned towards particle emissions from marine engines. Although regulations on NOx emission from ships have been implemented and sulfur content in marine fuel is now limited to 1.0 % in emission control areas, emissions from ship traffic is still an important factor especially in harbor cities. Mainly two ways for limiting the emissions from ships are presently being exploited: 1) lowering of the fuel sulfur content and 2) implementation of emission reducing technologies such as filters and scrubbers.

In this study emission data from a ship with a wet scrubber system installed is presented. The main engine is a MAN B&W 9L60 MC-C 2 stroke Diesel engine. Maximum continuous rating was 88-90 % during measurements. The effect of the scrubber operating in seawater mode on particle emission was tested during two days in February 2011using two different heavy fuels (1.0 % and 2.3 % sulfur). The main focus was on measuring the particle number concentration and size distribution before and after the scrubber system.

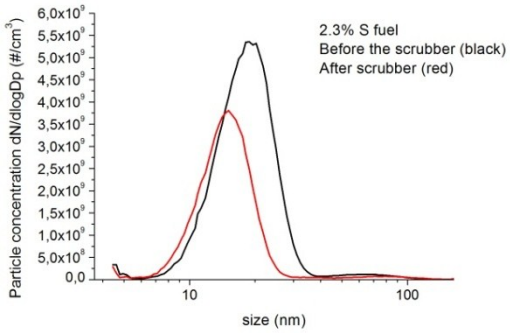

Figure 1. Particle size distributions measured by SMPS before and after the scrubber using 2.3 % S fuel.

Particle measurements were performed in this study using an SMPS and an ELPI. The results show that combustion particles from the ship have a bimodal size distribution, both before and after the scrubber system (figure 1). The two peaks in the bimodal particle size distributions measured by the SMPS system were found at 8-10 nm and 50-60 nm respectively for 1.0 % S fuel and at 15-20 nm and 70 nm respectively for 2.3 % S fuel. Upon changing from 1.0 % S fuel to 2.3 % S fuel the total particle number concentration was found to increase by a factor of 4.8-6.4 when measuring before the scrubber system. Particle number concentrations measured in the size interval 20-1000 nm using SMPS, ELPI, and CPC were found to be in generally good agreement. It was found that the scrubber system decreases the emitted particle number concentration (#/cm^3) by 30-55 % averaged over a 1 hour measurement period for specific operating conditions (figure 2). SMPS diameters are electrical mobility diameters and ELPI diameters are aerodynamic diameters, no conversion between the two has been applied yet.

Elemental analyses of particles collected on the top six ELPI impactor stages (particles >200 nm aerodynamic diameter) by SEM/EDX, show that the carbon content of the particles was reduced by 50-60 % by the scrubber. Increase in the percentage of sulfur, sodium, silicon, iron, nickel, chromium, vanadium, and magnesium in the particle mass was observed. The chemical composition of the salt containing particles measured after the scrubber resembles that of the fuel oil better than that of sea water, indicating that the salt particle formed in the scrubber are condensates of the fuel.

In conclusion, nanoparticles were characterized in the ship exhaust gas before and after a wet scrubber system.

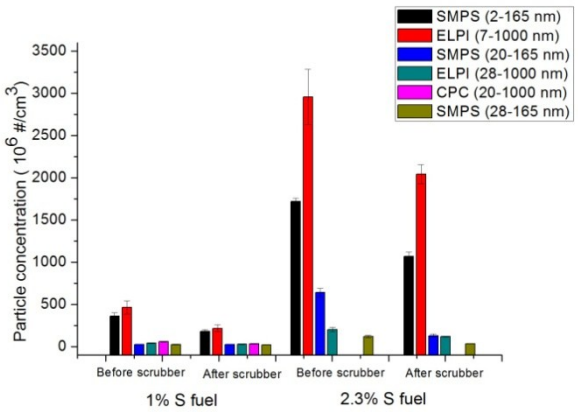

Figure 2. Comparison of PN concentration measured by SMPS, ELPI and CPC for 2.3 % S fuel and 1.0 % S fuel.

New Findings on Submicron Sea Salt Source Flux

J. Ovadnevaite, D. Ceburnis, H. Berresheim and C. O'Dowd

School of Physics and Centre for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland Galway, University Road, Galway, Ireland

Keywords: sea salt, sea spray source function, marine aerosol, HR-ToF-AMS.
Presenting author email: jurgita.ovadnevaite@nuigalway.ie

Sea spray aerosol is a significant component of the aerosol population in the marine environment, and given that 70% of the Earth's surface is oceanic, sea spray contributes significantly to the global aerosol budget (Vignati et al., 2010). In order to better understand and quantify these effects, detailed information on the chemical composition, along with size distribution and abundance, is required.

The high-time resolution sea salt measurement by a High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS) enabled the quantification of sea salt mass in both increasing and decreasing wind speed regimes up to 26 m s^{-1}. A mass flux source function was also derived and found to have a power-law wind speed dependency with an exponent of 3.1 for increasing winds and 2.3 for decreasing winds. Whereas, submicron aerosol particles are expected to be uniformly mixed in the marine boundary layer, an effective sea spray aerosol production flux was estimated from the sea spray concentration divided by a filling time and multiplied by the marine boundary layer height.

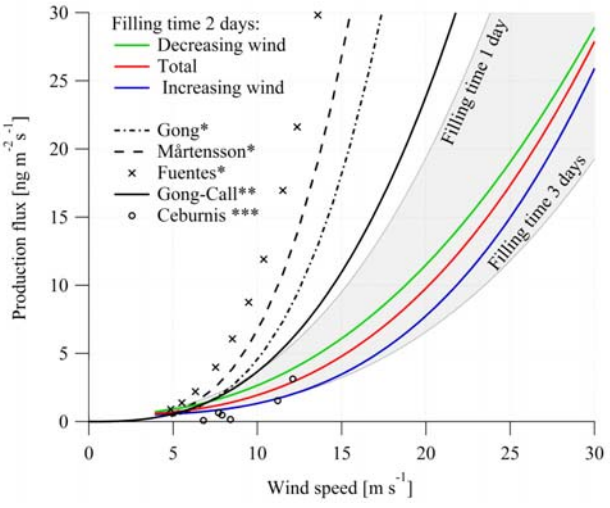

Figure 1. Production flux dependence on the wind speed. Color lines represent the flux derivations from the AMS sea salt measurements at different wind speed regimes. Grey area represents the flux variability due to the different time of filling. Black lines illustrates fluxes derived from the parameterizations by Gong (2003), Mårtensson et al. (2003) , Callaghan et al. (2008), Ceburnis et al. (2008) and Fuentes et al. (2010).
*number flux presented in the original work was recalculated to the mass flux; **includes differential whitecap - to - aerosol productivity derived by Gong (2003), ***fluxes calculated from the data presented.

A comparison with already existing source functions derived from the whitecap method is presented in Figure 1. It suggests that previous schemes based on the Monahan whitecap - wind speed approach significantly over-estimate the submicron mass flux. There could be several reasons for that: one is the whitecap area - to - wind speed parameterization and another is the parameterization of differential whitecap - to - aerosol productivity. The former parameterization has recently improved by applying a digital image processing of sea-state photographs and removing the subjectivity in determining the intensity threshold. Replacing the Monahan component of the source flux with the more recent Callaghan et al. (2008) whitecap – wind speed relationship brings the Gong (2003) source function closer to the ones presented in this study; however, the comparison also points to an over-estimation of the differential whitecap - aerosol productivity component of the source flux function.

Presenting author email: kristina@ar.fi.lt

The chemical composition of Sea Spray Aerosol (SSA) consists of both an inorganic and organic fraction which depends on biological activity, trophic level interactions and wind speed regime. Organic matter may be internally mixed with the sea salt particles or be a part of bacteria, viruses and transparent-exopolymer-gels, all of which are enriched in aggregate SSA (Ovadnevaite *et al*, 2011)

The aim of this study was to investigate the size resolved SSA composition of the Baltic Sea water with a special emphasis on the water soluble and water insoluble organic matter (WSOM and WIOM, respectively) and salinity of the water. Thus the marine aerosol generation chamber was built and the comparison of the seawater to the freshwater and the mixture of water from these two was made to better understand the influence of water salinity on the seaspray particle composition and formation processes. The water for the chamber measurements was collected from two separate coastal locations: the Baltic Sea and the Curonian Lagoon near Preila, Lithuania.

The WSOM and WIOM fraction of the aerosol generated from the Baltic seawater sample increased with the decreasing particle size measured as the aerodynamic particle diameter (Fig. 1). The WIOM significantly contributed to the three smallest impactor stages while WSOM most significantly contributed (50 – 86%) to the larger particle stages (0.32 – 3.2 μm) using fresh water sample and the relative concentrations of the OM were considerably higher using fresh water than the corresponding values using seawater. However, a closer inspection reveals that the absolute OM (WIOM + WSOM) concentrations for the two samples were actually quite similar. The higher OM fraction of the fresh water sample was due to much lower absolute salt concentration, as expected for the aerosol generated from the fresh water. Despite that fact, some low salt concentration was measured in the composition of the generated particles and confirmed that salt is an important component of the particle generation from the water. Another prominent feature of the fresh water lagoon sample is the large concentrations of the WSOM observed on all size ranges, except the first stage corresponding to the smallest particles and can be related to the large cyanobacteria blooms which are common in the Curonian Lagoon during this period of the year creating highly eutrophic conditions due to anthropogenic pollution.

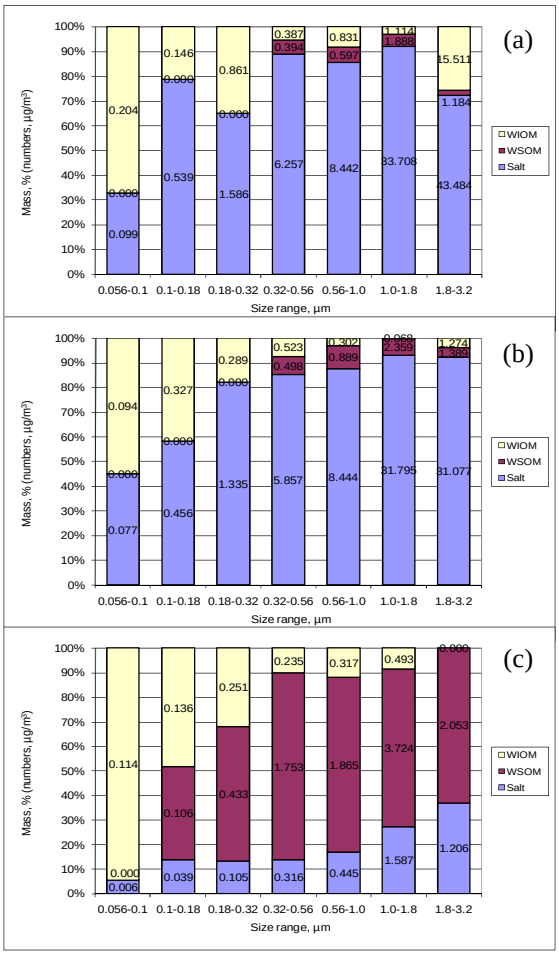

Figure 1. Size-resolved relative concentrations of the sea salt, WIOM and WSOM in the SSA generated from (a) the Baltic seawater, (b) the 50:50 mixture and (c) the fresh lagoon water.

Keywords: sea spray, primary marine aerosol, phytoplankton, HR-ToF-AMS.
Presenting author email: darius.ceburnis@nuigalway.ie

Marine aerosol enrichment by biogenic organic matter (OM) has been linked to phytoplankton activity (O'Dowd et al., 2004), thus having a strong seasonal impact on both the Earth's albedo and climate. In addition to a seasonal cycle, sea-spray generation and its enrichment with OM is a very dynamic process producing regular OM plumes over N.E. Atlantic (Ovadnevaite et al., 2011). Plankton-enriched seawater contains a complex mixture of dissolved and particulate organic carbon components (POC and DOC) producing both water soluble and insoluble organic aerosol species (Facchini et al., 2008; Russell et al., 2010); this warrants detailed laboratory studies aimed at establishing a link between observed ambient aerosol OM and its very primary form (e.g. Fuentes et al., 2010).

Laboratory studies using the microalgal species *Emiliania huxleyi, Leptocylindrus danicus* and *Cylindrotheca closterium* were performed by on-line and off-line analytical techniques using a sea spray production chamber and an ageing chamber with day-light and ozone. Under controlled conditions a sea spray highly enriched in OM was produced with levels similar to Facchini et al. (2008) (Figure 1) over a period of 48 hours.

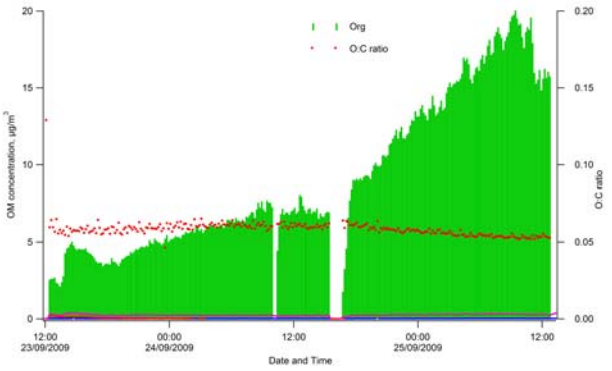

Figure 1. OM concentration and O/C ratio evolution in *Emiliania huxleyi* enriched sea water.

HR-ToF-AMS, [1]HNMR and HTDMA techniques confirmed OM composition of highly hydrocarbon-like, water insoluble OM characteristic of unsaturated lipids exhibiting low hygroscopic growth factor (Figure 2). Freshly produced OM, while largely insoluble, was far less oxidised (less sugars) than the OM reported by Facchini et al. (2008). The HTDMA measurements revealed a gradual change in physical properties as contribution of OM increased along with a certain degree of external mixture.

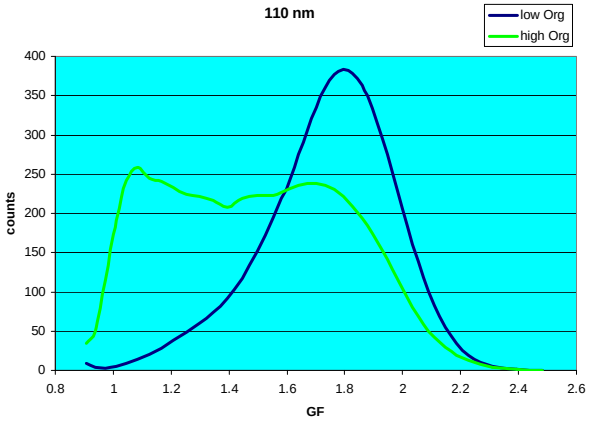

Figure 2. Change in hygroscopic growth factor of 110nm particles during *Emiliania huxleyi* experiment.

Processing primary sea spray with light and/or ozone caused a gradual change in chemical composition (preserving low GF and slowly increasing O/C ratio) supporting primary origin and atmospheric evolution of observed ambient OM while not excluding trophic level interactions.

Ca' Foscari University in collaboration with SAVE S.p.A. and Ente Zona Industriale (EZI) has been studying the "Marco Polo" airport (45°30'40''N, 12°20'38''E – Tessera, Venice - Italy) emissions since June 2009, by monitoring the main atmospheric variables and the major pollutants concentration revealed in the study area. Specifically, the chemical species monitored every hour are: SO_2, PM_{10}, O_3, NO, NO_X NO_2, CO, methane and non-methane hydrocarbons, while meteorological variables sampled are wind speed and direction, solar radiation intensity, precipitation rate, and temperature. The sampling site (a parking area near the airstrip – site 1 in figure 1) was chosen estimating the main fallout points of aircraft emissions below 1000 m and neglecting the other sources. This was done by processing the air traffic data provided by SAVE SpA, using a Lagrangian model SPRAY (Tinarelli et al., 1994) that is part of the SCAIMAR modeling system, managed by EZI. Moreover, from November 2011 to June 2011, 200 samples of PM_1 were collected every 48 hours on a quartz filter by two Tecora Skypost PM HV at low volume (2.3 m^3 h^{-1}), at two sites located at the start and the end of Venice airport airstrip as shown in figure 1 (site 2, 3). The major components were analyzed by ICP-OES (Inductively Coupled Plasma - Optical Emission Spectroscopy). These sites were chosen to estimate the airport emission contribution by studying the different concentration of PM_1 and elemental concentration in the PM_1 as a function of the wind direction.

Results show that i) the concentration of PM_1, PM_{10} and the ratio PM_1/PM_{10} increase with the environmental temperature decrease (as shown in figure 2), likely due to the emission increase from several different sources, as well as by the changes in climate conditions that favor their concentration; ii) there is no significant difference in PM_1 concentration between two sites, suggesting a low contribution of the airport; iii) some samples exhibit different elemental concentration in PM_1 suggesting that the two sites are contaminated by several sources, contributing differently; iv) statistical analysis of atmospheric concentration revealed in three sites a significant contribution of the vehicular traffic source.

Presenting author email: gtitos@ugr.es

In this work we study the influence of road traffic emissions on urban air quality and the relationship between particle matter, PM_{10}, gaseous pollutants and aerosol number concentration at an urban environment in southern Europe (Granada, 37.18ºN, 3.58ºW and 680 m a.s.l.). Levels of PM_{10} and gaseous pollutants were supplied by the Andalusian Government (Department of Environment, www.juntadeandalucia.es/medioambiente) from a nearby station (0.5 km). Furthermore, black carbon (BC) mass concentration was measured with a Multi-Angle Absorption Photometer (MAAP) using a mass absorption efficiency of 6.6 m^2g^{-1} and fine particle number concentration (N) in the size range 20-450 nm was measured with a UFP-3031 from TSI. Both instruments are run side by side at the CEAMA station (Lyamani et al., 2010). The UFP-3031 is able to run continuously with little maintenance and does not require radioactive source. This fact in conjunction with the growing interest in studying ultrafine particles due to their harmful effect on human health (Araujo and Nel, 2009) make this instrument suitable for air quality monitoring networks.

The diurnal variability of all parameters analyzed was strongly influenced by road traffic activity. CO, NO_2, BC and N increased during traffic rush hours (6-8 GMT), decreased during the day due to dispersion owing to a higher PBL height and the reduction of traffic emissions, and increased again during the afternoon rush hours showing a second peak around 17-19 GMT (Figure 1). The increase in N and BC levels during rush hours was more pronounced than for the other pollutants denoting direct exhaust of traffic emissions. PM_{10} presented a peak a little bit later in the morning (around 9-10 GMT) mainly due to formation of secondary aerosols. During the weekends, lower peaks were observed as a consequence of traffic reduction.

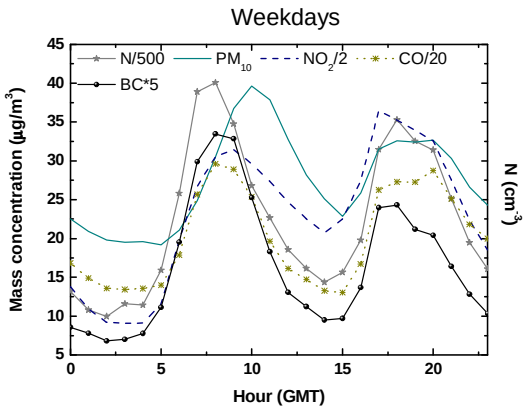

Figure 1. Diurnal evolution of N, PM_{10}, NO_2, CO and BC.

The diurnal pattern of the number of particles obtained in Granada is characteristic of urban environments. In this sense, a completely different pattern was observed at the rural background station El Arenosillo where the UFP-3031 was operating during two weeks. The total number concentration at El Arenosillo was considerably lower than in Granada being the diurnal pattern characterized by a single peak around midday. A different behaviour depending on the size range considered was also observed.

There is a recent interest in studying the representativeness of different metrics (Pey et al., 2008) in order to establish appropriate strategies in monitoring networks. In this sense, the relationships between number concentration and PM_{10} and BC mass concentration have been analyzed. A significant correlation between daily averages of PM_{10} and N (R^2 = 0.51) and between BC and N (R^2 = 0.72) have been obtained. The correlation between mass concentration and N in the size ranges 20-30, 30-50, 50-70, 70-100 and 100-200 nm is shown in Figure 2. As can be observed, the correlation coefficients change significantly depending on the size range considered, being higher for larger particle size.

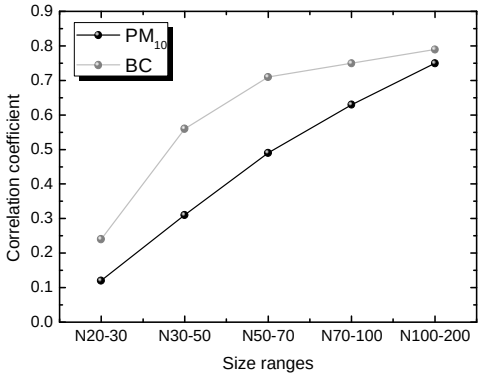

Figure 2. Correlation coefficient between daily mean PM_{10} and BC versus number concentration in different size ranges.

Short term control efficiencies of dust suppressants to reduce fugitive dust

Sehyun Han, Yoonho Seo and Yongwon Jung

Department of Environmental Engineering, Inha University, 253 Yonghyun-Dong, 402-751, Incheon, Korea
Keywords: PM_{10}, fugitive dust, suppressants, wind erosion, control efficiency.
Presenting author email: jungyw@inha.ac.kr

Fugitive dust is a typical air pollution source generated by wind erosion of exposed area or construction activities. There are many control measures to prevent the fugitive dust emitted from exposed area, such as windscreens, shelters, confinement, and wet suppression. Wet suppression can be considered the most effective method among them. Water and chemicals are the two major suppressants used in the wet suppression. Watering without chemical binders is usually used as a temporary measure. The application of chemical binders is the most commonly used and cost-effective method for controlling dust emissions by binding particles together to enhance the resistance to wind erosion and physical disruption. Certain benefits and advantages can be obtained by the addition of chemical binders to the water used for dust suppression. The available chemical binders include bituminous-asphaltic compounds, polymers, resins, surfactants, calcium lignosulfonate, and others.

Estimation studies on the long-term control efficiencies of dust suppressants have been conducted by some researchers (Gillies *et al*, 1999). However, the studies on control efficiencies of chemical binder in the initial short-term stage have not received much attention, although some data has been published (Chang *et al*, 2003).

This study focuses on investigating the short-term control efficiencies of dust suppressants. To estimate them with minimum efforts and time, we made a lab-scale wind tunnel, which made it possible to carry out experiments in a laboratory with a test soil bed of small size. Control efficiencies of dust suppressants were estimated using the data of dust concentrations simultaneously measured from both upstream and downstream of the test soil beds treated with chemical binders. Dust concentrations were measured using Dusttrak (TSI, Model 8520). To investigate how control efficiencies of dust suppressant vary depending on wind speed, chemical spraying intensity, chemical mass concentration in water, and the duration of test, test runs were carried out for the four suppressants including water. Test soil beds were dried at least for five days to have equilibrium moisture of the test day.

As shown in Figure 1, preliminary results show that polymer and cellulose type dust suppressants have higher control efficiencies than $CaCl_2$ type dust suppressant at the test conditions used in this study. It also shows that during 10 minute test runs control efficiency of $CaCl_2$ type dust suppressant gradually decreases with time, whereas those of polymer and cellulose type dust suppressants remain relatively constant. As shown in Figure 1, water has the lowest dust control efficiencies among the dust suppressants. It is also clear that dust control efficiency of water decreases with time more rapidly than those of the other chemical binders do.

All the results showing the effect of wind speed, chemical spraying intensity, and chemical mass concentration in water on dust suppression efficiencies will be presented and discussed.

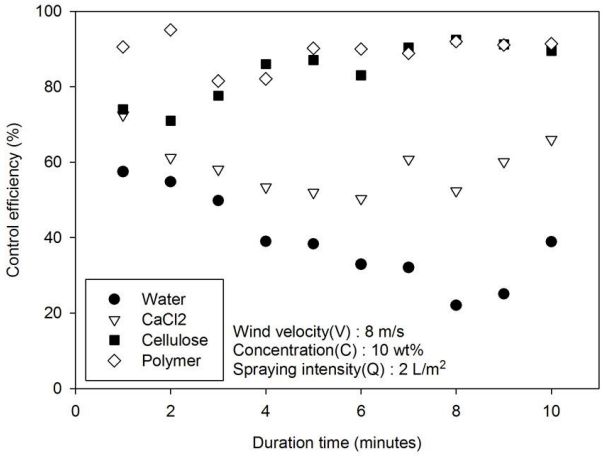

Figure 1. Dust control efficiency vs. duration time.

Source apportionment of PM-bound PAHs, *n*-alkanes and inorganic ions in an urban environment in southeastern Spain

J. Gil-Moltó, N. Galindo, M. Varea and C. Chofre

Department of Physics, Miguel Hernández University, Avda. de la Universidad s/n, 03202, Elche, Spain
Keywords: PM, PAH, alkanes, water-soluble ions, PMF.
Presenting author email: j.gil@umh.es

Aerosol concentrations and chemical composition have been extensively studied during the last years due to their known adverse health effects on humans. The magnitude of these effects can significantly vary depending on the study location, primarily due to differences in air pollution sources and meteorological conditions. Therefore, source apportionment is a crucial exercise in determining environmental pollution control strategies. Among the different available techniques, PMF is a powerful and valuable multivariate statistical tool for source identification.

PM1, PM2.5 and PM10 low volume samples (2.3 m^3/h) were collected from October 2008 until July 2009 in the city of Elche (southeastern Spain). The samples were analysed to determine the concentrations of 17 polycyclic aromatic hydrocarbons (PAHs), *n*-alkanes from C_{16} to C_{40} and major water-soluble ions (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, NO_3^- and SO_4^{2-}). The sampling site, classified as urban background, was located on the roof of a building at the Miguel Hernández University, adjacent to a major city avenue, in a highly ventilated area.

PMF analyses were performed on each PM fraction concentration data. The spring-summer and autumn-winter periods were considered separately because of the different organic and inorganic compound behaviour with temperature and solar radiation.

Mean concentrations of particulate matter, total PAH (TPAH), *n*-alkanes (T*n*-A) and ions (TIons) for the spring-summer (S-S) and autumn-winter (A-W) seasons are shown in Table 1.

Table 1. Mean concentrations during the study period.

Fraction	PM (μg/m³)		TPAH (ng/m³)		T*n*-A (ng/m³)		TIons (μg/m³)	
	S-S	A-W	S-S	A-W	S-S	A-W	S-S	A-W
PM1	10.8	8.66	0.42	1.03	9.71	13.02	6.02	4.07
PM2.5	12.8	14.76	0.56	1.22	11.96	18.31	6.37	6.5
PM10	41.36	23.79	0.61	1.28	19.02	18.89	17.72	8.42

In the western Mediterranean basin, PM10 levels are strongly affected by Saharan dust intrusions (Galindo *et al* 2008), as shown by the higher concentrations obtained in spring-summer with respect to those measured in the autumn-winter period. TPAH were predominantly associated with fine particles, as reported in previous studies (Cecinato *et al*, 1999), meanwhile *n*-alkanes size distributions were seasonally dependent.

PMF studies were carried out in a trial to discriminate different potential sources. As an example, figure 1 presents the results of the PMF analysis for PM1-bound PAHs and *n*-alkanes in the spring-summer period.

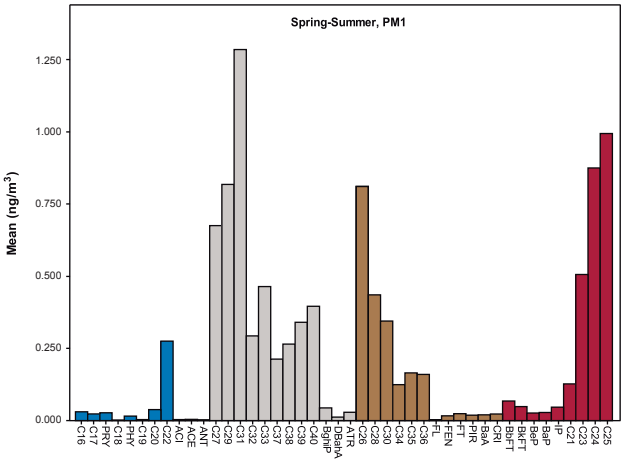

Figure 1. PMF factors for PM1 in the spring-summer period.

Four factors explained 95% of the total variance. The outcomes suggest that different sources account for odd-carbon (C27-39) and even-carbon (C26-C36) *n*-alkane emissions. These factors can be related to biogenic and anthropogenic sources, respectively (Abas and Simoneit, 1996).

Bivariate correlations among ions, PAH and *n*-alkanes were also carried out. Statistically significant relationships between TPAH and Ca^{2+} in PM1, PM2.5 and PM10 were found for the autumn-winter period. This can be explained considering that traffic exhaust is the primary PAH source, while Ca^{2+} is mainly emitted by traffic-induced resuspension during autumn and winter.

Pollutants associated to atmospheric particles in urban areas have been characterized in many studies throughout the world. Pollutant sources are either natural (e.g. volcanoes, forest fires) or of anthropogenic origin (traffic, industries, domestic heating). The nature of surfaces as well as weather conditions and atmospheric turbulence influence the aerosol deposition. Previous studies in Nantes (France) on the Pin Sec catchment allowed the chemical characterization of total atmospheric deposition. In order to improve our knowledge of aerosol dry deposition on this catchment an original approach has been developed.
Our objective here is to present the instruments set up in the district of the Pin Sec to measure dry and wet atmospheric deposits and to show the results of a one- year survey.

The original approach carried out in this long-term study (September 2010 to October 2011) combines particle collectors (Partisol 2000 FRM), a covered pluviometer and frames on which test samples of different urban materials are fixed (tiles, glass, bitumen etc…). A meteorological station and an ultrasonic anemometer supply meteorological and micrometeorological data. Measuring instruments have been installed on the roof of a 4-store building in the Pin Sec catchment; the data should be representative of the global quality of atmospheric deposition on this catchment. Pollutants analysed are heavy metals, pesticides and Polycyclic Aromatic Hydrocarbons.
The analysis of deposited airborne particles on test samples was performed through beryllium 7 (^{7}Be) used as a tracer. Aerosol concentration is given by the Partisol. This methodology will allow calculating a monthly dry deposition velocity of particles and determining deposition fluxes. The percentage of the different surfaces (glass, bitumen, tiles, etc.) on the Pin Sec catchment was estimated in order to calculate an annual dry deposition flux.
Regarding monthly wet deposition, the flux is calculated as the ratio of the mass of pollutants collected in the covered pluviometer to the active surface of the catchment.

Finally, in order to validate the use of ^{7}Be as tracer of atmospheric deposition, a Low Pressure Impactor (LPI) was used allowing the measurement of aerosol size.

The medium diameter (D50) of ^{7}Be atmospheric on particles varies from 0.50 to 0.59 µm. These values are in good agreement with the literature (Ioannidou, 2011). It confirms the fixation of ^{7}Be on accumulation mode of atmospheric aerosol. A good correlation between the distribution of Pb mass and ^{7}Be activity tends to appear. The same pattern is observed for Zn. As a whole, metals are mainly distributed in the fine fraction (0.47<D50<0.62 µm). The same is observed for the detected PAH (Benzo[a]pyrene; Benzo[b]fluoranthene; Benzo[ghi]perylene; Benzo[k]fluoranthene; Fluorene), (0.41<D50<0.67 µm). This affinity of pollutants for the accumulation mode was observed in other studies for PAH (Sanderson *et al.* 2005) and for heavy metals (Song, 2011). Therefore, ^{7}Be seems to be representative of the distribution of particulate trace metals and PAH. Thanks to those results, concentration of pollutants measured on air particle will be combined with the data of the one-year survey of ^{7}Be deposit (Roupsard *et al* 2012) in order to get the dry deposition flux.
Concerning wet deposition, concentration of heavy metals, PAH and pesticides were measured during the whole sampling period allowing to calculate the annual wet deposition flux.

In the future, this original approach of the dry deposition taking into account urban parameters such as the type of surface, the atmospheric turbulence and the meteorological conditions will be compared with a classical method using boxes to collect total atmospheric deposition.

Evidence of regional-scale biomass burning contributions to urban aerosols in the Western Mediterranean

Presenting author email: mar.viana@idaea.csic.es

Recent studies evidence that carbonaceous aerosols emitted during biomass burning processes (natural or anthropogenic) may contain high amounts of carcinogenic compounds (Lewtan, 2007) as well as black carbon particles with a potentially high impact on health and air quality in urban environments (Andreae & Gelencsér, 2006). The main source of biomass burning aerosols in European urban environments is regional-scale transport (from rural areas towards cities), and in central and Northern European regions the use of this fuel for residential purposes (mainly heating) may also be a relevant source. However, major knowledge gaps remain regarding the quantification of the contributions from this source in major European cities. Paris is one of the first to have quantified the impact of biomass burning on urban air quality (up to 20% of $PM_{2.5}$ at an urban background site in winter, Favez et al., 2009). Biomass burning emissions are significant contributors to air quality degradation, and they are especially relevant due to their SOA-generating potential. Recent works point out to a high contribution of SOA to the ultrafine particle size range, thus stressing the higher hazardous potential of SOA (which penetrates thus deeper into the respiratory tract).

In Southern Europe, biomass burning is a much less frequent practice than in central and Northern Europe due to the characteristic Mediterranean climatology. It takes place mainly in rural areas, and its purpose is residential heating and/or agricultural (e.g., burning of agricultural residues). However, as a consequence of meso-scale air mass circulation biomass burning aerosols originated in rural areas may be detected in urban areas. The proportion of SOA in these cases is generally enhanced through transport. Within Mediterranean urban areas, biomass is only rarely used as a fuel for residential heating purposes, and mostly in high-income residential area (recreational use).

The aim of this work is to detect the presence and assess the potential contribution of biomass burning aerosols to $PM_{2.5}$ mass and composition in Barcelona. Two main sources were targeted: regional-scale emissions (reaching Barcelona through meso-scale transport), and local-scale emissions (for heating and recreational purposes).

To this end, a 2-week dedicated monitoring campaign was devised at two locations in Barcelona: the university campus, and a high-income residential area where residential/recreational biomass burning emissions were expected. The campaign was carried out in January 2011. Two sets of identical instruments were set up: one high-volume $PM_{2.5}$ sampler (MCV, S.A), one Streaker (analysing only the fine PM fraction), one laser spectrometer (GRIMM), and one absorption photometer (MAAP at the university site, and microAeth AE51 at the residential area). A detailed chemical characterisation (up to 65 elements and components) of the 24-hour $PM_{2.5}$ filter samples was carried out. The hourly and daily time variation of black carbon (BC) and PM chemical components were analysed, with special attention to hourly BC and K levels. An estimation of K^+ was obtained with a daily time resolution.

Source apportionment analysis allowed us to detect regional-scale biomass burning contributions to urban aerosols in Barcelona. Regional-scale biomass burning aerosols were mixed with secondary aerosols as a consequence of transport in the meso-scale, and showed a characteristic hourly trend with night-time maxima, coinciding with the land-to-sea breeze (Figure 1). We conclude that residential biomass burning emissions were not detectable in neither of the monitoring stations, possibly due to the fact that their contribution is too short in time (only a few hours/day).

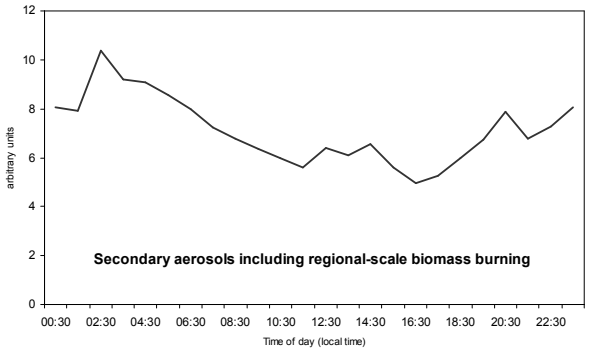

Figure 1. Mean hourly evolution of the secondary aerosol source (including regional-scale biomass burning tracers).

The effect of size, location, occupancy and microclimatic factors on air quality of university lecture rooms

M. Braniš[1] and K. Stupková[1]

[1] Charles University in Prague, Faculty of Science, Institute for Environmental Studies, Albertov 6, 128 43 Prague 2, Czech Republic

Keywords: indoor air quality, school, particulate matter, microclimate

Presenting author email: brains@natur.cuni.cz

As has been repeatedly documented in scientific literature, one of the most polluted indoor microenvironment can be found at schools. School buildings and classrooms suffer from poor air quality from two reasons: (1) Schools in cities are frequently situated in quarters or near streets with dense traffic and the infiltration of freeway particles into the school buildings represents an important source of pollutants (Janssen et al. 2001; Green et al. 2004) and (2) High levels of particulate matter in schools are frequently attributed to human activity and insufficient frequency of cleaning which is not capable in removing deposited particles (Branis et al., 2005; Fromme et al., 2007). Since these particles are only partly removed, they can be resuspended again and again. To ascertain the effect of infiltration and resuspension under various conditions (such as position of the classroom with respect to outdoor sources, its size and occupancy) we performed a year long project in three university lecture rooms situated in the centre of Prague.

Twenty-four hour mass concentrations of size-segregated aerosol were measured simultaneously in three university lecture rooms and outdoors in the central part of Prague (Czech Republic) by a five-stage A - F (<0.25µm, 0.25-0.5µm, 0.5-1.0µm, 1.0-2.5µm and 2.5-10µm) Personal Cascade Impactor Sampler (PCIS). Identical sets of instruments were deployed at the outdoor and indoor sites. Other variables such as CO_2, ventilation, temperature, relative humidity, occupancy were monitored as well. The measurements were performed during all seasons of the year during 11 three to four-day long campaigns involving working days as well as weekends and holidays.

The results documented that finer indoor size fractions (below 500nm) were significantly affected by outdoor concentrations while coarse particulate matter levels ($PM_{2.5-10}$) were predominantly dependent on the number of students in the lecture rooms. Nevertheless, some effect of human presence on the PM below 500nm was recorded as well, indicating a possible effect of the so called personal cloud (Table 1; Figure 1). The level of particulate matter concentrations corresponded to the proximity to the adjacent street (the closer the lecture room the higher the average PM concentration) and to the size of the size of the lecture room (the smallest was the space the highest PM concentrations were recorded).

In addition, concentrations of carbon dioxide frequently reached values over 1500ppm and higher. One of the common problems in all the three lecture rooms was very low relative humidity (around 30-35%). The results of the study not only confirmed previous results but also showed that measurements in one classroom per school may be insufficient because differences in position, size and occupancy may affect the concentrations of aerosol from which the estimates of exposure are made for the whole population of students in a particular school.

Impact of port activities on urban air quality at a Mediterranean coastal city

N. Pérez[1], J. Pey[1], C. Reche[1], X. Querol[1], A. Alastuey[1] and J. Cortés[2]

[1] Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, Spain
[2] Autoritat Portuaria de Barcelona, Spain
Keywords: PM_{10} and $PM_{2.5}$ chemical speciation, port emissions
Presenting author email: noemi.perez@idaea.csic.es

Important ports in the Mediterranean represent a significant impact on air quality. The APICE Project (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions; www.apice-project.eu) pretends to reduce harbour emissions to the atmosphere by adopting mitigation strategies, that will be taken at local (specific abatement measures for each harbour) and transnational (common strategies to be applied in the five harbours involved in the project) scales. In the framework of this project long monitoring campaigns were carried out during one year (2011) at five Mediterranean ports: Barcelona (Spain), Genoa (Italy), Marseille (France), Thessaloniki (Greece) and Venice (Italy). With the objective to assess the impact of harbour activities on urban air quality, simultaneous measurements were also carried out at the urban areas.

In the urban area of Barcelona the main source of atmospheric pollution is road traffic (Amato et al., 2009), although emissions from industry, power generation, construction, and harbour activities are also relevant. Owing to the location of the harbour and the wind regime (with high frequency of sea breezes), harbour pollution affects the urban area.

We present here an intercomparison study of atmospheric particulate matter levels and composition measured simultaneously at the Barcelona port and at an urban background monitoring site (Palau Reial) from February to June 2011.

Daily 24-hour ambient PM_{10} and $PM_{2.5}$ samples were collected on quartz fibre filters using high volume samplers for gravimetric determination and, for a selection of these filters, the chemical analysis of carbonaceous components (OC and EC), soluble ions (Cl^-, NO_3^-, SO_4^{2-} and NH_4^+), and major and trace elements was performed, following the procedure described in Pey et al. (2010).

Available results (February-June 2011) show that daily average PM_{10} levels during this period were higher at the port (34 µg/m^3) than at the urban site (30 µg/m^3). For $PM_{2.5}$, similar levels were obtained, with average levels of 21 and 22 µg/m^3 at the port and the urban site, respectively. The daily PM_{10} limit value (50 µg/m^3) was exceeded during 3 days at the port and 2 days at the urban site.

Regarding the chemical composition of PM_{10} and $PM_{2.5}$ (Figure 1) the main difference was found for mineral matter, being more than 50% higher at the port in both fractions (12 vs. 6 µg/m^3 in PM_{10}), probably reflecting emissions from the new port extension works, but also handling of materials. Elemental carbon (EC) was more than 50% higher at the port in $PM_{2.5}$ (2 vs. 1 µg/m^3), probably due to the heavy truck transport. Sulphate was more than 20% higher at the port in PM_{10} (4 vs. 3 µg/m^3) reflecting ship exhaust and local industrial emissions (oil refinery).

Trace element levels were in general higher at the port for both PM_{10} and $PM_{2.5}$. Differences higher than 50% were found for road traffic tracers (Cu, Zn, Sb, Sn) and higher than 40% for fuel oil combustion tracers (V, Ni), reflecting emissions from the oil refinery and ship exhausts. Tracers of industrial emissions, such as As, Cd, Pb and Mn, presented also differences higher than 40% at the port with respect to the urban area.

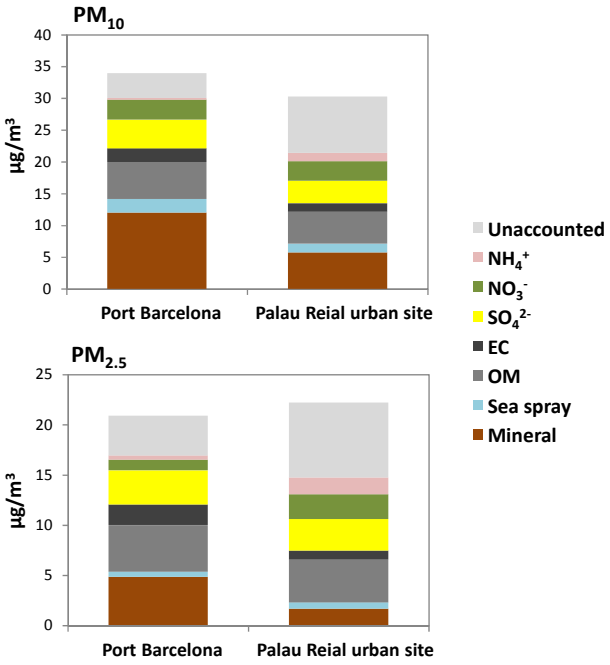

Figure 1. Comparison between main PM_{10} and $PM_{2.5}$ components measured at the port of Barcelona and Palau Reial urban site.

Keywords: DMPS, urban aerosol, number concentration, diurnal variation, atmospheric nucleation.
Presenting author email: salma@chem.elte.hu

Particle number size distributions were determined in the near-city background, city centre, street canyon and road traffic tunnel environments in Budapest. Measurements were performed by a flow-switching type differential mobility particle sizer (DMPS) in an electrical mobility diameter range of 6–1000 nm in 30 channels, with a time resolution of ca. 10 min.

Daily average particle number concentrations are shown in Table 1. Median daily concentrations varied by a factor of 33 from the background to the tunnel. The median and maximum number concentrations increased monotonically and substantially with the intensity of road traffic, which implies that the major source of particles is vehicular emission. The maximum measured concentration of 465×10^3 cm^{-3} was obtained in the tunnel. Mean contribution of ultrafine particles to the total particulate number and its standard deviation for the listed environments were (76±9)%, (79±6)%, (86±3)% and (85±2)%, respectively, which indicates that the combination of the primary emissions and atmospheric nucleation maintains more or less constant ultrafine contribution.

Mean diurnal variation of particles averaged by the time of day for the different environments exhibited similar structure. They contained three concentration peaks. The first peak occurred between 7:00 and 10:00 local time, and it was explained by vehicular emissions during morning rush hours. The third peak showed up in the evening between 19:00–22:00, and it was also related to traffic emissions but it was shifted from afternoon rush hours (that occurs between 16:30 and 18:00 in Budapest), mostly as a result of the daily cycling in meteorological parameters. The second peak appeared around midday for residential environments, and it was related to new particle formation and consecutive growth. The importance of atmospheric nucleation was clearly revealed by the diurnal variation of the mean ratio of ultrafine particles to the total particulate number, which exhibited a huge midday peak for the nucleation days, and no peak for the days without nucleation.

Table 1. Minimum (N_{min}), median (N_{med}) and maximum (N_{max}) daily number concentrations of aerosol particles in various environments in Budapest. The unit is 10^3 cm^{-3}.

Environment	N_{min}	N_{med}	N_{max}
Near-city background	1.25	4.3	10.1
City centre	2.7	11.8	20
Street canyon	4.9	23	41
Road tunnel	3.7	143	392

New particle formation occurred on 27% of all days in the city centre on a yearly scale. Its frequency showed an apparent seasonal variation. There were significant differences between the environments as far as nucleation frequency is concerned. It was the largest for the near-city background, and it was the smallest for the street canyon. No nucleation event was observed at all in the tunnel. Particle growth was usually finished within 1 day. Growth processes that were developing for two days were identified in the background. One of them is shown in Fig. 1. Special types of banana curves were also identified.

This work was supported by the Hungarian Scientific Research Fund under grant K84091.

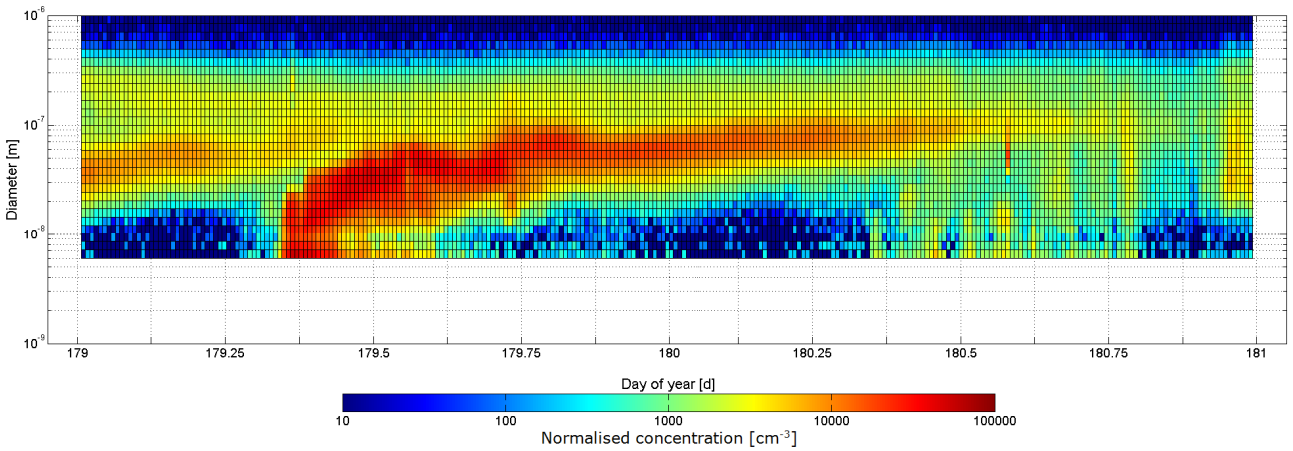

Figure 1. New particle formation event and consecutive growth developing for two days in the near-city background of Budapest on 28–29 June 2011 (Tuesday–Wednesday).

Black carbon mixing state in Paris megacity

M. Laborde[1], M. Gysel[1], T. Tritscher[1], M. Crippa[1], Zs. Jurányi[1], P.F. DeCarlo[2], A. Prévot[1], U. Baltensperger[1]

Black carbon (BC) is the result of incomplete combustion and is nowadays mainly of anthropogenic origin. BC is the main light absorbing material in atmospheric particulate matter and is therefore of interest for climate studies. It is usually non-hygroscopic upon emission and becomes hygroscopic with time via the condensation of secondary aerosol thereby forming a water-soluble coating (Stier et al., 2006).

Such aging of BC dramatically changes its role in climate forcing. Hydrophilic coating will enhance its cloud condensation nuclei activity, lower its lifetime and increase its light scattering and absorption efficiency.

Presently, only a few studies have performed ground based measurements of BC's mixing state and hygroscopicity in urban areas (Healy et al., 2011; McMeeking et al., 2011). This study aims at filling up this gap by investigating aerosol hygroscopicity and mixing state in Paris with a particular focus on BC particles.

A Single Particle Soot Photometer (SP2, Droplet Measurement Technology) was used along with a Hygroscopicity Tandem Diameter Mobility Analyzer (HTDMA) and an Aerosol Mass Spectrometer (HR-ToF-AMS). The SP2 allows the determination of the number concentration of BC containing particles (>0.4 fg BC/particle), their BC core size and their coating thickness along with the number concentration of purely scattering particles (<0.4 fg BC/particle). The HTDMA was used to determine the growth factor probability distribution function (GF-PDF) defined as the ratio of wet (90 % RH) over dry particle mobility diameters.

The positive matrix factorisation (PMF) method was applied to the organic trace of the AMS in order to identify their sources (Fig. 1a). We will here focus on three time periods when either traffic, biomass burning or background aerosol were the most prominent organic aerosol components, distinguished by a respective dominant contribution of hydrocarbon-like organic aerosol (HOA), biomass burning organic aerosol (BBOA) and oxidized organic Aerosol (OOA) in the PMF (Fig. 1a).

The air mass influenced by background aerosol contains the highest number fraction of thickly coated BC particles (Fig. 1b) which is consistent with the lowest non-hygroscopic mode at GF=1 (Fig. 1c). A mode of more hygroscopic particles (GF>1.5) dominates, indicating the presence of purely scattering particles or coated BC particles (Fig. 1b). The air mass influenced by traffic shows the lowest number fraction of coated BC, consistent with the distinct non-hygroscopic mode at GF=1. The background aerosol can also be seen in the presence of a more hygroscopic mode and a high fraction of purely scattering particles (Fig. 1b). The air mass influenced by biomass burning shows a higher number fraction of coated BC particles than the traffic influenced one, and the less hygroscopic mode is shifted from GF=1 to GF~1.1, indicating that the soot particles from biomass burning contain substantial organic coating. On the other hand, the very hygroscopic mode of the background aerosol at GF~1.6 is not as strongly seen as for the other two cases.

Further experimental results corroborating the above observations as well as results on the importance of BC mixing state on its CCN activation behaviour will be provided.

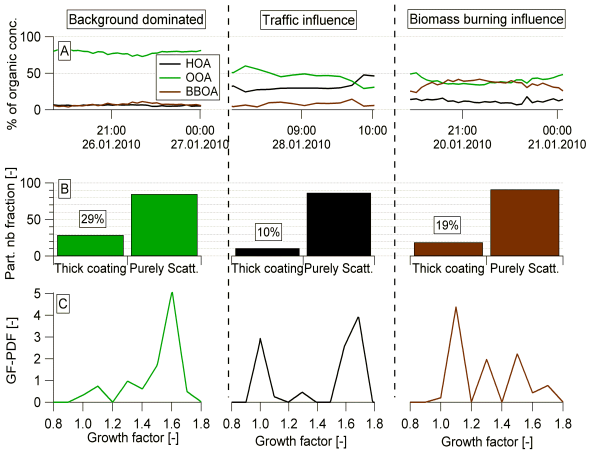

Figure 1. a) AMS: Organic aerosol factors retrieved by PMF b) SP2: Number fraction of BC containing particles with a thick coating and number fraction of purely scattering (both at optical diameter between 250 – 280 nm) c) HTDMA: Growth factor distribution (GF-PDF) of 265 nm particles.

Keywords: saccharides, organic compounds, PM2.5, urban aerosols.
Presenting author email: krumal@iach.cz

Saccharides are the most abundant group of the natural molecules, produced in large quantities by photosynthesis by plants and microorganisms. They form also a major part of cellular structure of plants and animals (Lindhorst, 2007). Saccharides are sources of energy for living organisms and basic structural unit of plant tissues – cellulose (glucose) and hemicellulose (xylose, arabinose, mannose and galactose) (Ek, 2009). Cellulose is the most abundant biopolymer, representing 40 – 50 % of dry weight of wood while hemicellulose represents 20 – 30 % of dry weight of wood. Another type of plant biopolymer is lignin which represent 20 – 30 % of dry weight of wood (Simoneit, 1999). Saccharides could be emitted to the atmosphere during burning of biomass, resuspension of soil particles, wind abrasion of leaf surfaces and sea spray (Wan, 2007) and they are present in biological aerosol particles (spores, pollens, fungi, algae, protozoa, bacteria, viruses and fragments of plants and animals) (Jia, 2010). Microorganisms, plants and animals can release into the atmosphere primary saccharides (monosaccharides and disaccharides) while fungi, lichens and bacteria produce saccharidic polyols (sugar alcohols; arabitol, mannitol and sorbitol) (Caseiro, 2007).

The concentrations of saccharides (monosaccharides, disaccharides and sugar alcohols) in the atmospheric aerosols were measured in Brno in the Czech Republic in spring, summer, autumn and winter of 2010 and in winter of 2011. The concentrations were measured in PM2.5 aerosol samples, over one week in each season. Measured monosaccharides included D(-)fructose, D(+)glucose, D(+)mannose, D(+)galactose and D(+)xylose. Disaccharides included D(+)maltose, D(+)sucrose and D(+)trehalose. Sugar alcohols included arabitol, sorbitol, manitol and myo-inositol.

The mean mass concentration of PM2.5 aerosols was in the range from 13.9 μg m^{-3} in summer to 39.3 μg m^{-3} in winter. The highest concentrations of monosaccharides and disaccharides were measured in spring of 2010. The most abundant saccharide in this season was sucrose. Disaccharides represent 65 %, monosaccharides 12 % and sugar alcohols 23 % of the total sum of measured saccharides in spring 2010. Contributions of sugar alcohols increase in the other seasons (53 – 59 %). Sucrose as a dominant disaccharide was determined in the range from 7.7 ng m^{-3} (winter 2010) to 85.4 ng m^{-3} (spring 2010). The most abundant monosaccharide was glucose in the range from 5.3 ng m^{-3} (winter 2010) to 11.4 ng m^{-3} (summer 2010). From the group of sugar alcohols, dominant myo-inositol was determined in the range from 23.1 ng m^{-3} (spring 2010) to 55.9 ng m^{-3} (autumn 2010).

Figure 1 shows the mean concentrations of the sum of saccharide compounds in individual seasons. Results including detailed concentrations of individual saccharides and optimalization of extraction from QMA filters with different solvents will be presented.

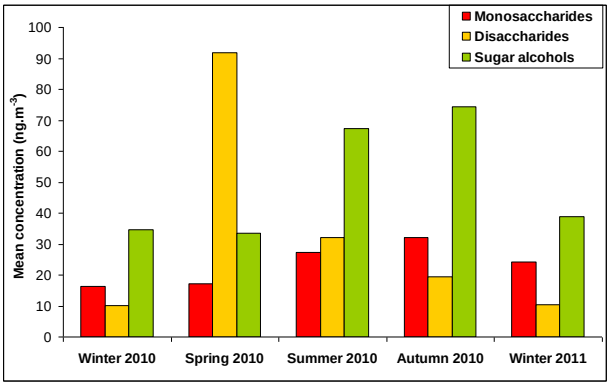

Figure 1. The mean concentrations of the sum of the saccharide compounds in individual seasons.

Source apportionment of the organic aerosol fraction by comparing positive matrix factorization, EC-tracer-method and ^{14}C-analysis

Wagener, Sandra[1,2], Langner, Marcel[1], Perron, Nolwenn[3], Hansen, Ute[1], Moriske, Heinz-J[2], and Endlicher, Wilfried[1]

Source apportionment of organic aerosol can be performed using several techniques. The positive matrix factorization (PMF) is a multivariate receptor model to determine potential sources of any origin. ^{14}C measurements allow distinguishing between non-fossil (biogenic or biomass burning (BB)) and fossil carbon. The EC tracer method distinguishes between primary and secondary organic aerosol (POA and SOA), assuming that fossil POA and EC have the same sources (Turpin and Huntzicker, 1995).

From Feb 2010 to Oct 2010, PM_{10} and PM_1 24 hr samples were taken at a traffic site, a park and a background site in Berlin. Tracers for SOA and POA and biomass burning were determined by GC-MS, whereas organic and elemental carbon (OC and EC) were measured by an OC/EC-Sunset analyzer. Additional samples for ^{14}C- and corresponding OC and EC analysis were taken in Jan, Jun, Jul and Oct 2010 at the traffic site and the park. Analysis was performed with a Single Stage Accelerator Mass Spectrometer.

PMF produced two biogenic SOA and four POA factors, with major contribution of biomass burning (Wagener *et al.* 2012). The SOA fractions at all stations varied between 9-47% in PM_{10} and 11-72% in PM_1, with higher values in the warmer months. For the EC-tracer-method, the sampling period was divided into periods with high and low biomass burning contributions (conform to warmer and colder months), as levoglucosan clearly influenced the OC/EC-ratio (correlation > 5). The EC tracer method yields SOA estimations comparable to PMF for the traffic site, but lower ones for the park, in the non-BB-period also for the urban background (table 1). This deviation is all the

Table 1: PM_{10} SOA contribution to OC, in %, from PMF and EC-tracer, calculated by scenario.1: excluding samples with SOA events; scenario.2: using the lowest OC/EC ratio.

	BB-period		Non-BB-period		
	sc.1	PMF	sc.1	sc.2	PMF
Park	11	18	17	22	41
Traffic	14	9	17	26	18
Urb. backgr.	15	15	30	32	47

bigger that EC-tracer-derived SOA also includes the fossil fraction. This is assumedly due to little traffic at these sites and the (relatively) large contributions of biogenic primary OC compared to fossil OC, which are falsely counted to the $[OC/EC]_p$ ratios.

The biogenic contribution to OC determined from ^{14}C-analysis on total carbon (TC) was 27-100% at the traffic site and the park, with higher values occurring in the warmer season, but even between PM-fractions. Calculated values of biogenic SOA (OC_{bioSOA}) reached up to 93%. These high values have not been expected and exceed clearly the values calculated by PMF, leading to the question whether the ^{14}C method overestimates the biogenic contribution to OC. Besides the measured biogenic contribution to TC, OC_{bioSOA} is also dependent on the levels of biomass-burning OC (OC_{bb}), which are determined by measurements of levoglucosan and lev/OC_{bb} ratios at the respective areas. Lower lev/OC_{bb} ratios lead to lower OC_{bioSOA}. This ratio, often not available, needs to be taken from literature and varies strongly with wood types. Thus, calculations have been performed with varying lev/OC_{bb} ratios (fig. 1), the lowest one stemming from PMF results. The latter leads to closer, but still lower OC_{bb} than calculated with PMF, resulting in higher OC_{bioSOA}. This raises the question whether PMF

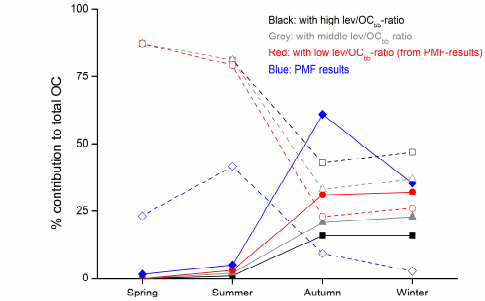

Figure 1: %contribution of OC_{bb} (continuous) and OC_{bioSOA} (dotted) to OC from PMF results (traffic site, PM_{10}) and ^{14}C-analysis with varying lev/OC_{bb}-ratios;

overestimates OC_{bb} or if lev/OC_{bb} ratios in this area are much lower than in other areas. Summarized, biogenic SOA in urban areas makes up a substantial fraction of OC, over all in warm months, whereas wood burning contributes strongly in the colder seasons. Variations with different apportion techniques indicate that the EC tracer method seems to fit better to areas with higher contributions of fossil combustion and for ^{14}C-analysis, measurements of the actual lev/OC_{bb}-level are utile. It turns out that comparisons are important to revise the results and may give hints to possible information gaps and future investigation approaches.

This work was supported by the DFG.

Chemical and optical characterization of aged fossil fuel aerosol

L. Marmureanu[1], J. Vasilescu[1], A. Nemuc [1], D. Nicolae[1] and L. Belegante[1]

[1] National Institute of Research and Development for Optoelectronics, Magurele, 077125, Romania
Keywords: scattering coefficient, aerosol component composition, fossil fuel
Presenting author email: mluminita@inoe.inoe.ro

The atmospheric load of anthropogenic aerosol species is determined by factors such as emission, aging, convective transport and deposition processes, the level of scientific understanding being recognized to be medium and low. The optical parameters estimations have uncertainties linked with emission sources, optical properties, mixing and separation from natural background aerosol, state of mixing, method of mixing, and asphericity (IPPC 2007).

This study aims to characterize suburban aerosol during winter (2012) when soil dust influence is reduced due to snow coverage, and to investigate chemical, physical and optical properties of the aerosol during day time. Most frequent aerosol type investigated is the one resulted from traffic and from different types of fuel for domestic use such as wood or fossil fuel.

For this study were used three different types of equipments in order to obtain a detailed characterization of the aerosol load. Aerosol Mass Spectrometer (AMS) was used to characterizes submicron particles from the chemical point of view. AMS has a measurement size range of $0.04 < 2r <\sim 1000$ nm, and can deliver size-resolved particle composition using electron impact ionization. (Allan et al., 2004). The AMS is capable of deriving volatile and semi-volatile nitrate, sulphate, ammonium, organics and chloride (Takegawa et al., 2005). A Nephelometer (model 3563) designed for long-term monitoring of visual range and air quality at ground-based was used to continuously monitor the light scattering coefficient of airborne particles (Anderson et al, 1996). Aerodynamic Particle Sizer (APS) more sensitive to micron particle give information of size range between 0.5 and 20 µm (Peters. et al, 2003)

The AMS and APS results are in good correlations related to size distributions of submicron particle measured.

From the AMS output the presence of ions with m/z 44, 57, 60 and 73 were analyzed in order to identify the age of organic aerosols and their possible source (Adler et al, 2011). Higher concentrations of m/z 44 indicates the presence of oxygenated organic aerosols (OOA). During the entire period of measurements f 44 were between 0.0946 ± 0.00519 and 0.0987±0.019, values that characterize semi volatile OOA as defined by Ng et.al (2010) (f 44=0.07±0.04). The prominent peaks of the OOA were found at m/z 28, 43, 44, 55, 69 series characteristic to alkenes and alkanes (Slowik et al. 2010).

We have been observing correlation between oxygenated organic aerosol and NOx as previously observed by Zhang et al.(2005), Herndon et al.(2008). NO is emitted into the atmosphere also during fossil fuel use; in Magurele and Bucharest this type of fuel is used for heating. The data analyzed showed that NO_3 is internally mixed with NH_4 (ammonium nitrate) and in a very low proportion internally mixed with SO_4 like ammonium sulfate. Phenomena is explained by availability of ammonia, low temperature (~-10^{0}C) that causes ammonium nitrate to be stable and with high relative humidity (~ 80% measured at 10 m altitude-near the place of measurements).

Optical properties of the aerosol were extracted from nephelometer that gives real part refractive index (scatter and backscatter). The three wavelengths of the nephelometer were used to characterize the aerosol type related to scatter coefficient. The scatter coefficient was analyzed for different type of chemical species SO_4, Chl or NH_4. The suitable wavelength for this is at 700 nm and it showed association with total organics and NO_3 (fig.1)

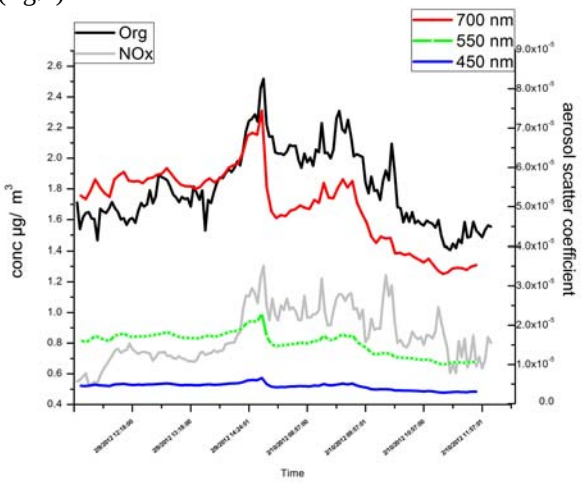

Figure 1 Distribution of chemical composition and aerosol scatter coefficient

Influence of Meteorological Variables on Particle Number Concentration in Madrid

E. Alonso-Blanco[1*], A. Hidalgo[2], F.J. Gómez-Moreno[1], and B. Artiñano[1]

[1] Dept. Medio Ambiente, CIEMAT, Av. complutense, 40, Madrid, Spain
[2] Dept. Química Analítica e Ingeniería Química, Universidad de Alcalá, Alcalá de Henares, Madrid, Spain

Keywords: Fine particles, Meteorology, Particle concentration, SMPS, Urban aerosols
*E-mail: elisabeth.alonso@ciemat.es

One of the most important contributors to air pollution is the content of particulate matter. The characterization of atmospheric particles is necessary to know their potential effects in human health because the particle size-area ratio establishes its deposition in the respiratory system and the interaction with biomolecules (Oberdörster *et al*, 2005). Particle number concentration in the atmosphere and its time of permanence are highly dependent of the meteorological variables in each moment. Besides, particle number concentration influences the radiative balance, because of dispersion and absorption processes of the solar radiation (IPCC, 2007; Calvo *et al*, 2010).

In this work, we have analyzed the influence of the meteorological variables in the particle number concentration and in the particle size distribution in the period 2007-2011, continuing the studies of Gómez-Moreno *et al* (2011). The annual, seasonal, monthly and weekly averaged patterns have also been studied.

The measurements have been carried out at the CIEMAT facilities, located northwest of Madrid (Spain). It has a population density greater than 5000/km^2, heavy traffic and light industrial activity, this allows studying its plume as a typical urban plume.

A Scanning Mobility Particle Sizer (TSI-SMPS; DMA 3081 with CPC 3022 or CPC 3775) for the size range 15-600nm was installed. The meteorological parameters have been measured in a permanent tower. For this study, we have used those months with more than 50% of available data.

In Madrid, during the last 5 years, there was a slightly decreasing tendency of the particle number concentration (Fig.1). During the first 2 years (2007-2008), the average particle number per year was 9918 and 7325 particles cm-3 respectively, meanwhile during 2009-2011 it was around 6000 particles cm-3. During the last 3 years, there was an increase in the average wind speed per year, with a slight decrease during 2011, meanwhile during 2007 and 2008 the average wind speed was the lowest of the studied period. By the end of 2011, when the wind speed starts to have low values there is an increasing tendency in the particles number concentration.

It is necessary to emphasize that during 2009 it was incorporated to the SMPS a nafion drier. At the same time, a European Directive reducing permitted sulphur contents in fuel was adopted. Therefore, both changes could have influenced in the measurements performed from this date. During the studied period it was observed an increase of the particle number concentration from November to January. It was produced by a highest atmospheric stability, due to the presence of thermal inversions. During spring there is a lower particle concentration associated to the presence of strong winds that dilute the contaminants in the area closest to the surface.

During all the period, the Aitken mode is the predominant, while the accumulation and nucleation modes maintain similar concentrations. However, by the end of 2010 and the beginning of 2011, while the averaged wind speed per month suffers a remarkable decrease, this tendency changes and the accumulation mode predominates over the nucleation mode. This is due to the highly atmospheric instability, the winds are strong and dilute the gaseous precursors capable of forming particles corresponding to that mode.

Hence, the conclusion is that during the period of the study there is a decreasing tendency in the particle number. The concentration of the matter particulate in the atmosphere depends not only on the emission sources, but also on the meteorological variables that control the atmospheric dynamics.

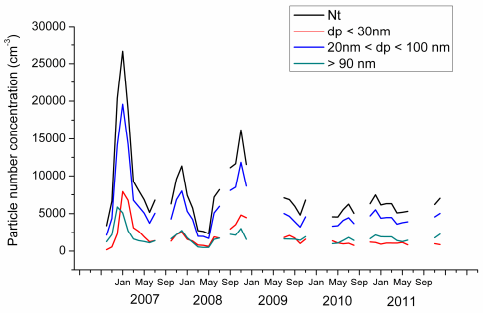

Figure 1. Evolution of the total particle number concentration and the different modes for the last five years in Madrid.

ABSTRACT:

Analytical method to quantify particulate-phase high molecular weight mono-carbonyls (C#>5) and di-carbonyls has been developed by adopting 2,4-dinitrophenylhydrazine (DNPH) derivatization followed by high performance liquid chromatography/ultra-violet (HPLC/UV) detection. Satisfy reproducibility and precision of the measurements were achieved. This method was applied for measuring the carbonyls in PM2.5 collected on quartz-fiber filters, sampled in Xi'an, China from 2008 to 2009. Nonanaldehyde was the most abundant compound, followed by octanaldehyde, hexanaldehyde and heptaldehyde, accounting for 40%, 20%, 12% and 11% in the total quantified carbonyls. For dicarbonyls, the concentrations of methylglyoxal were much higher than that of glyoxal. The seasonal variations of the particulate-phase mono-carbonyls and dicarbonyls were similar with those in the gas-phase, namely winter > autumn > spring > summer (except octanaldehyde). Strong correlation among those carbonyls was observed in winter, resulting from low temperature partitioning, weaker photochemical reaction, and more primary emission sources. On the contrary, vehicle emission, cooking emission and photochemical reactions are the major pollution source in Xi'an in summer.

Spatial patterns of high-resolution AOD and PM over Israel

Sorek-Hamer M.[1], Broday D.M[1], and Levy R.C[2]

The aerosol retrieval algorithm of the Moderate Resolution Imaging Spectroradiometer (MODIS) has been developed to retrieve aerosol properties globally. Under favorable conditions (clear sky over dark surfaces), MODIS provides a daily global coverage of its standard 10x10 km^2 aerosol products. This spatial resolution is useful for analysing the regional aerosol distribution and for studying events that show spatial extent (e.g. transboundary aerosol transport) but is too coarse for assessing the aerosol variation at the local scale. Li *et al.* (2005) have modified the MODIS algorithm to retrieve the aerosol optical depth (AOD) at a 1x1 km^2 resolution over Hong Kong, and found that relative to the standard 10x10 km^2 aerosol products the 1x1 km^2 aerosol products correlated better with the ground PM_{10} measurements and accounted for their spatial distribution. Recently, a new algorithm - Multi-Angle Implementation of Atmospheric Correction (MAIAC) - was developed for MODIS (Lyapustin *et al.* 2011), which also provides aerosol products at a 1 km resolution. The 1x1 km^2 MAIAC data may offer a clear advantage over the 10x10 km^2 standard MODIS aerosol products by improving our ability to characterize air quality at ground level using satellite-borne aerosol products, thus reducing exposure estimation errors.

It can be expected that as the spatial resolution of the aerosol products improves, their spatial coverage will increase. However, it is not clear if the added resolution provides higher noise or whether it represents improved aerosol signal. In this study we analyzed high-resolution (1x1 km^2) AOD data over Israel from two models: a new MODIS product obtained using a modification of the benchmark dark target algorithm and output of the new MAIAC algorithm.

In general, as the resolution of the aerosol product improved more data points were retrieved over the study area, with a ratio of ~85:8:1 between the number of the retrieved data points for the 1x1 km^2, the 3x3 km^2, and the 10x10 km^2 products, respectively. Moreover, as the resolution improved, the range of the AOT values became wider and the STD and the variance slightly increased (Table 1).

In order to find relationships between high resolution AOD and ground PM concentrations, we analyzed the AOD and PM data from several representative days using two parameters: their pertinent mean and coefficient of variation (CV=STD/mean). The CV of the AOD increased as the resolution increased (Fig. 1), with the highest CV obtained at the 1x1 km^2 resolution, close to the CV of the ground PM_{10}.

Table 1. Range and variance of AOD over Israel at different spatial resolutions in two days.

	AOD 17.1.07			**AOD 20.10.10**		
	10x10 km^2	**3x3 km^2**	**1x1 km^2**	**10x10 km^2**	**3x3 km^2**	**1x1 km^2**
Range	0.062 - 0.305	0.056 - 0.644	0.041 - 0.714	0.243 - 0.506	0.231 - 0.673	0.203 - 0.848
Variance (x 10^{-3})	2.96	3.8	4.7	2.9	3.6	3.9

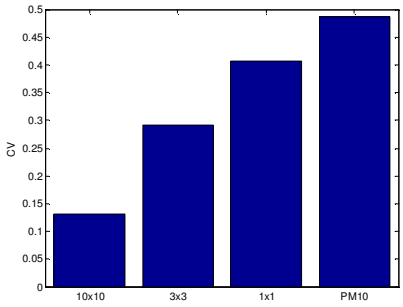

Figure 1. CV of AOD at different spatial resolutions, and of ground PM_{10} observations across all Israel on 17.1.07.

A comparison between the MODIS and the MAIAC 1x1 km^2 products suggests that the spatial patterns of the 1x1 km^2 AOD data partially represent one or more of the following (GIS) layers: roads, land use, and observed PM_{10} and $PM_{2.5}$ concentrations.

We expect that the 1x1 km^2 AOD product will enable improved correlations between ground PM and satellite-borne aerosol products, and help in assessing the true spatial variability of ambient PM, thus enabling to estimate reliably exposure to fine PM for public health applications.

Real time characterization of ambient aerosol at Prague suburban site during wintertime

P. Vodička, O. Makeš, J. Ondráček and J. Schwarz

Institute of Chemical Process Fundamentals of the AS CR, Prague, Czech Republic
Keywords: urban aerosol, high time resolution, OC/EC, AMS
Email: vodicka@icpf.cas.cz

Wintertime behavior of ambient aerosol was studied at Suchdol urban background site in Prague, Czech Republic in December 2010. The semi-online field OC/EC analyzer (Sunset Inc.) and the C-ToF aerosol mass spectrometer (AMS; Aerodyne Inc.) were used for measurements. The instruments were sampling using a common inlet equipped with a $PM_{2.5}$ cyclone. The AMS measured ca PM_1 fraction due to technical parameters. Samples were collected in two-hour intervals by ECOC instrument and analyzed by modified EUSAAR_2 protocol (Cavalli *et al*, 2010). The AMS measured in one-minute time resolution and results were averaged as required. Measurements covered 99% of the period.

In Fig. 1 the diurnal patterns of selected aerosol components are shown. It is well visible that the organic carbonaceous aerosols prevailed. If we take into account elements bound with carbon in organics, concentrations of organic matter (Org.) measured by the AMS are in good agreement with concentrations of organic carbon (OC) determined by the OC/EC analyzer (Takegawa *et al*, 2005). These two parameters are well correlated; the Spearman correlation coefficient of all time series between OC and Org. that was found to be 0.97.

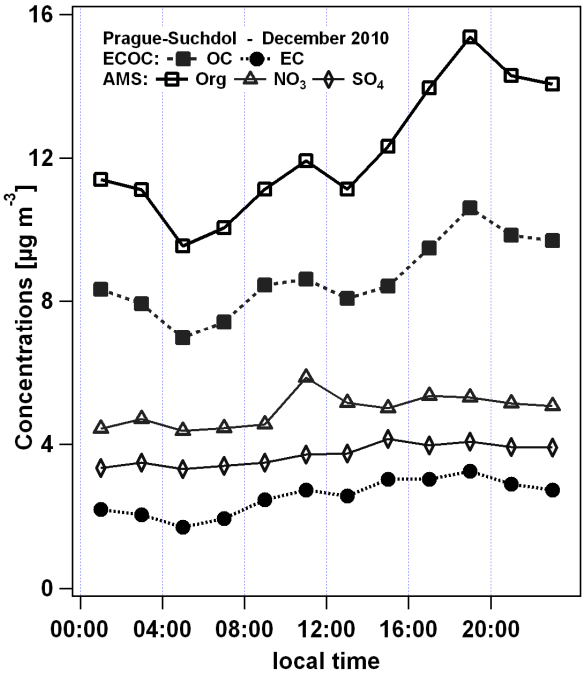

Fig.1. Averaged diurnal cycles of selected aerosol fractions

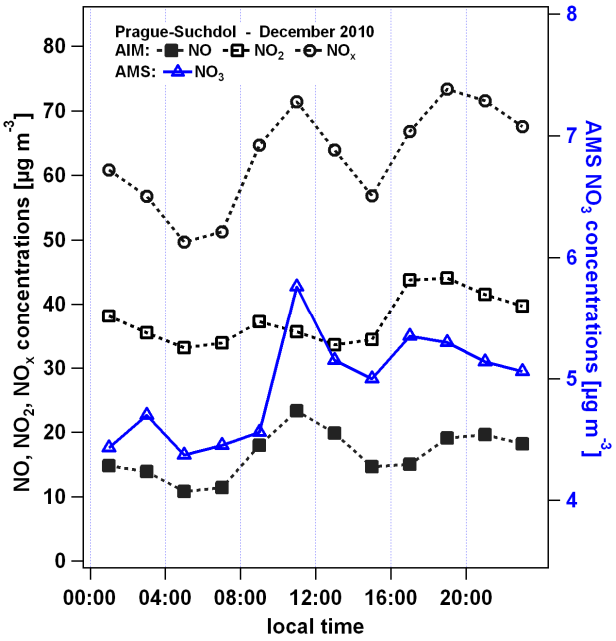

Fig.2. Comparison of averaged diurnal cycles of NO_3 aerosol fraction with nitrogen trace gases

AMS and ECOC data are also compared with meteorological (temperature, humidity, wind speed and direction, global radiation) and air quality (PM_{10}, SO_2, NO, NO_2, NO_x, O_3) data obtained from automated immission monitoring (AIM). For example, in Fig. 2 averaged diurnal variations of nitrogen trace gases are compared with NO_3. Spearman correlation coefficients were counted from all time series averaged into 2 hour means. Correlations between NO_3 and NO, NO_2, NO_x has found to be 0.50, 0.65 and 0.64, respectively. Similar analyses provide insight into the possible mechanism of aerosol formation and behavior at this site.

This work was supported by the Grant Agency of the Czech Republic under grant P209/11/1342.

Levels and chemical composition in airborne particulate matter (PM10) of eastern Andalusia (SE Spain)

A.M. Sánchez de la Campa[1], R. Fernández-Camacho[1], Y. González-Castanedo[1] and J.D. de la Rosa[1]

[1]Associate Unit CSIC-University of Huelva "Atmospheric Pollution", University of Huelva, Campus El Carmen E21071 Huelva, Spain

Keywords: Eastern Andalusia, PM10, traffic, trace element.

Presenting author email: ana.sanchez@pi.uhu.es

Andalusia is the second largest region in Spain, representing the 17% of the territory, with more of 8 M inhabitants. It's located in the boundary between two continents (Europe and Africa) being the place where the Mediterranean meets the Atlantic across the Strait of Gibraltar. Andalusia displays a complex orographic, with very different climatic and topographic patterns.

Seven representative monitoring sites (urban background, traffic hot-spot and urban with industrial influence) of eastern Andalusia have been selected to characterize levels and chemical composition of atmospheric particulate matter (PM10) during four years (2007-2010) (Table 1). These studies may supply relevant information for the air quality management (Putaud et al. 2004; Querol et al. 2004a,b; Hueglin et al. 2005), and also identify and quantify the different anthropic and natural contributions to PM in eastern Andalusia areas.

1161 filters were sampled and analysed for major and trace elements, water soluble ions (NH_4^+, SO_4^{2-}, NO_3^-, Cl^-) and total carbon, a total of 65 elements and compounds, using Inductively Coupled Plasma (ICP-MS and ICP-OES), Ion Chromatography and LECO instrumentation, respectively.

A study of air mass origin has been performed for one ideal monitoring station located at 37ºN 3ºW, using HYSPLIT4 model (Draxler and Rolph, 2003). We have used this model to gain insight on the influence of long-range transport to air pollutant levels (e.g. air masses from North Africa).

The mean concentration of PM10 of eastern Andalusia monitoring stations are in the range described at other sites urban-industrial (28-57 µg/m^3) and heavy traffic hot spots (46-50 µg/m^3) of Spain (Querol et al. 2004a). PM10 levels show simultaneous concentrations peak coinciding with maximum in summer when the North African dust outbreaks are more frequent. A decreasing trend of North African dust outbreak frequency is observed from 2007 to 2010, while the Atlantic air masses manifest an opposite tendency.

The highest concentrations of crustal components were measured in eastern Andalusia, compared to western Andalusia (de la Rosa et al. 2010). Also, the highest concentrations of anthropogenic sulphate were recorded in Bailén and traffic hot-spot monitoring stations. Cnm concentrations were highest in Granada Norte monitoring station.

Peak concentrations of V, Ni and Rb are registered in Bailén, derived mainly from the combustion of coke in brick factories, while the Rb is related with the emissions of K in the combustion of olive husk. Also, peak concentrations of V were registered in the traffic stations. On the other hand, hot-spot traffic sites in Granada and Málaga display the highest concentrations of Sn and Sb of Andalusia.

Table 1. Location and mean concentration PM10 (µg/m^3) of the monitoring stations selected for the study.

Station	Province	type	Latitude	Longitude	PM10 (µg/m^3)

PM level in Seoul metropolitan subway cabin indoor during the rush hour

S.-B. Kwon[1], J.B. Kim[1], J.H. Song[1], Y. Cho[1], D.S. Park[1], W. Jeong[1] and C.H. Shin[2]

[1]Subway IAQ Research Corp., Korea Railroad Research Institute, Uiwang, Gyeonggi, 437-757, Korea
[2]Seoul Metro, Seoul, 156-080, Korea
Keywords: PM10, PM2.5, subway cabin, rush hour
Presenting author email: sbkwon@krri.re.kr

In the modern society various types of transportation mode are utilized, among them the subway system is the one of the main transportation mode in which more than 7.21 million people ride a day in Korea. Also, there are increasing concerns on air quality of subway system including platform, tunnel and cabin indoors. Since the indoor air of subway system contains particulate matters (PM) of heavy metals generated from frictions of wheels, break-pads, and pantographs. The air cleaning of subway cabin is important since the cabin indoor is the most time spent space by passengers of subway. In our previous study conducted on the morning rush hour showed the average level of PM10 was about 142 μg/m^3 in Seoul subway (Kwon *et al.*, 2008). In this study, we measured PM concentrations in a subway cabin during the rush hour. Coarse mode particles defined as the particle sizes of 2.5~10 μm and fine mode known as PM2.5 (smaller than 2.5 μm in size) were monitored by real time optical particle sizer and indoor concentration was compared with outdoor concentration.

The size distribution of cabin indoor particulate matters (PM10 and PM2.5) were measured by the optical particle sizer (OPS, TSI model 3330) during the morning rush hour (07:00~10:00) for 4 weekdays between September to November 2011. In order to perform the on-board measurement, the OPS was installed on the cabin shelf at the Sinjeong subway depot before its departure. Figure 1 shows the transient PM10 and PM2.5 concentration levels in a cabin during the rush hour. All data were averaged from four days measurement. Averaged PM10 concentration was 95.7 μg/m^3 and PM2.5 was 57.7 μg/m^3. Approximately 60% of fine mode particles were found among PM10 in a subway cabin.

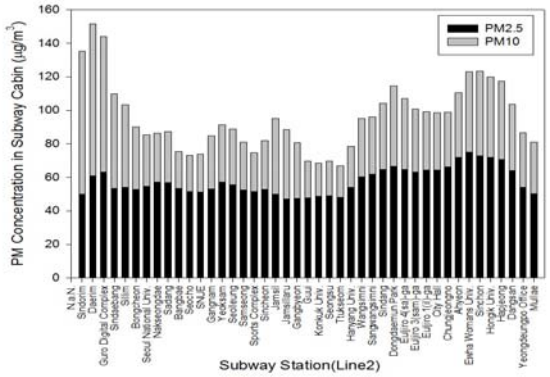

Figure 1. Transient PM10 and PM2.5 concentrations in a subway cabin.

Since the Seoul metro Line 2 is a loop lane circulating the boundary of central Seoul (total length = 60.2 km), we referred the outdoor PM concentration of averaged monitoring results from Air Quality-Climate Change Information of Seoul (AQCCI, 2011). During the 4 week days of on-board measurement, PM10 and PM2.5 of subway cabin indoor and outdoor concentrations were correlated as shown in Figure 2. It reveals that subway indoor PM is linearly correlated with outdoor PM concentration (R^2 = 0.94 for PM10, 0.99 for PM2.5). The ratio of indoor to outdoor (I/O) was 1.53 for PM10 and 1.43 for PM2.5. It is obvious that the indoor PM concentration of subway cabin is significantly affected by outdoor PM concentration and the indoor concentration is higher than that of outdoor by 48%.

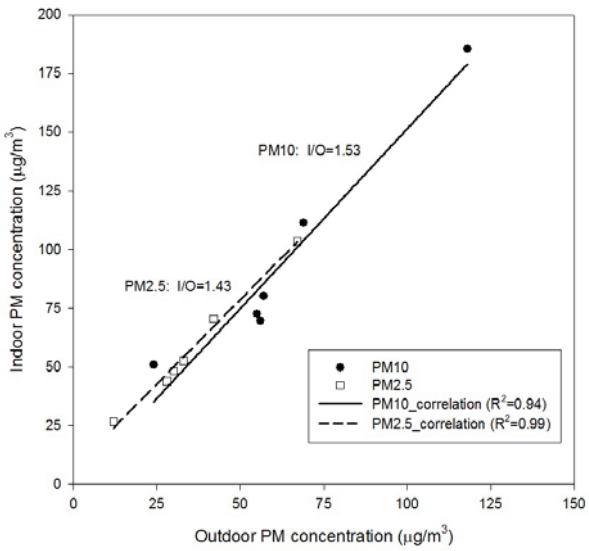

Figure 2. The ratio of indoor to outdoor PM concentration.

School Children's Personal Exposure to Ultrafine Particles in Urban Environments

M. Mazaheri[1], M. Mokhtar[1], R. Jayaratne[1] and L. Morawska[1]

[1] International Laboratory for Air Quality and Health, Institute of Health and Biomedical Innovation, Queensland University of Technology, Brisbane, Queensland 4001, Australia
Keywords: ultrafine particles, personal exposure, Nano Tracer, schools.
Presenting author email: m.mazaheri@qut.edu.au

This work was motivated by the limited knowledge on personal exposure to ultrafine (UF) particles, and it quantifies school children's personal exposure to UF particles, in terms of number, using Philips Aerasense Nano Tracers (NTs). This study is being conducted in conjunction with the "Ultrafine Particles from Traffic Emissions and Children's Health (UPTECH)" project, which aims to determine the relationship between exposure to traffic related UF particles and children's health (http://www.ilaqh.qut.edu.au/Misc/UPTECH%20Home.htm). To achieve this, air quality and health data are being collected at 25 schools within the Brisbane Metropolitan Area in Australia over two years. The school children's personal exposure to UF particles in the first 17 schools are presented here. These schools were tested between Oct 2010 and Dec 2011. Data collection is expected to be complete by mid 2012.

Four NTs were available for this project, 3 of which were used for data collection and one was the reference unit. The NT is a hand-held battery-operated instrument that measures particle number concentration up to 10^6 cm^{-3} and particle size in the range of 10-300 nm within the breathing zone. At each school, three to six 8 to 11 years old school children, who gave consent to participate in the study, were asked to carry the NT and a global positioning system (GPS) all the times for a total period of 24 hours. The children were instructed to wear the NT around the waist using a dedicated belt and were requested to have it in his or her close proximity during the 24 hours of measurements when it was not being worn (e.g. during sports activities, when using the bathroom and sleeping). Each child and their parents or guardians were asked to record their travel times and activities, during non-schooling and schooling hours, and the time and duration when the sampler was not with the child at any particular time.

63 children in the 17 schools (S01 – S17) participated in this study. Time series of the UF particle number data during the 24 hours of measurements for each child were used to identify the peak concentrations in the first instance. Each child's exposure was quantified over a total of 24 hours, as well as for school hours only, non-school hours, and commuting.

Figure 1 shows the children's' average exposure to UF particles during schooling activities (indoors and outdoors) over the 24 hours of data collection at each individual school. These preliminary results show that children's exposures during indoor and outdoor activities were lowest at S09 and highest at S03 and S02, respectively.

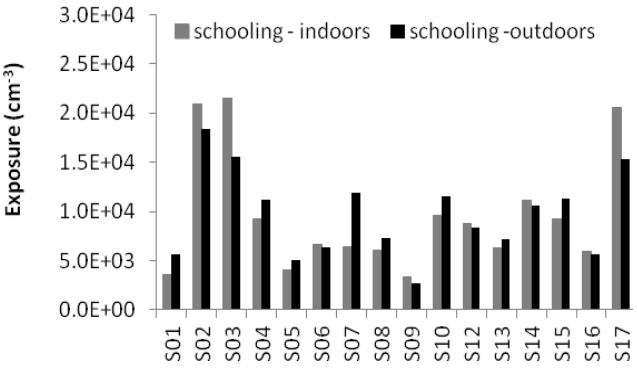

Figure 1. Average children's exposure to UF particles during school hours (indoors and outdoors) at each school.

Figure 2 shows the children's average exposure to UF particles during after school hours and transport over the 24 hours of measurements. The non-schooling hours also include commuting and are affected by many factors relating to different children activities during after school hours. Children attending S07 and S08 had higher exposures during commuting and S01 had the lowest.

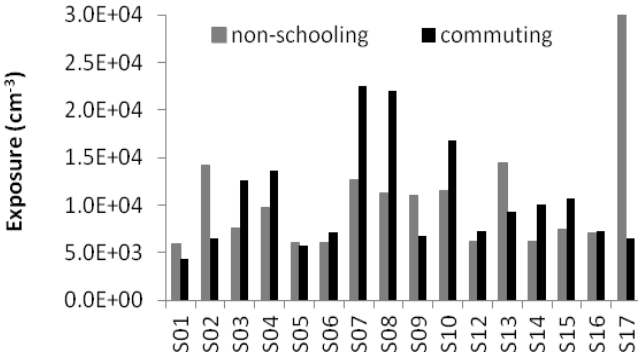

Figure 2. Average children's exposure to UF particles during after school hours and transport at each school.

Preliminary analysis indicates that the results are consistent with the general characteristics of the schools and local traffic conditions during the data collection.

Distribution characteristics and trends of $PM_{2.5}$ and PM_1 -bound polycyclic aromatic hydrocarbons (PAHs) over an urban Mediterranean area

St. Pateraki[1,2], D.N. Asimakopoulos[2], Th. Maggos[1], and Ch.Vasilakos[1]

Keywords: PM, PAHS, Meteorology, Urban Pollution

Presenting author email: stella@ipta.demokritos.gr

Airborne particulate matter (PM) is one of the most important markers of the urban air quality, especially with respect to a number of chronic respiratory diseases. On one hand, epidemiology suggests that especially the smaller diameter particles which are able to reach deeper lung regions, have considerable impact on health even at concentrations below the present ambient air quality standards. On the other hand, Polycyclic Aromatic Hydrocarbons (PAHs), are ubiquitous constituents of urban aerosols and of major and well justified health concern since some of them are thought to be among the strongest known toxic, mutagens and carcinogens. 17 PAHs have been classified as priority pollutants by the USEPA based on their toxicological profile with benzo(a)pyrene (BAP) being considered as the most toxic and known to induce lung cancer and DNA binding ((Ravindra et al. (2008)). Sources, emitted amounts, gas/particulate partitioning coefficient of PAHS, atmospheric loss mechanisms such as long range transport and photolysis are potential factors affecting the seasonal variability of atmospheric PAHs (Kume et al. (2007)).

Five daily $PM_{2.5}$ and PM_1 measurements were deployed simultaneously, with the use of low volume gravimetric samplers, in two different environments within the Athens basin, during the period 20/3-2/8/2008. The sampling stations were selected carefully, taking into consideration their pollution characteristics and sources: Aegina is a coastal background monitoring station located in the countryside at some distance from anthropogenic PM emission sources while Votanikos is an urban-industrial monitoring station generally dominated by traffic, under the influence of industrial particulate matter emissions. The whole procedure which was followed for the determination of the PM concentration was according to EN14321. Sampling and analysis of Polyaromatic Hydrocarbons (26 PAHs) performed according to ISO 12884. The meteorological data (temperature, wind speed, relative humidity) for Aegina and Votanikos were provided by the Agricultural University of Athens and the Hellenic National Meteorological Service, respectively.

This work addresses three different tasks: (i) to record the $PM_{2.5}$ and PM_1 levels (ii) to characterize chemically the collected samples in connection with the associated PAHs (iii) to investigate the trends for both PM mass and PAHs (molecular weight, number of rings, carcinogenicity) during the different prevailing meteorological cases (wind, temperature, humidity, atmospheric circulation) and most importantly (iv) to explore the pathways of aerosols transportation (mass and composition) from and towards the Greater Athens Area (G.A.A.).

The daily concentration levels of $PM_{2.5}$ and PM_1 did not exceed 38.0 and 32.5 $\mu g/m^3$, respectively. The recorded $PM_{2.5}$ values appeared to exceed the E.U. daily limit (25 $\mu g/m^3$) three and two sampling days in Votanikos and Aegina, respectively. Irrespectively of the type of the environment, PM_1 appeared to constitute the most significant part of the $PM_{2.5}$ mass (61%-95%). It is of great importance to mention the equal $PM_{2.5}$ levels at the different environments on 25/3, 2/7 and 2/8 as well as the significant associations between $PM_{2.5}$ (r: 0.76) and PM_1 (r:0.80).

As far as polyaromatic hydrocarbons are concerned, they were mainly accumulated at the center station and more specifically at $PM_{2.5}$.The same assumption can be also made for the $PAHs_{Cancer}$ (Fig. 1). It is of great importance to mention not only the higher AvgΣPAHs concentrations at PM_1 of the coastal station than those at $PM_{2.5}$ but also the higher $Avg\Sigma PAHs_{Cancer}$ concentrations (Fig. 1). Generally, B(ghi)P was the most abundant PAH at Aegina and B(b)F at Votanikos station.

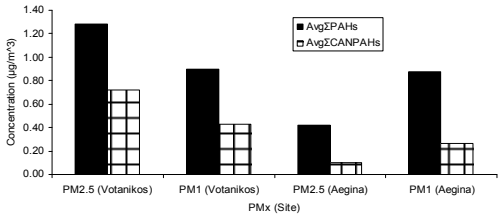

Figure 1. Average ΣPAHs and $\Sigma PAHs_{CAN}$ for each PM fraction and station

Investigating each day separately, with the only exception being 21/7/08, 2-methylnaphthalene prevailed in Aegina. At the city center the PAHs distribution was more complicated with uniform trends for both fractions being registered only at 20/3 and 25/3 with the B(b)F and B(ghi)P prevalence, respectively.

Health effects of aerosols are particle size dependent. In cities the particle concentration is often elevated due local sources. These sources have different temporal and size characteristics. In addition to the local sources, also long rang transport and local weather conditions affect the particle number size distributions in the urban atmosphere.

We have investigated how the particle number size distribution at an urban background location in Helsinki is affected by local sources and weather conditions. One year of particle number size distribution data along with meteorological data was used. To reduce the complexity of the data set we used cluster analysis (Beddows *et al*, 2009). In this way the number size distributions were separated into six groups. For each of these six groups the mean particle number size distribution is shown in figure 1.

Clusters 1 and 2 were common when the air was affected by fresh road traffic emissions. Cluster 3 was frequent when the wind came from downtown Helsinki, probably due to aged traffic emissions or ship emissions. Cluster 4 and 5 were characteristic for clean air and for air containing many long range transported particles.

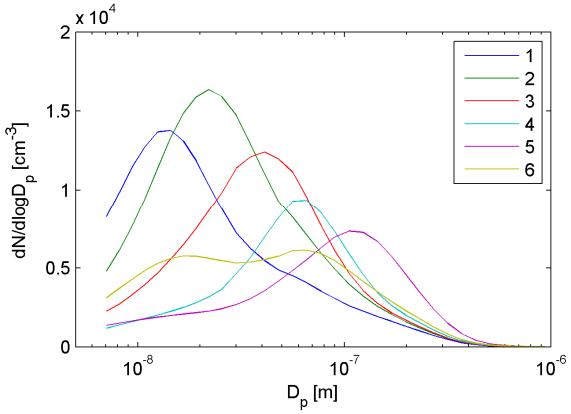

Figure 1. Mean size distributions of the six clusters.

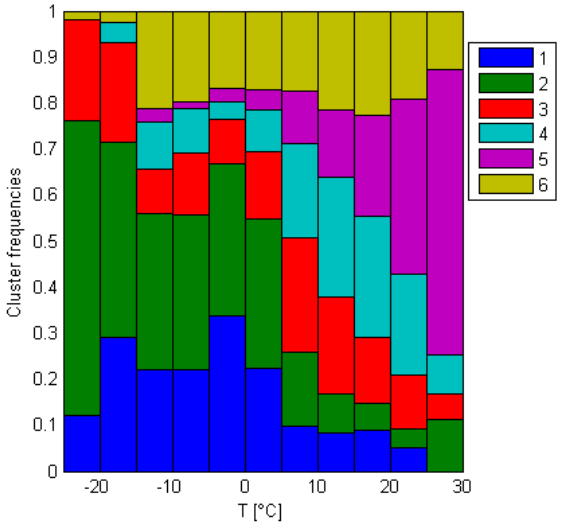

Figure 2: Frequencies of clusters as a function of temperature.

Figure 2 shows that cluster 1, 2, and 3 are most common at low temperatures. Comparison to figure 1 shows that the particles number size distributions are often dominated by particles with diameters below 50 nm when temperatures are low. One reason for this is probably increased vehicular emissions at low temperatures (Olivares *et al*, 2007). Another probable reason is less vertical dilution in winter.

At high wind speeds the particle number size distribution was more often dominated by nucleation mode particles.

Ionic composition of PM_{10} and $PM_{2.5}$ in urban-traffic and urban background sites within the Thessaloniki Major Area (TMA), northern Greece

E. Gounari, D. Lazarou, E. Manoli, D. Voutsa, C. Samara

Environmental Pollution Control Laboratory, Department of Chemistry,
Aristotle University of Thessaloniki, University Campus, 54124 Thessaloniki, Greece
Keywords: chemical composition, PM10/PM2.5, sulfate, urban aerosols
Presenting author email: dvoutsa@chem.auth.gr

Thessaloniki is a densely populated Greek city constantly exceeding the EU limits for PM_{10}, particularly at traffic impacted sites in the city centre. Previous studies have investigated the ionic composition of ambient PM, and the size distribution of major anions and cations (Voutsa *et al*., 2002; Tsitouridou *et al.*, 2003; Terzi *et al*., 2010). Recently, the analysis of PM_{10} at two urban sites within the city indicated that ionic species were major components of PM_{10} mass with average contributions 14% and 16%, respectively. The dominant anion was SO_4^{2-} followed by NO_3^-, while the dominant cations were Ca^{2+} and NH_4^+ (Terzi *et al*., 2010). Nevertheless, further understanding of the ionic composition of atmospheric particles, particularly those in the fine fraction, is required.

The aim of the present study was to investigate the ionic composition of PM_{10} and $PM_{2.5}$ at two sites within Thessaloniki, UT (urban-traffic) and UB (urban-background) (Figure 1). PM_{10} and $PM_{2.5}$ samples were concurrently collected during the warm season of 2011 according to EN-12341 and EN-14907, respectively. Low Volume Samplers (Ingenieur Derenda, Berlin) equipped with PM10 and PM2.5 inlets were employed operating at constant flow rate 2.3 m^3/h. PM_{10} and $PM_{2.5}$ ionic fractions were collected on Φ 47 mm Teflon filters (Zefluor™ membranes, Pall 2μm). Each sampling had a 24-h duration starting at 00:00. PM_{10} and $PM_{2.5}$ samples were analyzed by ion chromatography for major ions according to previously standardized procedures (Terzi *et al*., 2010).

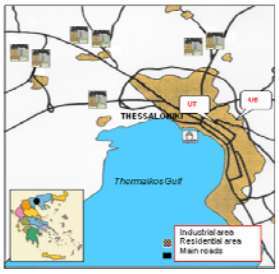

Figure 1. Map of the TMA showing the locations of sampling sites (UT: urban traffic site, UB: urban background site)

Similarly to previous findings, both PM fractions were significantly higher in the UT site (Table 1). This site exhibited lower $PM_{2.5}/PM_{10}$ ratio suggesting stronger impact of traffic induced resuspension of road dust.

Table 1. Mean±SD for PM_{10} and $PM_{2.5}$ mass concentrations (μg/m^3) and $PM_{2.5}/PM_{10}$ ratios

	PM_{10}	$PM_{2.5}$	$PM_{2.5}/PM_{10}$
UT	48±10	26±6	0.54±0.1
UB	28±9	17±6	0.64±0.1

The average concentrations of anions associated to PM_{10} and $PM_{2.5}$ are presented in Figure 2. These values are in general agreement with those previously found in the same area during the warm period (Samara and Tsitouridou, 2000; Terzi et al., 2010; Tsitouridou et al., 2003; Voutsa et al., 2002). The PM_{10} fractions of all anions were similar at the two sampling sites. The concentrations of SO_4^{2-} and Cl^- associated to $PM_{2.5}$ were slightly higher at the UB site, whereas the $PM_{2.5}$ fraction of NO_3^- was significantly higher at the UT site suggesting photochemical formation of nitrate aerosol from vehicular NOx emissions. Correspondingly, the $PM_{2.5}/PM_{10}$ ratios of Cl^- and SO_4^{2-} (Table 2) did not exhibit remarkable spatial difference in contrast to those of NO_3^- that was significantly higher at the UT site designating its strong affection by traffic emissions. Very high $PM_{2.5}/PM_{10}$ ratio values, close to unity, were found for SO_4^{2-} at both sites and for NO_3^- at the UT site suggesting total distribution in the fine particle fraction in contrast to Cl^- that exhibited a significant coarse fraction.

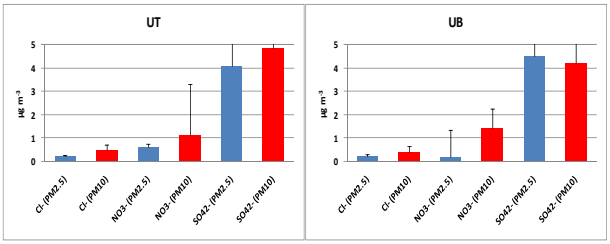

Figure 2. Average concentrations of anions associated with the PM_{10} and $PM_{2.5}$ particle fractions at two sampling sites.

Table 2. $PM_{2.5}/PM_{10}$ ratios for ionic concentrations

	Cl^-	NO_3^-	SO_4^{2-}
UT	0.61±0.33	0.99±1.91	0.92±0.24
UB	0.72±0.35	0.24±0.32	1.09±0.24

Particle size distribution of *n*-Alkanes and PAHs in urban and industrial areas of Algiers, Algeria

Atmospheric particulate organic matter (POM) contains a wide variety of constituents that may induce adverse effects to human health and/or can be used as markers for the emission sources. Thus, the deep understanding of the POM composition is a suitable tool whenever the source identification is attempted with the purpose of pollution control or toxicants abatement. Anthropogenic *n*-alkanes are associated to fossil fuel utilization and are derived from both incomplete fuel combustion and lubricant oil evaporation. On the other hand, biogenic sources of *n*-alkanes include particles derived from epicuticular waxes of vascular plants (e.g., leaf debris) and direct suspension of pollen, micro-organisms and insects (Yassaa et al., 2001 and references therein). The percentage distributions of *n*-alkanes are source-specific and therefore provide useful information about their origin. PAHs are emitted from a number of sources (e.g. fossil fuel combustion, waste incineration, oil refining, steel and iron manufacturing, or coke and asphalt production), however the release from motor vehicles has been identified as the predominant source in urban areas (Rogge et al., 1993 and references therein). Both mutagenicity and carcinogenicity of PAHs released concurrently to emission exhausts or adsorbed on ambient aerosols have been conclusively demonstrated through bacterial and in-vivo/in-vitro mammalian cell assays as well as through epidemiological studies. The potential health effects of PAHs are usually attributed to the number of aromatic rings and structure; in particular, many congeners having four to six rings, such as benzo(a)pyrene and indeno(1,2,3,-cd)pyrene, are carcinogenic or genotoxic. Since particles varying in aerodynamic diameters display different capabilities of entering the human respiration system, information on the particle size distribution of particulate matter components is essential to estimate their aftermaths on health.

In this study, the size distribution of ambient air *n*-alkanes and polycyclic aromatic hydrocarbons (PAHs) associated to particles, was investigated at an urban and industrial sites of Algiers, Algeria. Size-resolved samples (<0.49 µm, 0.49-0.95µm, 0.95–1.5 µm, 1.5–3 µm, 3–7.2 µm and 7.2-10 µm) were concurrently collected from the two sampling sites using five-stage high volume cascade impactors. After extraction and cleanup PAHs were analyzed by gas chromatography/mass spectrometry with electron impact ionization (GC/EI-MS) while n-alkanes were analyzed by gas chromatography/ flame ionization detector (GC/FID).

At both site, *n*-Alkanes and PAHs were primarily associated with small particles. Generally, more than 85 % of the total concentrations of *n*-alkanes and PAHs were accumulated in particles <1.5 µm. The size distribution diagram of *n*-alkanes indicates the existence of a bimodal distribution, which can be explained by non-equilibrium.

The size distributions of total *n*-alkane concentrations and biogenic *n*-alkanes derived from epicuticular waxes of vascular plants in an urban area of Algiers are shown in Fig. 1. Both alkanes showed similar distributions indicating that these pollutants are mostly generated from combustion of fossil fuels and biomass burning.

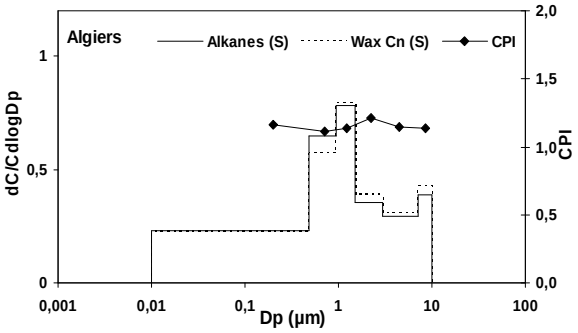

Figure 1. Differential distribution curves of total *n*-alkanes and biogenic *n*-alkanes recorded in urban area of Algiers.

Unimodal distribution of high molecular weight PAHs basically reflects the gas-to-particle conversion after their emission, whereas the low molecular weight PAHs were distributed in bimodal distributions, which can be interpreted by partitioning to larger particles by vaporization and sorption processes.

The air pollutants emitted from biomass burning in North Korea to the air quality in Seoul, South Korea

In Sun Kim [1], Yong Pyo Kim [1], Ji Yi Lee [2], Lan Jin [1]

[1] Departent of Environmental Science and Engineering, Ewha Womans University, 11-1 Daehyun-Dong, Seodaemun-Gu, Seoul, 120-750, Korea
[2] Department of Environmental Engineering, BK21 Team for Biohydrogen Production, Chosun University, 375 Seosuk-Dong, Dong-Gu, Gwangju, 501-759, Korea
Keywords: North Korea, PAHs, levoglucosan, CMB, backward trajectory analysis
Presenting author email: supidang@gmail.com

South Korea is contiguous to China, Japan and North Koreas, so air pollutants transported from outside South Korea should be investigated. Kim (2010) identified that air pollutants emitted from out of South Korea effect on approximately 30% of the ambient PM 10 concentrations in the SMA based on the modelling results.

Energy consumption in North Korea is less than in other countries (Table 1). North Korea might emit a small amount of air pollutants compared to China. However, North Korea is next to Seoul Metropolitan Area (SMA) and the air quality in North Korea is considered inferior to in neighbour countries.

Table 1. Total primary energy consumption for 2008 (unit: quadrillion Btu (%)) (EIA, 2011)

China	85.06	(17.25%)
Japan	21.87	(4.44%)
South Korea	9.88	(2.01%)
North Korea	0.88	(0.18%)
World	493.01	

In this study, the chemical mass balance (CMB) model and the backward trajectory analysis were conducted to understand the influences of air pollutants' emission from North Korea to South Korea, especially Seoul. CMB model were applied to analyze the source apportionment of particulate polycyclic aromatic hydrocarbons (PAHs) at Seoul between 2006 and 2007. In order to strengthen the uncertainty of CMB result, the trend of levoglucosan (1,6-anhydro-b-D-glucopyranose) concentration at Seoul is also discussed.

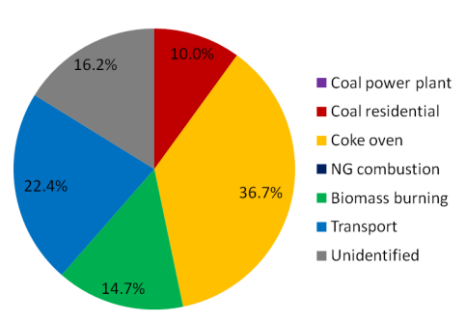

Figure 1. The fraction of the source contributions for particulate PAHs at Seoul for the whole sampling period.

To understand the transport of air pollutants emitted from North Korea, the backward trajectories in the sampling days were estimated and classified to four cases depending on which area the trajectories predominantly passed through.
Based on the contribution of biomass burning calculated by the CMB and the trajectories, the influence of air pollutants from North Korea to Seoul is quantified. Furthermore, statistical analysis was applied to supplement those results.

Abstract review

Several epidemiological studies have shown an association between particulate air pollution and health effects. It of great consensus among the scientific community that suspended particulate matter is considered as one of the most harmful pollutant, particularly the inhalable particulate matter with aerodynamic diameter less than 10 micrometers (PM_{10}) causing respiratory health effects and heart diseases. The effects of aerosols on human health are significant and are determined by both their size and their chemical composition. The critical level is the exceeding average daily concentration appearing among other cases, during Sahara dust episodes, a natural phenomenon that degrades the air quality in the urban area of Volos.

The city of Volos is a coastal city of medium size in the Thessaly region and extends along the northern Gulf of Pagasssitikos, on the east coast of Central Greece. The case of Volos is an interesting example, where in recent decades urbanization and increased industrialization have resulted in deterioration of air quality in the region. The meteorological factors play an important role in the development of air pollution, and the complex topography of Volos exacerbate air pollution episodes.

The main objective of the present work is the study of suspended particulate matter temporal evolution in the city of Volos. For this purpose, concentration measurements of the particulate matter with an aerodynamic diameter less than 10 μm (PM_{10}), for a 5-year period (2007–2011) are analyzed.

Table 1. Descriptive statistics for PM_{10} daily concentrations ($\mu g/m^3$) in the city of Volos.

	2007	2008	2009	2010	2011
Mean ($\mu g/m^3$)	46.5	44.6	36.3	38.8	46.4
St. Deviation ($\mu g/m^3$)	21.6	20.5	17.1	26.9	33.0
Median ($\mu g/m^3$)	44.0	42.9	33.8	35.1	37.9
Minimum ($\mu g/m^3$)	5.1	3.3	2.4	6.7	8.4
Maximum ($\mu g/m^3$)	157.5	158.0	132.2	325.0	285.0
Number of exceedances	**123**	**114**	**49**	**66**	**96**

Air pollution data were obtained by a monitoring station, fully automated, which was established by the Municipal Water Supply - Sewage in Greater Area of Volos, located in the centre of Volos. The analysis shows that the PM_{10} concentration levels remain higher than corresponding thresholds for human health protection set by the European Union, during the examined period (Table 1).

Moreover, from the statistical analysis of the 5-year measurements of daily PM_{10} concentrations it is showed that the mean seasonal variability of the examined concentrations presents a minimum during the warm period of the year 2009, against a maximum during the cold period of the year 2007 (Figure 1).

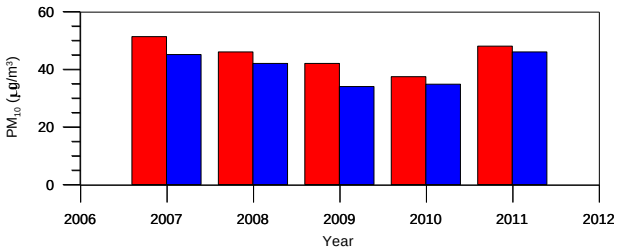

Figure 1. Temporal evolution of average seasonal PM_{10} concentrations at the city of Volos during the cold (red color bars) and the warm (blue color bars) period for 2007-2011.

"Supersite" project is a detailed study of some chemicals, physical and toxicological parameters in the atmosphere of Emilia-Romagna region (Italy) and their assessments by epidemiological, environmental and health models. The project rises from the necessity to improve knowledge about environmental and health aspects of fine and ultrafine aerosol, in primary and secondary components, in atmosphere.

Some field campaigns (intensive observation program) are defined and measures are carried out with a high time resolution and detailed chemical speciation. The aim of this paper is to supply an overview of preliminary results in the two monitoring sites, combing chemical, physical measures and meteorological parameters.

The first field campaign was from 15th November up to 7th December 2011. During the campaign different measures were carried out in two sites: urban background station (MS) of Bologna (Italy) and rural site (SPC) about 30 Km north-east of Bologna in the Po Valley.

The activities performed in two sites were:

- real time chemical speciation (organic, sulphate, nitrate, ammonium, chloride) in range 40-600 nm, by aerosol mass spectrometer (W-ToF High Resolution Aerosol Mass Spectrometer System, Aerodyne),
- PM2.5 and PM1 β-absorption measures,
aerosol size distribution (5.6-560 nm) using Fast mobility particle spectrometer (FMPS, TSI-3091),
- number concentrations by optical particle counter (OPC monitor, FAI Instruments),
- ions, metals, EC/OC and organic speciation (PAH, Nitro-PAH, Oxi-PAH sugars, carboxylic acids).

Some preliminary results are discussed. PM1 and PM 2.5 mass concentrations show an evident common trend for the two sites as shown in fig. 1. Divergences seen in some days (principally on 28th November) can be attributed to the fog formation in the SPC site, occurrence not evident in Bologna MS site. It is evident a change of chemical composition passing from 27th to 28th November as shown in fig. 2.

AMS speciation data confirm values observed in urban and rural sites in the Po Valley (Carbone *et al.*, 2010).

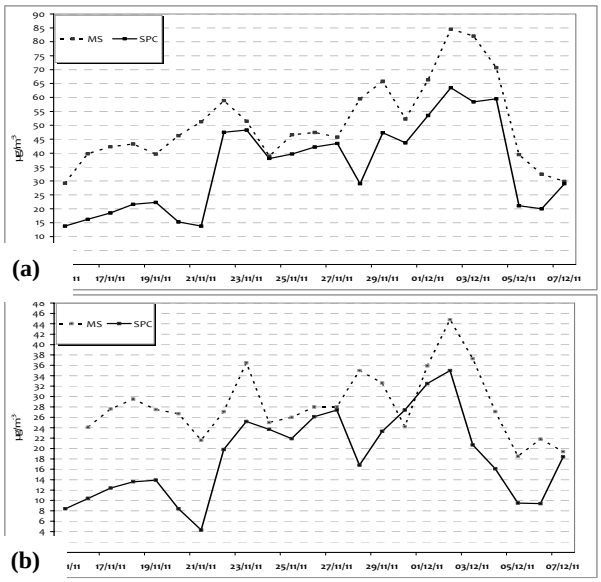

Figure 1. PM2.5 (a) and PM1 (b) mass concentration trend in MS and SPC.

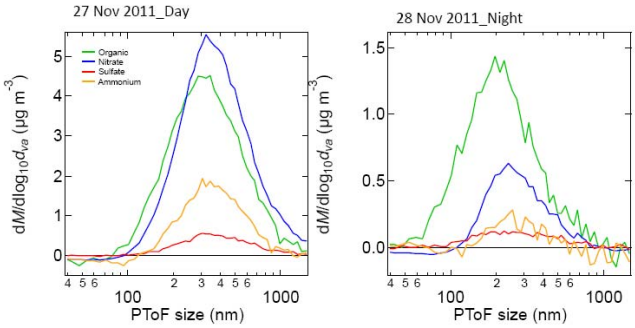

Figure 2. Mass speciation distribution on 27th November and on 28th November in SPC.

This research was conducted as part of the "Supersite" Project, which was supported and financed by Emilia-Romagna Region and Regional Agency for Prevention and Environment under Deliberation of Regional Government n. 428/10.

Bias caused by adsorbed water in standard gravimetric PM10 measurements

K. Imre[1], A. Gelencsér[2] A. Molnár[1] and V. Dézsi[3]

Presenting author email: kornelia@almos.uni-pannon.hu

Water is a highly variable but very often predominant constituent of atmospheric aerosol particles. The interaction between aerosol particles and water vapor plays a crucial role in many fundamental atmospheric processes. Adsorbed water may significantly increase the size of the particles which in turn enhance the extinction (mainly scattering) of visible light in the atmosphere. This is manifested in strongly reduced standard visibilities at high relative humidities.

The online measurement of PM10 mass concentration is carried out worldwide with instruments using the β-ray attenuation method (BAM). As a reference the gravimetric method (GMM) is widely accepted. The biggest uncertainty in the measurement of the PM10 mass concentration is caused by the fact that atmospheric water may significantly influence the mass and size of the aerosol particles.

In Europe, monitoring of PM10 is regulated by CEN standard (EN 12341), the β-ray absorption and gravimetry are the most widely used. Gravimetry is the reference method in the PM10 measurements. This method gives information about the aerosol concentration only after 48h, while beta-attenuation method provides data in high time resolution. According to the regulations, the gravimetric mass measurements are carried out at RH=50±5% and T=20±1°C. In both cases the water vapour content of the air and consequently the absorbed water can cause positive artefact during the sampling. This is the result of the hygroscopicity and hysteresis of the aerosol particles. As it is well known, at higher RH the particles can absorb the water vapour, therefore their size and mass can grow. On the other hand, when RH decreases the particles begin to lose the absorbed water. In the most cases this weight loss is less than the previous mass growth, due to hysteresis.

The aim of this work is to study the effect of water vapour on the aerosol mass measurement by both methods. First we tested the gravimetric method. Each filter (Whatman) was weighted before and after sampling to determine the aerosol mass on the filter. The sampling was carried out by a Hi-vol (Digital DH-80) sampler and a FH 62 IN (FAG) beta monitor. The experimental period was between 4 November 2008 and 18 March 2010 in a residential site in Budapest, Hungary. The hygroscopic behaviour of the aerosol particles were investigated in a chamber, where the RH was adjusted between RH=20% and RH=90%.

First we studied the water uptake of the aerosol particles from RH=50% to RH=90%. After the humidification, the RH was reduced back to 50%, and on the basis of the "remaining water mass" the effect of hysteresis was estimated.

Our results show that because of the hysteresis of the aerosol mass concentration can be overestimated by up to 16%. From these results we can conclude that the aerosol mass at RH=50% cannot be considered as dry mass. In order to verify it, the mass measurements were continued at lower (<20%) RH, this reduction resulted in further loss in the aerosol mass. The average aerosol mass deficit was 4.56%, while its maximum value reached 16.8%.

Finally, we concluded that the PM10 mass concentration measured at 50% RH can be overestimated by 2% to 17%. In Fig. 1 the degree of this overestimation is presented for the time interval of this study.

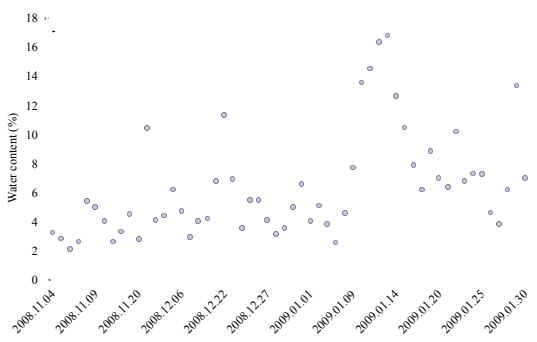

Figure 1. The water content of aerosol samples at RH=50% relative to RH=20%

Beta-attenuation is an online method and the sampling is usually carried out at ambient relative humidity. During the online measurement the aerosol particles are usually not conditioned and, as a consequence, most of their water content taken up from the atmosphere distorts the measurement. Heating of the sampling line is a possible solution to eliminate the error caused by the water content but this may lead to loss of volatile compounds. Therefore humidity correction should be applied on these data. The water uptake of the particles from the same period was measured between RH=20% and RH=95% and the mass growth factors were calculated ($GF=mass_{wet}/mass_{dry}$).

Chemical characterization of fine particulate matter collected in Budapest

T. Szigeti[1], V.G. Mihucz[1,2,3], M. Óvári[1,2,3] and Gy. Záray[1,2,3]

[1]Department of Analytical Chemistry, Eötvös Loránd University, Budapest, Hungary

Increasing amounts of harmful gases and particles emitted from different pollutant sources into the atmosphere represents a risk for human health and local environment. Recently, the increasing concern about air pollution in populated cities has required the monitoring of pollutants in atmospheric particles.

In the present work, a comprehensive chemical characterization of fine particulate matter (PM2.5) collected in Budapest (Hungary) was carried out. During the two-year-long sampling period, a high-volume aerosol sampler equipped with a PM2.5 head was used for the collection of the aerosol samples.

The monthly collected samples were taken onto quartz fiber filters. Seven parameters – PM2.5 mass, total carbon (TC) and water soluble carbon (WSC), occurrence of total and water–soluble trace elements, major anions and NH_4^+ – were used to characterize PM2.5 aerosol fractions.

Two types of sample preparation were applied: microwave-assisted *aqua regia* extraction and water extraction by sonication. In both cases, an inductively coupled plasma sector field mass spectrometer was used for the determination of the concentration of twenty-one trace metals (Bi, Cd, Co, Cr, Cu, Fe, Ga, Li, Mn, Mo, Ni, Pb, Pt, Rb, Sb, Sn, Te, Tl, U, V, Zn). Beside the trace metal content, the concentration of seven water-soluble anions (SO_4^{2-}, NO_3^-, Cl^-, CH_3COO^-, F^-, Br^-, NO_2^-) were determined by ion chromatography. A spectrophotometric method was used for the quantification of water-soluble NH_4^+. In order to get information about the organic content, the concentration of total and water-soluble carbons were determined by a C/N analyzator.

The mean PM2.5 mass concentrations was 23.0 μg/m^3, meanwhile the target value for this parameter set by the European Commission as annual mean value is 25.0 μg/m^3 to enter into force in January 2015.

The highest concentration values were observed for total carbon, which accounted for 20-50% of the total PM2.5 mass. The water-soluble part of TC was about 25%, thus about 10% of the PM2.5 fractions consisted of WSC compounds.

The highest average concentrations for the investigated trace elements were observed for Fe, accounting for about 75% of the total measured trace element content in Budapest. Trace metal concentrations in Budapest are similar to concentration data measured in other European cities. On average, the measured water–soluble part of trace elements typically constitutes about 20% of the total trace element concentration obtained. In the aqueous extracts, the highest concentrations were registered for Fe and Zn. Seasonal change of trace element concentrations was found in the case of crustal elements and some trace metals connected to anthropogenic source such as Cd and Pb in the total concentration and water-soluble fractions.

Sulphate and nitrate ions were the dominant anions in both cities. Seasonal changes in the NO_3^- and SO_4^{2-} were observed. Stoichiometric calculations demonstrated the contribution of sea salt–SO_4^{2-} to the PM2.5 aerosol fractions.

Monitoring of PM2.5 urban aerosol fractions is necessary because finer particles have a stronger impact on human health. This work can be considered a pilot study in Hungary since the PM2.5 aerosol fractions are not as regularly investigated as the PM10 fractions. Moreover, health limit values have not been yet set by the decision makers of the EU for the investigated elements. Therefore, the results of the present work obtained especially for trace elements are important because they could be useful for the EU decision makers in order to establish health limit values for the elements found in PM2.5 urban aerosol fractions. Comparing the obtained PM2.5 mass and concentration of the measured components with the results reported in other European cities, it can be concluded that Budapest is a moderately polluted city in Europe.

Presenting author email: bernhard.vogel@kit.edu

The spatial and temporal variation of selected aerosol and gas phase parameters is assessed in long term measurements for the Karlsruhe (Germany) area with an automated self calibrating mobile laboratory. As measurement platform a tramway (AERO-TRAM) operating in the public transport is used. Beside the gas phase components O_3, CO, CO_2, NO, and NO_x particle number density and particle number distributions are measured. For the year 2010 measurements on more than 2300 runs are obtained resulting in an extraordinary dataset for ground based mobile applications. The AERO-TRAM operates on two selected lines. Both lines connect the rural and suburban hinterland of Karlsruhe with the city centre. They are crossing areas with high concentrations of particles and trace gases and areas where only background concentrations are expected. Therefore, the obtained comprehensive dataset is useful for determining regional variation of particles and trace gases as well as for the identification of source areas.

The analysis of the measured number densities gives a concentration gradient between the city centre and the suburban areas of only 30 %. In comparison the NO_x concentrations are about 50 % lower in the suburban.

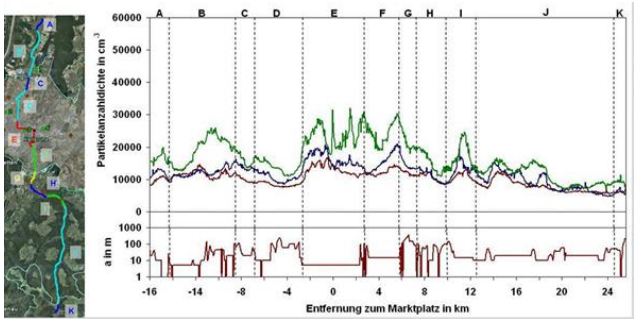

Figure 1. Median of the running mean of the particle number density for 2010 at different stability conditions. Green = stable stratification, blue = neutral stratification, red = unstable stratification (upper panel). Distance of the track to the next road (lower panel).

Figure 1 shows the distribution of the median of a running mean of number density for the year 2010 along the track and its dependence on the turbulence conditions. It can be seen that there is no remarkable gradient of the number densities between the distinct regions but the concentration level differs up to a factor of 2 in depending on the turbulence state of the atmosphere. This shows the difficulty of measuring an effect of emission reduction measures. Figure 2 gives the median values as a function of the wind velocity. As expected these concentrations are lower for the higher wind speeds but there is no uniform behaviour for the different areas. In the city centre there is almost no effect visible whereas in the northern vicinity the concentration level is considerable higher for the lower wind speeds.

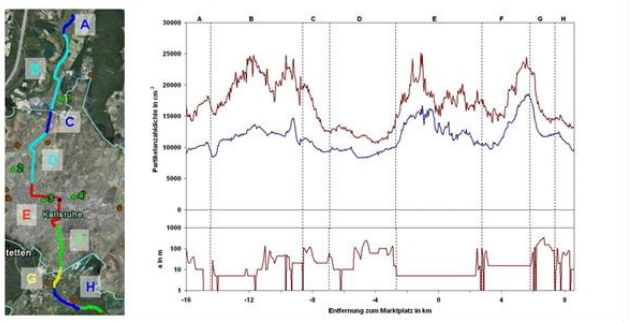

Figure 2. Median of the running mean of the particle number density for 2010 at different ranges of wind velocity. Red = 1-5 m s^{-1}, blue = > 5 m s^{-1} (upper panel). Distance of the next road (lower panel).

The investigation of the influence of the wind directions shows the impact of elevated single sources in the area on the number densities that so far could not be detected by the standard monitoring stations in that area.

Short-term variation in near-highway air pollutant gradients.

Keywords: UFP, PM2,5, Black Carbon, traffic
Presenting author email: patrick.berghmans@vito.be

Aerosol particles emitted from road traffic significantly contribute to high levels of air pollution and, at the same time, the population exposed to these particles is very large. Today, these particles represent one of the main sources of air pollution in the urban environment. Recent interest has focused on the health effects of ultrafine particles because of the documented toxicity and the larger concentration contrast near motorways of UFP than for PM10 or PM2.5. Air pollution due to vehicle exhaust at urban areas is known as local hot-spot pollution phenomena. Some previous studies reported the decreasing trends of particle concentrations within a few hundred meters apart from highways or freeways (Hitchins et al., 2000; Zhu et al., 2002). The Netherlands introduced guidelines, to prohibit siting new schools within 200 m of a busy road for protecting the health of students. Levels of UFPs are strongly influenced by traffic emissions and meteorological factors downwind of a highway (Zhu et al., 2002; Hagler et al., 2009). However, little is known about the relationship between traffic-generated UFPs and meteorological factors, such as wind speed, on highways. Studies have shown that concentrations of UFP as well as other primary vehicular emissions are elevated near highways but then decrease to background within several hundred meters primarily as a result of dilution.

As part of a study to assess the exposure risks related to particulate matter in the outdoor environment of a childcare centre nearby a highway in the centre of Antwerp city, particle mass concentration and number concentration were measured at both sides of the highway. One of the objectives of this study was to compare the contrast of UFP, PM(2.5) and soot (BC) measured simultaneously at 2 near-highway locations, in order to gain more insights in the causes of variations in the magnitude and extent of traffic-related pollutant gradients near highways. The results were compared with datasets from previous studies on urban monitoring where measurements were performed on several urban locations, a street location and a background location and data from the local air quality network at an urban background station.

The measurements at both locations included UFP (CPC 3783 and 3786, TSI), number concentration (Nanocheck, Grimm), black carbon (Aethalometer, Magee Scientific AE-42) and PM2.5 (Partisol, Thermo Instruments). Moreover, the meteorological conditions were also measured at one high-way location. During the campaign one measurement location was placed directly at the north side of the highway at about 100 m and one measurement location was placed about 50 m south of the highway. In this way it was possible to determine the air pollution from the highway traffic during periods with southerly wind direction. During southerly wind subtraction of the results from the two sites can be used to evaluate the concentrations resulting from the highway traffic alone.

The mean PNC at the high-way locations and the street location was significant higher than at a background location, indicating that vehicles exhaust considerable amounts of UFPs. For the entire measurement campaign the average particle number per cm^3 was a factor of 3 higher at the highway locations and a street location compared to a background location. The contrast was similar for soot concentrations. In PM(2,5) concentrations less contrast was found. Particle mass of PM2.5 originating from the highway traffic were estimated to be less than 10%. This is in agreement with other studies, which have shown that the long range transported fraction of the particle mass is relatively high. Consequently, the fraction of PM2.5 originating from the highway traffic is low.

Mean PNC concentrations were poorly correlated with PM(2,5) and soot. At the street location, higher temporal variation of PNC concentrations occurred within each sampling day compared to the highway sampling locations, probably related to variations in traffic volumes, high-emission of individual vehicles, wind direction and distance to the traffic. Temporal variation was smaller at the background locations.
According to the measurement results, high levels of UFP were observable at low wind speeds and high traffic volumes. For example, UFP levels can be $>5*10^5$ particles cm^3 during rush hours when wind speed is <0.5 m/s.

Continuous atmospheric measurements of speciated mercury (Hg) (elemental mercury (GEM), reactive gaseous mercury (RGM), and particulate mercury (Hg_p)) were conducted in Rochester, NY from Dec 2007 to May 2009. A large coal-fired power plant (CFPP) on the northwest side of the city was shutdown in the spring of 2008. This shutdown resulted in a significant reduction in observed concentrations of the mercury species, ultrafine particle (UFP) number and other pollutants (Wang et al., 2011a, 2011b).

Figure 1 shows the quarterly concentrations of the three mercury species over the measurement period. It can be seen that the concentrations in the winter of 2007-08 (December 2007 and January-February 2008) show higher concentrations than the subsequent quarters. These decreases are statistically significant and suggest that the shutdown beginning in late February 2008 resulted in a decline in measured Hg concentrations.

In this study, positive matrix factorization (PMF) model and conditional probability function (CPF) were then used to identify the CFPP source effects based on Dec 2007 to May 2009 hourly concentration mercury species, particles, gaseous species and meteorological variables. The impacts of the CFPP on mercury species were quantified as a part of an extensive project assessing the contributions of CFPP and traffic to air quality in Rochester, NY.

^{7}Be and ^{210}Pb in both bulk deposition and atmospheric aerosols from Southwest Spain

R.L. Lozano*, E.G. San Miguel and J.P. Bolívar

Department of Applied Physic, University of Huelva, Huelva, 21071, Spain
Keywords: ^{7}Be, ^{210}Pb, deposition velocity
*Presenting author email: rafa.lozano@dfa.uhu.es

Activity concentrations of ^{210}Pb and ^{7}Be in aerosols in surface air were measured at Huelva, (37°16'07" N, 6°55'27"W), from July 2004 to April 2010. Additionally, bulk surface depositional fluxes of both ^{7}Be and ^{210}Pb were determined over a period for 16 months (April 2009 - July 2010).

The sampling station was chosen at an urban site, at the border of the city of Huelva (population ~ 150000). Aerosol samples were collected from ~ 10 m above ground at the El Carmen campus of the University of Huelva. In addition, four drums were deployed for collection of the bulk deposition.

Aerosol samples (PM10 < 10 μm) were collected onto quartz fiber filters (QF20 Schleicher & Schuell, 25.4 cm x 20.3 cm) with high volume samplers at a flow rate of 40 cfm (68 m^3 h^{-1}). Samples were taken for 48 hours every fifteen days. The whole procedure applied to atmospheric filters can be seen elsewhere (Lozano et al., 2011).

Bulk depositional samples were collected by using 4 drums with a total surface area of 4120 ± 30 cm^2. Data of the precipitation were recorded from a meteorological station close to the sampling site.

^{210}Pb and ^{7}Be were determined by gamma spectrometry through their 46.5 and 477 keV photons, respectively. Gamma spectrometry measurements were performed using an XtRa coaxial Ge detector (Canberra), with 38% relative efficiency and FWHM of 0.95 keV at the 122 keV (^{57}Co) and 1.9 keV at the 1333 keV (^{60}Co). The detector is coupled to a set of standard electronics components, including a multichannel analyzer, and was shielded with 15 cm thick Fe shield.

The ^{7}Be monthly depositional flux ranges from 5.6 up to 186 Bq m^{-2} $month^{-1}$ (Figure 1), with the lowest deposition value occurring during the summer months (June and July) when there is no precipitation. On the contrary, ^{210}Pb monthly depositional fluxes were one order of magnitude lower than ^{7}Be, ranging from 0.8 to 10.9 Bq m^{-2} $month^{-1}$.

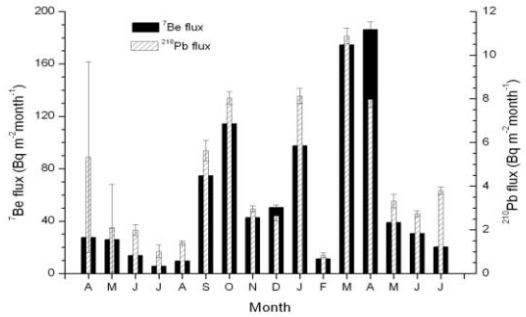

Figure 1: Monthly depositional flux of ^{7}Be and ^{210}Pb in Huelva, Spain

PM10 concentration ranged from 4.8 to 80.5 μg m^{-3} with a mean value of 34.9 μg m^{-3}. ^{7}Be in surface air ranged from 0.6 to 11.7 mBq m^{-3} with a mean of 5.1 mBq m^{-3}. The concentration of ^{210}Pb in aerosol samples ranged from 0.04 to 2.9 mBq m^{-3}, and a mean of 0.59 mBq m^{-3} (Figure 2). These ranges are comparable to those found in other coastal regions (McNeary and Baskaran, 2003).

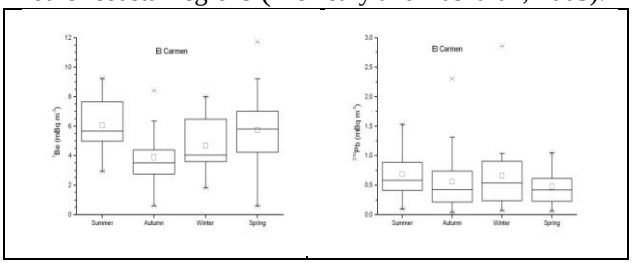

Figure 2: Concentrations of ^{7}Be and ^{210}Pb box diagram in Huelva, Spain.

The depositional fluxes and the atmospheric activity concentrations of ^{210}Pb and ^{7}Be have been used to determine the called "aerosol deposition velocity" at Huelva, which can be determined through the equation (e.g., McNeary and Baskaran, 2003):

$$V_d = F/C_s$$

F is the total flux of a nuclide to the Earth´s surface and C_s is the activity concentration of that nuclide in the surface air. The total deposition velocity for ^{7}Be ranges from 0.05 cm s^{-1} (July 2009) to 1.77 cm s^{-1} (April 2010), with a mean value of 0.50 ± 0.15 cm s^{-1}. Values for the total deposition velocity for ^{210}Pb vary between 0.06 cm s^{-1} (August – 09) and 1.33 cm s^{-1} (January – 10), with a mean value of 0.51 ± 0.12 cm s^{-1}. Deposition velocities obtained using these nuclides are quite similar. These data suggest that the ^{7}Be and ^{210}Pb have to be attached onto the aerosol particles by similar mechanisms.

The effect of winter salting on PM_{10} concentrations in the Rhine-Ruhr area

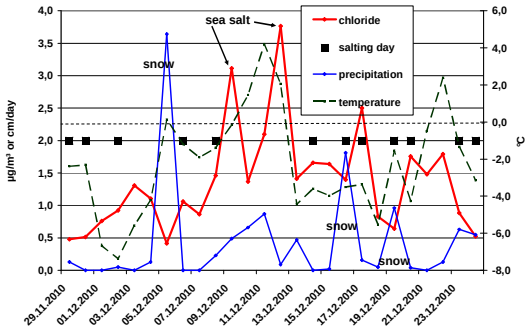
D. Gladtke, A. Olschewski, Th. Retny and P. Risthaus
North Rhine Westphalia State Agency for Nature, Environment, and Consumer Protection
45133 Essen, Germany
Key words: PM_{10}, winter salting, sea salt
Presenting author email: dieter.gladtke@lanuv.nrw.de

The winters 2009/2010 and 2010/2011 were relatively cold in central Europe. Even in the plains low temperatures and heavy snowfall caused massive traffic problems. Chemical analysis of PM10 samples from these winters was used to study the influence of winter salting on air quality and to determine how many days with exceedances of the limit values for PM10 could be neglected due to winter salting as it is described in EU Air Quality Directive 2008/50/EC (EC 2008).

A working paper of the European Commission (EC 2011) suggests to analyse the chloride concentration to identify the contribution of winter salting to PM10, if the composition of the chemicals used for salting is known. This method could well be applied in the Rhine Ruhr region because only sodium chloride was used for road salting in this area. Thus the contribution of winter salting to PM_{10} was calculated from the concentration of chloride in PM_{10}, after non salt chloride, estimated as the average chloride concentration during summer at days without a significant contribution of sea salt, was subtracted. Multiplication of the so evaluated salt derived chloride concentration by 1,65 resulted in the contribution of winter salting to PM_{10}. To check interferences caused by other sources of chloride the concentrations of calcium, potassium and trace metals as marker compounds for crustal material, combustion and industrial aerosols (Beuck et al. 2011) were also measureded. Only at three days these sources caused high chloride concentrations. Episodes with a high contribution of sea salt could be identified by back trajectories (Draxler et al. 2003). This made the separation of winter salting and sea salt possible.

Lists of days when roads were salted in 2009, 2010 and 2011 were provided by the municipal authorities. As figure 1 (see below) shows for a station at a highly frequented street canyon (Düsseldorf-Corneliusstrasse), the connection between these days (black squares) and salt concentrations (red line) is not clearly evident. The formation of sodium chloride aerosols after salting is a slow process strongly depending on meteorological conditions like temperature (green interrupted line) and precipitation (blue line).

Figure 1: Course of chloride concentration, precipitation, temperature and salt application days at Düsseldorf-Corneliusstrasse in December 2010



Aerosols from winter salting can spread several hundred metres, leading to slightly elevated salt concentrations also at background stations in the whole Rhine-Ruhr area. At these sites the annual contribution of winter salting to PM10 was 0,2 µg/m³ or lower, at traffic influenced sites it was about 0,5 µg/m³ in 2010. Even if these values are rather low compared with results from other areas (Diemer et al. 2011), 4 days with exceedances of the daily limit value of 50 µg/m³ for PM_{10} could be attributed to of the contribution of winter salting at 2 traffic influenced stations.

Composition and Source Identification of Ambient Single Particles on Haulbowline Island, Cork Harbour.

J. Arndt[1], R.M. Healy[1], D. Healy[1], L. Hacker[1], J.R. Sodeau[1] and J.C. Wenger[1]

Presenting author email: 104531485@umail.ucc.ie

Haulbowline, an island in the centre of Cork Harbour, Ireland, has been the subject of much environmental concern for the past two decades; until 2002 the island was the home of Ireland's heaviest industrial activity as the site for the Irish Steel plant. A 9 ha. (0.09 km^2) area on the eastern part of the island remains as a landfill for almost 500,000 tonnes of heavy metal-rich slag and other by-products of steel manufacturing (White Young Green, 2005). The island's location in Cork Harbour subjects it to marine, shipping and urban influences. The town of Cobh (over 11,000 inhabitants) is less than 1 km to the north and Cork City (over 200,000 inhabitants) is approximately 10 km to the north-west. Also in close proximity are a number of pharmaceutical plants and an oil refinery. The aims of this study were to investigate single particle composition and sources in this environment, with a particular interest in possible airborne particulate matter (PM) from the Irish Steel waste site.

To this end, an aerosol time-of-flight mass spectrometer (ATOFMS, TSI model 3800) was deployed on the island where it sampled ambient air for seven weeks in August and September 2011. Over 700,000 individual particle spectra were generated and then classified using the *K*-means algorithm. Based on their mixing state, size distribution and temporality, 14 major particle types were identified including; domestic coal, peat and wood combustion, shipping, sea salt, soil, traffic and several organic carbon types. Mass concentrations for each particle type were reconstructed using data from a Scanning Mobility Particle Sizer (SMPS, TSI model 3081). Also operating at the site was a Waveband Integrated Bioaerosol Sensor (WIBS-4) used for the detection and quantification of ambient fluorescent biological aerosol particles (FBAP) in the size range: ~0.5 - 13μm (Healy *et al*, 2012; Kaye *et al*, 2005). Where overlap was observed between the size measurement ranges of the WIBS-4 and ATOFMS techniques, comparisons were made to define the detected FBAP according to their chemical signatures/spectra obtained by the ATOFMS.

To establish if PM from the landfill was impacting the site, ion intensities for several metals, including As, Cd, Cr, Cu, Ni, Pb and Zn (White Young Green, 2008), were examined in terms of their temporality, wind dependence and correlation with the *K*-means particle types (Snyder *et al*, 2009). The majority of the metals exhibited dependences on wind directions associated with Cobh and Cork City, as well as similar temporality to several domestic combustion classes. This suggests that the metals detected by the ATOFMS were not associated with airborne PM from the Irish Steel landfill site. However, the ATOFMS was operated using an aerodynamic lens (TSI model AFL100) exhibiting relatively poor transmission efficiency for particles > 1 μm and therefore resuspended dust (a likely source of metals from the waste site) may not be detected as efficiently as submicron combustion particles.

This work was supported by the Irish Research Council for Science, Engineering & Technology. The authors would like to thank the Irish Naval Service on Haulbowline for access to the site and Met Éireann for providing the meteorological data.

Presenting author email: antonella.malaguti@enea.it

The aerosol produced by agricultural operations has significant contribution to the atmospheric aerosol loadings and, therefore, its impacts on visibility, climate forcing and human health should be considered.

This work shows the chemical composition and the morphology of agricultural aerosols produced during wheat harvest threshing, plowing, and wheat sowing. The aerosol was sampled with an 9-stage Andersen-Marple impactor with quartz filter and with a modified Millipore Swinnex 47 Polypropylene holder within the dust plume generated by the agricultural machines with teflo filter.

The aerosol sampling was carried out in three different periods: summer on 25 June 2009 for wheat harvest threshing, autumn on 7 and 8 October 2009 for plowing and winter on 17 November 2009 for wheat sowing. The sampling area is located near Comacchio Valleys (44 ° 36' 40.79" N - 12° 04' 10:52" E,-1m), in the Po Valley, in the north east of Italy, near Adriatic Sea.

The chemical composition of sampled aerosol was analyzed by the dissolution of the aerosol and the quartz filter in an acid mixture and analyzed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) (X Series spectrometer from Thermo Electron Corporation collision/reaction cell CCTED). The surface morphology and the elemental composition of the particles was studied on teflo filter by Scanning Electron Microscopy with an Energy Dispersive X-ray Spectrometer (SEM-EDS) (CARL-ZEISS EVO 40). The comparison of these two methodologies has allowed determining the markers of the natural sources of the aerosol.

The aerosol mass size distribution is different for the three agricultural operations under investigation: for plowing, the aerosol mass increases with the increase of aerosol size while for sowing and threshing has a second peak on the second and first impactor stage, respectively. Overall, the amount of aerosol produced is one order of magnitude higher during harvest threshing and plowing than during sowing.

The agricultural aerosol are mainly composed by organic particles and dust.

This work is part of the MINNI (Integrated National Model in support to the International Negotiation on Air Pollution) project, funded by the Italian Ministry of the Environment and carried out by ENEA.

ATMOSPHERIC FLUXES OF RADIONUCLIDES AT MALAGA (SPAIN)

C. Dueñas, M.C. Fernández, S. Cañete, E. Gordo and M. Pérez
Department of Applied Physics I, Faculty of Sciences, University of Málaga. 29071 Málaga (SPAIN)
E-mail: mcduenas@uma.es
Keywords: atmospheric aerosol, deposition, ^{7}Be, ^{210}Pb, precipitation

ABSTRACT.- Bulk atmospheric deposition of gamma radionuclides (^{7}Be, ^{210}Pb and ^{40}K) has been measured at Málaga (4º 28′ 80″ W; 36º 43′ 40″ N) a coastal Mediterranean station in the south of Spain, from January 2005 through December 2011 for monthly periods.

INTRODUCTION Berylium-7 is one of the radionuclide produced by spallation reactions of cosmic rays with light atmospheric nuclei.^{7}Be rapidly associates primarily with submicron-sized aerosol particles. Lead-210 which is one of the natural radionuclide of the ^{238}U decay series is widely used as a tracer. ^{210}Pb depositional pattern gave us information on continental aerosols in lower troposphere. These two radionuclides with their different sources and therefore are useful to understand the mechanisms of aerosol removal from the atmosphere. These radionuclides have measured routinely in many places of the word in order to study the description of environmental processes such as aerosol transit and residence times in the troposphere and aerosol deposition velocities . ^{40}K is found in most types of soil and can easily be transported by re-suspended material. Potassium is an important constituent of fertile soil and is an essential nutrient for plant growth and in the human diet. This nuclide have been previously associated with the arrival of coarse re-suspended material (PM10, particulate matter with diameter below 10 µm) from the African continent (Hernández et al., 2005b).

MATERIAL AND METHODS.- The sampling site is one of the environmental radioactivity monitoring network stations operate by the Spanish Nuclear Security Council (CSN). The sampling point was located above the ground, on the roof of the Faculty of Sciences, University of Málaga.
Monthly precipitation and dry fallout samples were routinely collected using a steel tray 1m^2 in area as a collecting system and polyethylene vessels of 50 l capacity for rainwater samples reservoirs. Measurements by gamma spectrometry were performed to determine the ^{7}Be and ^{210}Pb activities of the samples using an intrinsic REGe detector. The peak analysis of ^{7}Be (I= 10.52 %, 477.7 KeV) and ^{210}Pb (I = 4%, 45 KeV) was done using GENIE 2000 peak analysis software. The counting time was 172800s

RESULTS. The results from fluxes of ^{7}Be , ^{210}Pb and^{40}K were correlated with four parameters: rainfall amount, rainfall duration, number of dry days and number of wet days. The next table provides the correlation coefficients between the fluxes and the mentioned parameters.

	Flux ^{7}Be	Flux ^{210}Pb	Flux ^{40}K
Rainfall (mm)	0.81	0.88	0.66
Rainfall duration (min)	0.71	0.82	0.59
Nº of dry days	-0.45	-0.63	0.55
Nº of wet days	0.47	0.65	0.61

The fig. show the monthly fluxes of ^{7}Be and ^{210}Pb with precipitation. The depositions of ^{7}Be and ^{210}Pb were well correlated with the amount of rainfall. Such relations have been commonly observed and explained by the fact that rainfall constitutes the major depositional pathway of these radionuclides. As previously observed, correlation of rainfall with ^{210}Pb seems better than with ^{7}Be (Caillet el al., 2001) likely due to a relatively greater contribution of ^{210}Pb from dry deposition.

The importance of forest fires and dust on aerosol over Portugal's background

J.V. Monjardino, A.C. Carvalho, L. Mendes and F. Ferreira

Centre for Environmental and Sustainability Research - CENSE, Faculdade Ciências e Tecnologia, Universidade Nova de Lisboa, Almada, 2829-516 Caparica. Portugal

Keywords: Particulate matter exceedances, forest fires, dust, measurements, MACC reanalysis.

Presenting author email: jvm@fct.unl.pt

The determination of dust intrusions and forest fires emissions contribution to particulate matter (PM) concentration in the atmosphere is of great importance in all European Member States. In Southern European countries that is particularly important, due to their proximity to dust sources and to the high number of forest fires and area burned. These act as "grey sources" because the emitted amount of pollutants are strongly dependent on uncontrolled factors such meteorological, biological, and climatic.

The European Commission (SEC(2011) 208 final) accepted a methodology in order to quantify the natural sources contribution and to subtract exceedances attributable to them. Since 2005, Portugal and Spain have been jointly applying a common methodology to quantify daily African PM load during dust outbreaks (Escudero *et al.*, 2007), in the Iberian Peninsula, providing to their Environment Ministries reports that identify possible exceedances to the PM10 daily limit value caused by natural episodes. However, forest fires contributions' methodologies to account for their role in measured PM are still being refined.

The quantitative methodology presented in this paper is based on the analysis of time series of PM_{10} levels from regional background (RB) stations, representing Iberian Peninsula zones. In this sense, this work investigated the correlation between the RB stations and the remaining air quality network of the same zone for five Portuguese regions, for the year 2005. The authors started to study 2005, because it was the second highest year for area burned over Portugal in the last decade, and also due to the greater availability of PM measurements at the Portuguese RB stations.

Results have shown a good correlation for PM_{10} measured at RB stations and the rest of the monitoring network of each region, in dust events days (Figure 1). This allows the application of the quantification methodology. For cases where doubts were raised relating the origin of the air mass and the presence of dust influence the HYSPLIT back trajectory and cluster analysis were used at 500 m and 1000 m (Figure 1).

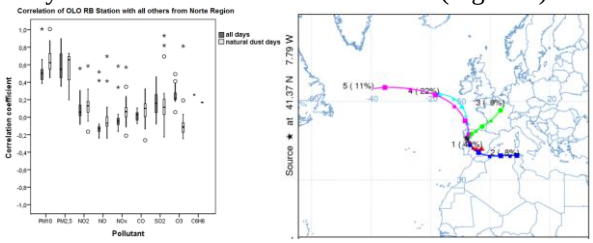

Figure 1: Correlation coefficients for OLO RB station for several pollutants, for all days and dust outbreak days, and HYSPLIT back trajectory cluster analysis.

In this work, the MACC reanalysis product of the global atmospheric composition (both on reactive gases and aerosols) was used to investigate which chemical species may be considered as predictors of aerosol large mode when all the biogenic and anthropogenic species are included into the MACC model (Stein et al., 2011; and Kaiser et al., 2011) over the area corresponding to the rural background station representativeness. The time series model results for CO, SO_2, NO_x, formaldehyde, organic, and black carbon into the two forms (hydrophobic and hydrophilic terms), large bin for dust and sea aerosol, over the MACC points near the rural backgrounds stations, were used in a step-wise regression, by month and MACC point, as possible estimators for the model aerosol large mode.

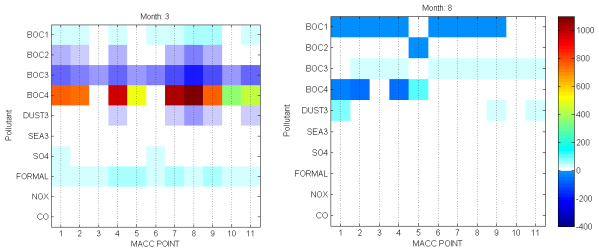

Figure 2: Step-wise regression coefficients for the MACC reanalysis over points near the RB air quality stations over Portugal, in March and August. Explanation: hydrophilic black carbon aerosol (BOC4), hydrophilic organic matter aerosol (BOC2), hydrophobic black carbon aerosol (BOC3) and hydrophobic organic matter aerosol (BOC1)).

As expected, different pollutants are considered as statistical significant estimators for the step-wise regression in different months. As an example, although formaldehyde could be considered an indicator for forest fire, it may not be an interesting indicator during months for high biological activity, as in Spring (March). During August, the more southern part of the country (points 9, 10 and 11) show positive coefficients for the larger dust bin, whereas in March the polynomial coefficient is negative over these areas. Higher values for the coefficients are obtained for the hydrophilic black carbon aerosol (BOC4), except for months were forest fires were active and devastating.

Keywords: sea salt, sulphate, methanesulphonate, Antarctic plateau,.
Presenting author email: udisti@unifi.it

In the period Nov 2004- Nov 2007, all-year-round aerosol was collected by PM10 and PM2.5 samplers and multi-stage impactors (4 and 8 stages, from 0.7 to 10 um) at Station Concordia (Dome C, East Antarctica, 75° 60' S, 123° 200' E, 3220 m a.s.l. and 1100 km away from the nearest coast).

Sea spray (marked by sea-salt Na) is a major component at DC, especially in winter, when it contributes 80-90% to the aerosol ion mass. In summer (Dec-Mar), ssNa is mainly in the coarse fraction (2.1-1.1 μm) at concentrations around 2-3 ng m^{-3}. In winter (Apr-Nov), the values are about 10 times higher, with a size-distribution shifted towards the sub-um fraction. The seasonal pattern of ssNa is explained by changes in the large-scale atmospheric circulation evaluated by synoptic-field analysis for the last 62 years. The 20 highest sea-spray events along the 3-year record were characterized by a weakening of the Polar High centre including DC (favouring advection of marine air masses), in relation with a deepening of the major sub-polar low over Ross Sea and its further expansion towards Vostok and DC. Such deepening resulted in a strengthening of the zonal winds along the coasts of east Antarctica, enhancing sea spray production. Back-trajectory analyses carried out for 8 major sea spray events revealed that size distribution is a function of air masses origin and lifetime over the Antarctic Plateau.

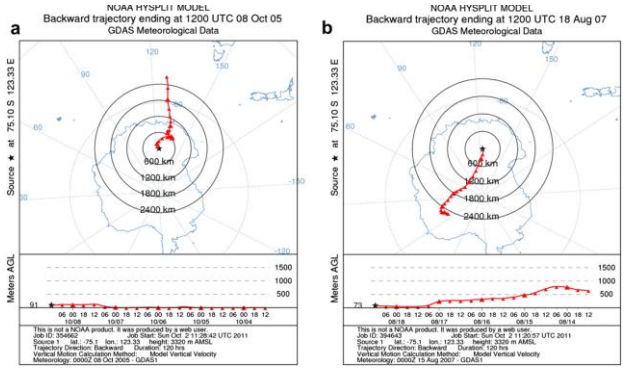

Figure 1. Backward trajectories for extreme ssNa concentration events with particulate distributed in the 2.5-1μm (a) and in the <1 μm (b) fractions.

Coarse sea spray is coming from the Indian-Pacific sector and their pathway over the Plateau is shorter. Sub-um particles are related to the transport over South Pole, probably coming from the Atlantic Sector and with longer Plateau trajectories (figure 1).

The different sea spray origin (from open sea areas or from sea ice surface) was also evaluated.

MSA and $nssSO_4^{2-}$, as markers of oceanic biogenic emissions, exhibit a seasonal cycle with summer maxima, but they show a different size distribution in early and late summer. In November, particles are distributed both in the accumulation mode (0.4-0.7 μm), and in the micrometric mode (1.1-2.1 μm). On the contrary, only the finest mode is present in February.

The two modes reflect a different speciation: acidic forms dominate in the finest mode, whereas MSA and $nssSO_4^{2-}$ are related to Na^+ or NH_4^+ salts in the micrometric particles. Such differences are related to different transport pathways. In the early summer, air masses arise mainly from Indian Ocean, where the sea ice margin is close to the coast and DMS is emitted at the interface air/sea. DMS is easily oxidised to H_2SO_4 and MSA by gas-phase reactions. In November, high velocity zonal winds over the coastal areas injects micrometric sea spray aerosol at high elevation, where it constitutes condensation nuclei for newly formed gas-phase H_2SO_4 and MSA, that form sodium salts. In February, by contrast, the gas to particle conversion of H_2SO_4 and MSA is dominant during the fast transport at high elevation of air masses coming from highly bio-productive oceanic sectors located as far north as 50 °S. This phenomenon leads to the highest concentrations of the acidic species over the whole year, with a distribution mode in the fine fraction of aerosols reaching Dome C.

Aerosols and trace gases have been measured at the Finnish Antarctic research station Aboa (73°03'S, 13°25'W) in Queen Maud Land during several summer campaigns but no comparisons with simultaneous measurements at the other stations in the region have been made. In this work we present data collected from Aboa during an International Polar Year campaign in December 2007 – January 2008 and compare them with data from the Norwegian station Troll (72°01′S, 2°32′E), approximately 540 km east of Aboa. At Troll there is a long-term monitoring program for aerosols and trace gases. Of these data we have here used the aerosol number size distributions, scattering coefficients, and surface ozone concentrations.

At Aboa aerosol number size distributions and volatility were measured in the size range 10 – 700 nm with a DMPS connected to a thermodenuder. Aerosol scattering and absorption were measured with 3-λ in situ instruments. PM1 filter samples and 12-stage impactor samples were taken for aerosol chemical composition. Gas-phase measurements were conducted with an ozone monitor and by taking daily canister samples. Ion concentrations were analyzed from the impactor and filter samples by ion chromatography at the University of Florence. Elemental and organic carbon and water-soluble organic carbon concentrations were analyzed from the quartz filter samples at Ghent University, Belgium. The canister air samples were analyzed for volatile organic compounds (VOCs) with gas chromatography at the Finnish Meteorological Institute.

Transport route calculations were done with trajectory models and more accurately by using a Weather Research and Forecasting model (WRF) model, modified for use in the Polar Regions. 3D wind data were measured with the Movable Atmospheric Radar for Antarctica (MARA) near the aerosol laboratory.

Light scattering coefficient showed similar temporal variation at both Aboa and Troll (Figure 1). Detailed analyses show that there are episodes when the peak first appears at Troll and 12-24 hours later at Aboa. Surface ozone concentrations at the two stations vary analogigally. Particles were clearly more volatile than ammonium sulfate in laboratory calibration and ambient aerosols at the SMEAR II forest site in Hyytiälä, Finland (Figure 2). The relationship between volatility and chemical composition will be discussed.

The MARA data and WRF model showed consistently that high wind speeds create turbulence and downward wind that brings gases and particles from upper atmospheric levels to the surface. This observation may probably be generalized to other Antarctic mountains and mountain ranges as well.

Aerosol number concentrations, size distributions and chemical composition have been studied at several stations around Antarctica. There exist long-term records of aerosol number concentrations, for instance from Neumayer and South Pole but aerosol number size distributions have been measured mainly during campaigns both at coastal stations and in the upper plateau at South Pole. The Norwegians recently started long-term size distribution measurements at the Troll station in Queen Maud Land (Hansen et al. 2009) but there are no long-term size distribution measurements from the upper plateau. The measurements presented here are the first step towards filling in this gap: particle number size distributions have been measured at the Dome C station (75˚S, 123˚E) in the upper plateau at about 3200 m amsl since December 2007. The size distributions in the size range 10 – 600 nm are measured with a differential mobility particle sizer (DMPS) and in the size range 0.3 – 15 µm with a Grimm Model 1.108 optical particle counter. They were first stopped at the end of year 2009 due to technical problems but they were continued again in December 2010, and the goal is to continue these measurements. In December 2010 also a new instrument, an Air Ion Spectrometer (AIS), that measures charged particle size distributions in the size range of about 0.4 – 40 nm, was installed at the station. The AIS produced good data until May 2011.

In addition to the size distributions, light absorption by particles has been measured at Dome C with a Radiance Research 3λ Particle Soot Absorption Photometer (PSAP). The PSAP reports absorption coefficients with a 0.1 Mm^{-1} accuracy. This is not good enough since most of the time absorption coefficients are below that at Dome C. Therefore all absorption coefficients were calculated from the raw signal and reference counts of the PSAP by taking long enough integration time between subsequent measurements of signal and reference. This makes it possible to get essentially indefinitely low detection limits – at the cost of time resolution, however (Springston and Sedlacek, 2007). The PSAP data processing also needs scattering coefficients. These are not being measured at Dome C. However, the measured size distributions in the size range 0.01 – 15 µm have been used to calculate light scattering coefficients in the same wavelengths as the PSAP measures. To do this a Mie code has been used, assuming spherical particles and varying refractive indices from that of sulfuric acid to ammonium sulfate and sea salt.

In this work we will present seasonal variation of the particle number and mass concentrations, modal structure of the size distributions, estimated light scattering and absorption, particle formation and growth and connections with the air masses. The modal structure of the size distributions was studied a with an automatic mode-fitting algorithm. Growth rates during the particle formation episodes were calculated.

There was a clear seasonal cycle in the number concentration data. The concentrations were at their lowest around July and August and at highest around January, which is in agreement with the data from all other stations in Antarctica. In the sunlit seasons there were from one to three modes in the size distributions, in the darkest period mainy only one. Strong new particle formation events were rare and only happened in summer when there is plenty of solar radiation available. However, a careful analysis of the size distribution data shows that these events did occur all year round, even in the darkest and coldest months June and July. These events were weak but not nonexistent, which is a new and interesting phenomenon, not reported earlier from the upper plateau of Antarctica.

The median scattering and absorption coefficients in the period when the DMPS, the OPC and the PSAP were all operational are presented in Table 1. The scattering coefficients and thus also the absorption coefficients in Table 1 were calculated using the refractive index of sulphuric acid (n_r = 1.426).

Table 1. Median scattering (σ_{sp}) and absorption (σ_{ap}) coefficients at the PSAP wavelengths in Dome C in December 2007 to November 2009.

	467 nm	530 nm	660 nm
$\sigma_{sp}(Mm^{-1})$	0.31	0.25	0.17
$\sigma_{ap}(Mm^{-1})$	0.019	0.017	0.015
ω_0	0.94	0.94	0.92

Li-ion secondary cells are one of the most advanced energy storage systems currently available as it provides one of the highest energy-to-weight ratios. Due to the high energy density of Li-ion batteries, they offer the best route for many advanced storage applications related to clean electricity (Hall and Bain, 2008). However, new commercial applications, such as hybrid and full electric vehicles, place increasing demands on specific capacity, power density, rate capacity and cycle life of the energy storage devices (Du Pasquier *et al.*, 2003; Wen *et al.*, 2008).

Lithium titanium oxide ($Li_4Ti_5O_{12}$, LTO) is recognized as a promising material for the negative electrode of Li-ion batteries as it is cheap and safe, and has an excellent cycle life (Du Pasquier *et al.*, 2003; Ohzuku *et al.*, 1995). However, the major drawback of LTO is its low electronic conductivity. To overcome this problem the particle size can be reduced to the nanoscale increasing the specific surface area, and decreasing the diffusion lengths within particles and the local current density (Arico *et al.*, 2005). For LTO an optimum size of about 17 nm has been reported (Kavan *et al.*, 2003). However, the current method of solid-state chemical reaction typically produces LTO particles with a diameter of the order of 1 μm. Another solution is to use metal dopants (e.g. Cu, Ag) (Wang *et al.*, 2009; Huang *et al.*, 2006). Currently the doping is typically carried out in a separate process which increases the complexity and costs of the production.

Here, pure and doped LTO nanoparticles are prepared in the gas phase with flame spray pyrolysis (FSP). It is a fast, dry, and single-stage process that enables the preparation of materials with high-purity (Mädler *et al.*, 2002). The precursor solution used for the studies contained lithium acetyl acetonate and titanium isopropoxide in mixture of toluene and 2-ethyl hexanoic acid (1:1). The silver and copper doping was performed by adding, respectively, silver and copper 2-ethyl hexanoic acid directly into the precursor solution. Finally, a vertical flow aerosol reactor was used to increase the high-temperature residence time and thus the crystallinity of the particles.

The resulting particles were found to be high-purity (99%), single crystalline nanoparticles with a primary particle size down to 10 nm. A uniform dopant distribution was observed in the doped LTO nanoparticles. The silver dopant nucleated independently and deposited on the surface of the LTO particles. The copper doping, on the other hand, reacted chemically with the LTO forming a double spinel structure (Karhunen *et al.*, 2011). Both dopants were found to improve the electrochemical performance of the LTO at high C-rates.

Presenting author email: d.kilian@lfg.uni-erlangen.de

Flame spray pyrolysis (FSP) is a versatile, easy to handle and cost-effective way for the production of nanoscale materials. Especially the synthesis of oxide materials can be carried out under atmospheric conditions. The high product purity and the possibility of mixing of several precursors for easy doping or production of compound materials (Teoh et al., 2010) makes FSP a promising technique for the production of electronic materials, namely insulator and semiconductor nanoparticles.

One application for semiconducting materials are low cost printable electron devices like thin-film transistors (TFTs) deposited from nanoparticulate dispersions. For the fabrication of TFTs, the synthesized nanoparticles are suspended into a liquid used for coating or printing the active semiconducting thin films, which are then integrated into TFT devices. To date, only n-type semiconductors have been reported for solution processed inorganic oxide semiconductors in TFTs. Therefore, the development of p-n junctions and thus p-type TFTs is a major goal, as this would lead to the fabrication of complementary metal oxide semiconductor (CMOS) structures. Fortunato presented results based on sputtering deposition of cuprous oxide Cu_2O (Fortunato et al., 2010) at room temperature leading to p-type TFTs. As sputtering is a cost-intensive technique alternative ways as described above for TFT processing are of special interest.

In this work the synthesis of p-type semiconducting CuO and mixed-phase Cu_2O/CuO is carried out by flame spray pyrolysis. After synthesis, the particles are collected by a filter unit and particle size, crystallinity and phase composition are analyzed by SEM, TEM, XRD and gas sorption methods as a function of process parameters. The focus of the work lies especially on formation of Cu_2O nanoparticles under atmospheric conditions. Copper Oxide in oxidation state Cu (I) is favored for electronic applications due to its lower intrinsic charge carrier concentration minimizing leakage current in TFTs. Furthermore, Cu_2O shows a higher charger carrier mobility than CuO favoring this material for transistor applications.

By properly adjusting the process conditions, it is possible to achieve either pure CuO or a mixed phase of Cu_2O/CuO nanoparticles. The phase diagram suggests that the flame temperature significantly influences the oxidation state of copper. In Fig. 1 a scanning electron microscopy (SEM) picture of copper oxide is shown. As typical for flame processes the particles show strong sintering.

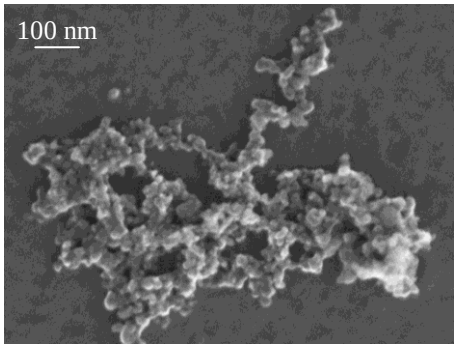

Fig. 1. SEM picture of CuO nanoparticle aggregate synthesized by flame spray pyrolysis

By gas sorption analysis of different samples specific surface areas between 40 – 140 m²/g can be achieved. Furthermore we could successfully synthesize mixed phases of CuO/Cu_2O under atmospheric conditions as it can be seen in the XRD diffractogram (Fig. 2).

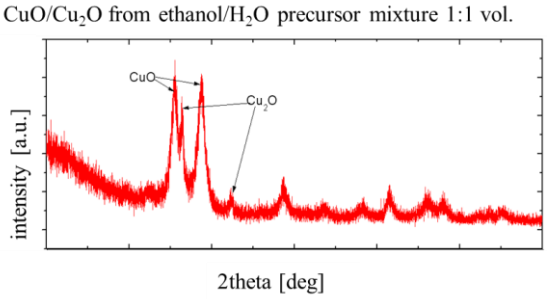

Fig. 2. XRD diffractogram of a mixed phase Cu_2O/CuO thin film on a SiO_2/Si substrate

First electric performance tests show significant p-type gating at low current levels and moderate off-state leakage.

Aerosol-derived antimony doped-tin oxide nanoparticles and studies on the influence of organic and inorganic shells in nanoparticle assemblies on the overall conductance

S.B. Bubenhofer[a], C.M. Schumacher[a], G.A. Sotiriou[b], R.N. Grass[a] and W.J. Stark[a]

Presenting author email: s.bubenhofer@chem.ethz.ch

Transparent conductive oxides are of high interest for transparent electrodes in solar cells or liquid displays and for infrared-reflecting applications. The most common material is indium doped tin oxide showing a high conductivity and transparence. Nevertheless a change to other doped tin or zinc oxides was driven in the last years by the low abundance of indium on earth.[1] Furthermore, the need to overcome the traditional vacuum deposition methods for more cost efficient and moreover even flexible devices, led to intensive investigation on nanoparticle film processing.

Good film forming behavior in nanoparticle deposition methods, as spin coating or dip coating, is based on highly stabilized dispersions, where normally surfactant molecules are added or a functionalization of the particles is necessary. The introduction of such impurities in the films, which cannot always be removed by heat post-treatment (flexible polymer substrates: temperature sensitive) mostly leads to an decrease in conductivity in the overall nanoparticle assembly.[2]

We therefore present the high temperature, aerosol synthesis of antimony doped tin oxide nanoparticles and a systematic study on the influence of organic and inorganic shells on the overall conductivity of assembled nanoparticles.[3] Flame spray synthesis was used as scalable and cost efficient process to produce high purity antimony doped tin oxide with a highly controlled dopant content.[4] The as-prepared particles were coated with three different organic surfactants using common dispersing processes. For comparison to well-known insulating shell thickness, additionally particles with in-situ coating of SiO_2 were produced.[5]

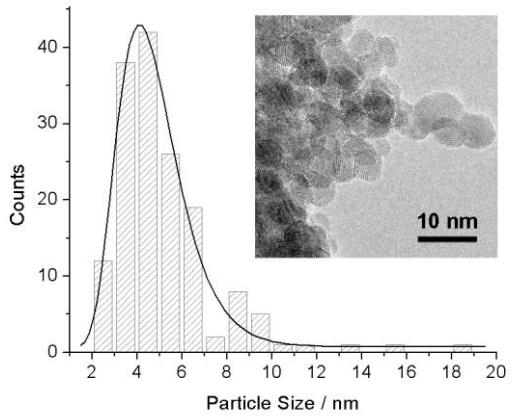

Figure 1. Antimony doped tin oxide nanoparticles produced by high temperature, aerosol flame spray synthesis.

The electron transport through the nanocomposites was tested for both organic and inorganic shell materials by measuring the electrical resistivity of pressed pills. Pure conducting nanoparticles, thin organic shells as well as thin, probably only partially coated SiO_2 shells showed a clear decrease in resistivity under pressure load due to irreversible compaction of the powder. However, thick polymer shells showed a relaxation of the resistivity when the pressure was decreased. For insulating SiO_2 shells of similar thickness the same reversible behavior in resistivity was observed and we could therefore describe this effect by electron tunneling through the insulating shell. The compression of the shell led to a decrease in thickness and therefore a higher electron tunneling probability.[6]

These findings on the influence of impurities such as surfactants or processing aids on the electron transport in assembled nanoparticle systems are important for improving the production of low cost, high performance electronics.

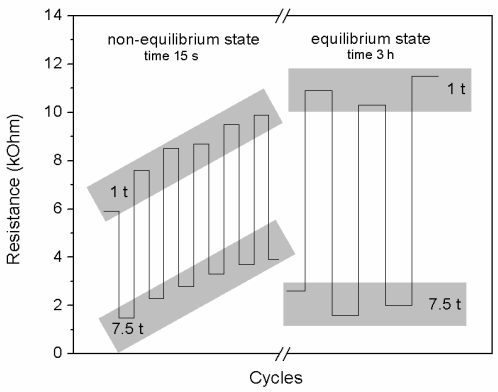

Figure 2. Reversible resistivity of polymer coated antimony doped tin oxide nanoparticle due to electron tunnelling probability changes under pressure cycles.

Size controlled flame synthesis of CuO nanoparticles for Li-ion batteries

O. Waser[1], A. Güntner[1], M. Heß[2], P. Novák[2] and S.E. Pratsinis[1]

[1]Particle Technology Laboratory, Department of Mechanical and Process Engineering, ETH Zurich, CH-8092 Zurich, Switzerland
[2]Electrochemistry Laboratory, Paul-Scherrer-Institute, CH-5232 Villigen PSI, Switzerland
Keywords: Nanoparticle production, Flame spray pyrolysis, Oxides nanoparticles, Copper$^{(II)}$oxide, Li-ion battery
Presenting author email: oliver.waser@ptl.mavt.ethz.ch

Recent developments in Li-ion batteries (e.g. $LiMn_2O_4$, $LiFePO_4$ or $LiCo_{1/3}Ni_{1/3}Mn_{1/3}O_2$) lead to enhanced performance or safety compared to the most commonly used $LiCoO_2$. All these insertion type materials, however, show an intrinsic barrier towards higher specific capacity, as their accessible Li-sites are limited before irreversible crystal structure changes occur. It is therefore believed that a substantial breakthrough in battery energy density necessitates a different concept of Li-ion storage materials (Cabana et al., 2010). Conversion type materials are considered as such a higher energy density alternative since lithium directly undergoes electrochemical reaction with a transition-metal compound, allowing multi-electron redox reactions with the general reaction equation (Li et al., 2011):

$$CuO + 2\ Li \rightarrow Cu + Li_2O$$

Copper oxide is thereby an attractive active material as it is inexpensive, relatively non-toxic, and offers about 2-fold higher theoretical energy density (1010 Wh/kg) than the currently used cobalt oxide (540 Wh/kg).

Flame spray pyrolysis (FSP) is a versatile and scalable technique for synthesis of mixed oxides, metal salts and even pure metals in the form of nanoparticles or porous films with closely controlled characteristics (Strobel & Pratsinis, 2007) including active materials ($LiMn_2O_4$, $Li_4Ti_5O_{12}$, $LiFe_5O_8$) for batteries (Ernst et al., 2007) and recently also in-situ acetylene carbon black coated $LiFePO_4$ (Waser et al., 2011). Characteristically for FSP synthesis, the primary-particle size can be easily controlled, offering ideal conditions for size-effect analysis in various applications.

In this work, pure CuO (copper$^{(II)}$oxide) nanoparticles of closely controlled primary particle diameter are made by the continuous and scalable FSP technique. The resulting particles were analyzed by X-ray diffraction (XRD), nitrogen adsorption (BET), transmission electron microscopy (TEM) and electrochemical performance testing as Li-ion battery material in composite electrodes vs. Li-metal.

The BET equivalent diameter (d_{BET}) of the CuO primary particles grows from 6 to 20 nm by increasing the ratio between precursor solution feed rate and dispersion O_2 flow rate. Enclosing the FSP flame with a quartz tube inhibits flame quenching by air entrainment, hence, increasing the particle diameter to 50 nm as a result of intensified sintering at higher temperature and higher precursor concentration (Teleki et al., 2006). Size control by precursor solution to dispersion gas flow rate variation, however, is not significant anymore, underlining the importance of air entrainment for size variation in open-FSP.

The FSP-made CuO particles show high initial discharge capacity (Fig. 1, diamonds) that scales inversely with CuO size and reaches a maximum of 1450 mAh/g for the smallest 6 nm CuO (d_{BET}). Outstanding reversible capacities of 930 and 800 mAh/g are obtained for intermediate CuO sizes of 20 and 50 nm, respectively, where larger (commercial) CuO of 670 nm (d_{BET}) shows only 450 mAh/g. The smallest particles (6 and 11 nm), however, encounter pronounced capacity degradation within few cycles only that may be attributed to electrical contact loss due to the strong volume changes upon conversion reaction.

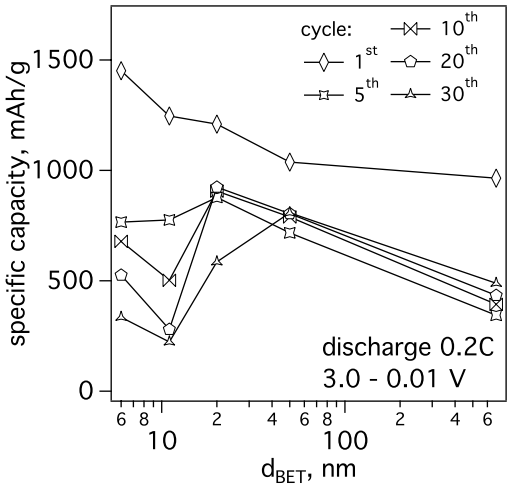

Fig. 1 Specific discharge capacity of FSP-made CuO nanoparticles of 6, 11, 20 and 50 nm in comparison to commercial CuO of 670 nm (d_{BET}).

IrO_2 is routinely used as oxygen evolution catalyst in proton exchange membrane (PEM) water electrolyzers. The commercially available Ir catalysts may have nanosized grains, but the overall particle size is in the micron scale. Since iridium is rare and very expensive, producing the catalyst in nanosize could reduce costs by enabling lower catalyst loadings.

In this work, IrO_2 and $Ir_xRu_yO_z$ nanoparticles were produced by two aerosol methods; chemical vapour deposition (CVD) and flame spray synthesis (FSP). Previously Ir catalysts have been manufactured by wet methods. (Marshall et al. 2006, 1134-1140).

For characterisation of the catalyst material, the onset potential of oxygen evolution was measured with a rotating disk electrode setup (RDE). The limiting current was measured by voltammetric sweeping in 0,5M H_2SO_4 at room temperature. For the electrolyzer, an ink is made of the catalyst powder which is then printed on Ti felt. This step may be overcome with the FSP technique as the catalysts may be directly collected on Ti felt.

In the CVD method, $IrCl_3$ and $RuCl_3$ were dissolved in dilute HCl in various proportions. The liquid was sprayed with atomiser to air flow in tubular furnace (500-1100°C). The precursors evaporated and reacted with air to form Ir, Ru, their oxides and mixtures of these. The flow was quenched with nitrogen and analysed with scanning mobility particle sizer (SMPS) and Fourier transform infrared spectroscopy (FTIR). All catalysts were studied by transmission electron microscopy (TEM) and X-ray diffraction (XRD). Particles were collected on gold substrates by electrostatic precipitation for measurement of the onset potential and limiting current.

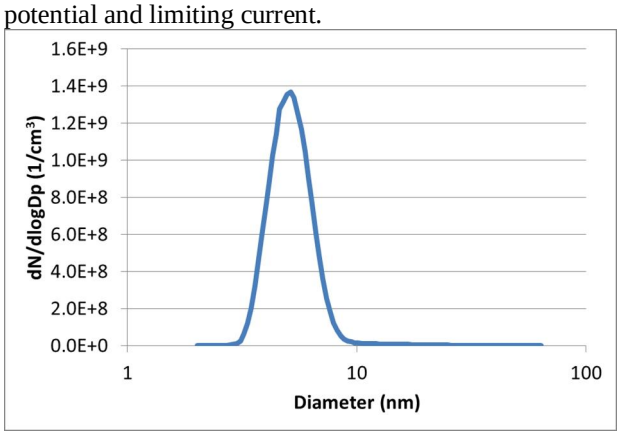

Figure 1: The DMA size distribution of IrO_2 particles produced by CVD.

The CVD IrO_2 particles had number average diameters of 5-10 nm (Figure 1 and Figure 2). The onset potential was 1450 mV and limiting current 27 mA. Ihe Ir-Ru mixture particles were significantly larger, 10-40 nm and had crystal size of 14 nm. Ruthenium species with higher vapour pressure caused the ruthenium

For FSP, $Ir(acac)_3$ and $Ru(acac)_3$ precursors were dissolved in ethanol-acetic acid mixture in several proportions. The liquid precursor was sprayed to methane flame. The formed particles were collected directly on quartz substrates and Ti-felts. The Ti-felt was well covered by the particles and could be directly used in electrolyzer experiments. The flow was also analysed by fast mobility particle sizer (FMPS).

The size distribution of the FSP catalysts was relatively wide and particle size was 10-100 nm (Figure 2). The particles were amorphous as collected and were heat-treated before catalyst tests. After heat treatment, the crystal size of the particles was 5 nm. The onset potential was 1460-1490 mV and limiting current 27-29 mA.

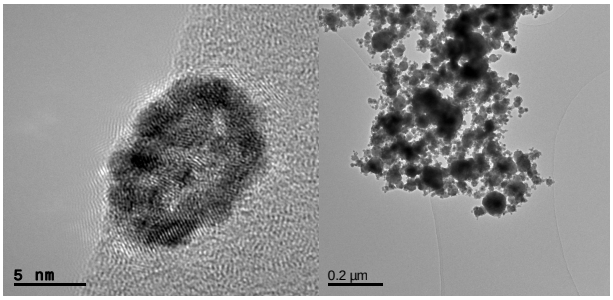

Figure 2: Left: IrO_2 particle produced by spray pyrolysis. Right: Ir_3RuO_8 particles produced by FSP .

Multimineral supplementation with nano-CaO as carrier matrix

J.T.N. Knijnenburg[1], F.M. Hilty[1,2], M.B. Zimmermann[2] and S.E. Pratsinis[1]

[1] Department of Mechanical and Process Engineering, ETH Zurich, Zurich, CH-8092, Switzerland

Iron deficiency (ID) is a health problem affecting approximately 2 billion people worldwide (Zimmermann and Hurrell, 2007). It is one of the most common micronutrient deficiencies, not only in developing countries but also industrialized countries are affected. ID adversely affects cognition and may cause fatigue and reduce work performance. Supplementation of iron was shown to be cost-effective to relieve ID (Wieringa *et al*, 2007).

Solubility (and therefore bioavailability) of iron compounds can be improved by increasing its specific surface area (SSA), i.e. decreasing its particle size to the nm range. Recently Rohner *et al* (2007) have prepared nanostructured $FePO_4$ by flame spray pyrolysis (FSP), where the SSA was as high as 195 m^2/g (~11 nm particle size). This iron phosphate has high solubility i.d.a. (a good predictor of potential in-vivo bioavailability) and is as bioavailable as $FeSO_4$ (the "gold standard") in rats.

Zinc deficiency (ZD) negatively affects growth and immune function, and ZDs often exist in the same areas as ID. Thus Hilty *et al* (2009) developed nanostructured iron/zinc compounds with nutritionally valuable amounts of zinc by FSP. The addition of zinc increased iron solubility i.d.a. and (as shown recently) bioavailability comparable to $FeSO_4$ (Hilty *et al*, 2010).

Very recently we have shown that the incorporation of calcium into nanostructured iron oxide increases iron solubility (Hilty *et al*, 2011) and potentially also bioavailability (Hilty *et al*, 2010) compared to pure iron oxide. For high dopant contents the solubility was comparable to $FeSO_4$. The increase in iron solubility is a result of the formation of a solid solution, decreasing the average bond energy of the crystal.

Here, nanostructured calcium oxide-based supplements are developed as carriers for iron/zinc fortification. Calcium oxide doped with nutritionally relevant amounts of iron and/or zinc was produced in one step with FSP. The mineral composition of the supplements was based on their Recommended Dietary Allowance (RDA) values, given for iron (8 mg), zinc (11 mg) and calcium (1000 mg) for males 19-50 years (Otten *et al*, 2006). Since significantly more calcium is required than iron or zinc, materials with a composition based on these RDA values mainly have the properties of calcium.

Solubility i.d.a. was very high for each of the elements, indicating these compounds should have very high in-vivo bioavailability. Particle size was found not to affect dissolution (Figure 1), in strong contrast to pure Fe_2O_3 where the solubility is strongly size-dependent. Calcium/zinc oxides showed the formation of a solid solution by measuring the unit cell volume. This is in contrast to the CaO-ZnO phase diagram where no such solid solutions are found.

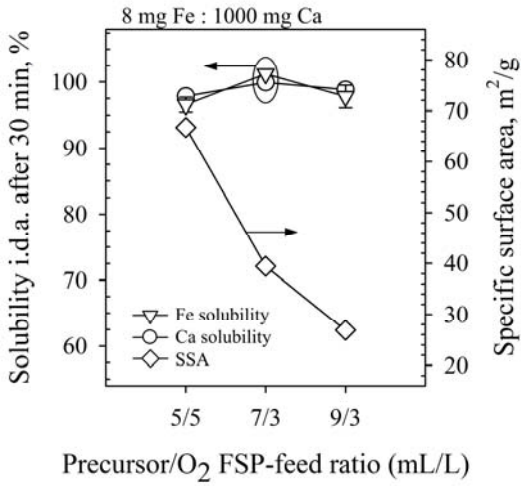

Figure 1. Specific surface area (diamonds), and iron (triangles) and calcium (circles) solubility as function of precursor/O2 FSP-feed ratio, of Ca/Fe oxide. Increasing the precursor/O_2 FSP-feed ratio decreases SSA, which does not influence calcium and iron solubility i.d.a.

Flexible superparamagnetic-plasmonic nanocomposite films with flame-made fillers

Georgios A. Sotiriou, Christoph Blattmann and Sotiris E. Pratsinis

Particle Technology Laboratory, Institute of Process Engineering, Department of Mechanical and Process Engineering, ETH Zurich, Sonneggstrasse 3, CH-8092 Zurich, Switzerland
Keywords: polymers, nanoparticles, iron oxide, silver.
Presenting author email: blattmac@student.ethz.ch

Polymer composites combine the desired functionalities of the host matrix and the inorganic fillers in sensors, optoelectronics, artificial muscles, optical components [1], to name a few applications. The addition of the filler may enhance a certain property of the matrix such as increased Young's modulus [2] and thermal stability or introduce new ones like luminescence and magnetism [3]. This class of materials is not new; polymer composites exist for many years, with perhaps the most well-known ones the automobile tires reinforced with carbon-black, giving them their characteristic color and durability. The superior performance of composite materials has prompted extensive research on both the invention of new types that exhibit unprecedented functionalities, and methods to improve and optimize their manufacturing [4].

When the dimensions of inorganic fillers are reduced to nanoscale, composite properties improve significantly and typically, much less filler is needed to achieve superior performance [1]. For example, the mechanical strength of silicone rubber improves progressively for smaller fillers [2]. The use, however, of nanosized fillers involves a major pitfall; they are difficult to be dispersed homogeneously in a polymer matrix without filler agglomeration [4].

An attractive functionality that can be induced to polymers by filler particles, is superparamagnetism [5]. Such polymers are typically made by embedding superparamagnetic iron oxide nanoparticles in the matrix. The resulting nanocomposites capitalize on the polymer flexibility and can be actuated by an external magnetic field with potential applications in biosensing (lab-on-a-chip) [6], controlled drug-release [7]. For most of these applications a homogeneous dispersion of nanoparticles in the polymer is crucial since formation of large agglomerates can deteriorate the final performance.

Here, a novel fabrication technique of inorganic/polymer nanocomposites is developed by flame-synthesis of nanofillers [8]. This technique allows for fabrication of free-standing multilayer films with tunable thickness composition and functionalities (e.g. superparamagnetic-plasmonic and -phosphorescent), surface smoothness at high filler-contents without formation of large agglomerates. The present fabrication technique can employ a large variety of nanoparticles [8,9] and polymers. In addition it is fast, highly reproducible and scalable [10], facilitating the commercialization of such nanocomposites.

Electrospray deposition of graphene nanosheets

L. B. Modesto-Lopez[1], O. V. Bilousov[2], J. J. Carvajal[2], F. Díaz[2] and J. Rosell-Llompart[1,3]

Graphene, a 2-D nanomaterial with unique properties (Zhu et al, 2010) is an attractive optically transparent conductor for optoelectronic applications (Blake et al, 2008). Particularly, graphene thin coatings may be used as saturable absorbers, to develop ultrafast pulsed laser technology (Cho et al, 2011). Recently, Chu et al (2010) electrospray-deposited single walled carbon nanotubes, a close relative of graphene, for use as saturable absorbers in the 1.5 μm region, although they can also be used in the 2 μm emission range (Cho et al, 2009). Electrospray is a liquid atomization method that leads to highly charged, nearly monosized micro- and nano-droplets, which has been applied to create thin films and coatings (Jaworek, 2007; Modesto-Lopez & Biswas, 2010). The small droplet size combined with the low flow rate characteristic of electrospray may be ideal to control the film thickness. In addition, the electrostatic control implies a virtual 100 % deposition efficiency. To our knowledge, however, no reports exist yet on the use of electrospray for depositing graphene films.

Therefore, the purpose of this study is to characterize the deposition patterns of graphene onto flat substrates as a function of electrospray operating parameters and to identify conditions leading to layer-by-layer deposition.

Graphene oxide (GO) was synthesized by oxidizing graphite with potassium chlorate in an acidic medium. GO was filtered and washed several times with HCl and distilled water until reaching a neutral pH of the filtrate. Graphene was then prepared by reduction of GO with iron. The obtained graphene nanosheets were filtered and washed with distilled water and ethanol, and then dried at 100 ºC for over 12 h in vacuum. Figure 1a shows a SEM image of a multi-layered graphene particle. Each layer is formed by hundreds of graphene nanosheets, which cannot be observed by SEM. The nanosheets exfoliate individually when suspended in ethanol, as can be seen by TEM (Figure 1b). Graphene was also characterized by Raman spectroscopy and XRD (Figures 1c and d, respectively).

In the electrospray-deposition experiments, graphene nanosheet powder suspensions were prepared in dimethylformamide (DMF). The suspensions were stable over many hours, allowing for sufficient time to carry out depositions. Electrospray was performed solely in the cone-jet mode. Highly stable spraying was obtained at a liquid flow rate of 1 μL/min and applied voltage of 4.4 kV for suspensions of < 0.5 wt % (relative humidity 39 %, temperature 24 ºC).

Electrosprayed graphene nanosheets were collected onto quartz substrates, and their optical characteristics (including linear and nonlinear transmission, nonlinear response dynamics for saturable absorption, saturation fluences, modulation depths and nonsaturable losses) are studied as a function of electrospray-deposition time and initial suspension concentration.

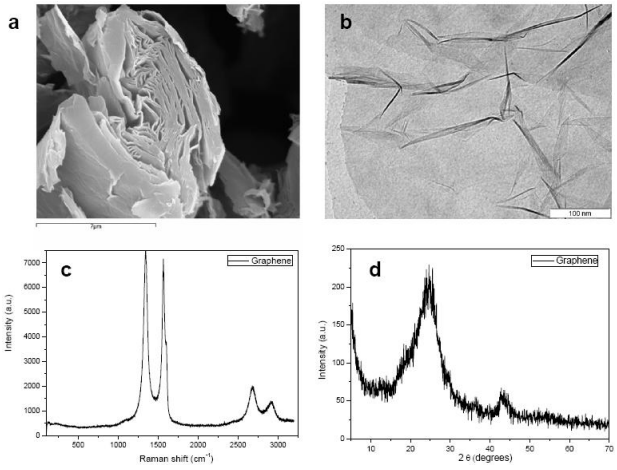

Figure 1. a) SEM of dry graphene layered structure, b) TEM of two superimposed graphene nanosheets, c) and d) Raman and XRD spectra of graphene, respectively.

A MEMS sensor based personal sampler for ultrafine particles

S. Merzsch[1], H.S. Wasisto[1], E. Peiner[1], I.Kirsch[2] and E. Uhde[2]

[1] Institute of Semiconductor Technology (IHT), TU Braunschweig, Braunschweig, Germany
[2] Dep. Material analysis and indoor chemistry, Fraunhofer Wilhelm-Klauditz-Institut, Braunschweig, Germany

Presenting author email: erik.uhde@wki.fraunhofer.de

In the production of consumer goods and building materials the use of nanomaterial as additives becomes more and more common. High-tech applications like printed electronics and solar-cells as well as daily life products like toothpaste and cosmetics are enhances by addition of e.g. TiO_2, ZnO, carbon spheres or tubes, and silver particles. Especially in the production environment, where large amounts of nanomaterial is handled and substantial exposure is possible, monitoring of the air quality is an important issue in respect to further use of this technology. In the production industry, a demand for personal monitors to assess the exposure of workers towards these particles undoubtedly exists (Tsai et al, 2011). Unlike a conventional particle counter, such a device must be small and lightweight, and the sensor and the electronics must be simple enough to allow a mass production at low costs.

Simple collection of the particles on filters or impactors offers an affordable solution to this, but requires complex laboratory analysis and can cannot provide timely warning in case of increased concentrations in the surrounding environment.

A MEMS (micro-electromechanical system) based approach was proposed to weigh extremely small particles (Hajjam 2010). This concept was developed further to design a particle detector for use in personal monitors. A joint project (NANOEXPO) examines the possibility of use thermally excited cantilevers as sensors for ultrafine particles. The project aims towards developing a small personal dosimeter-like sampler that collects and weighs ultrafine particles over a work shift.

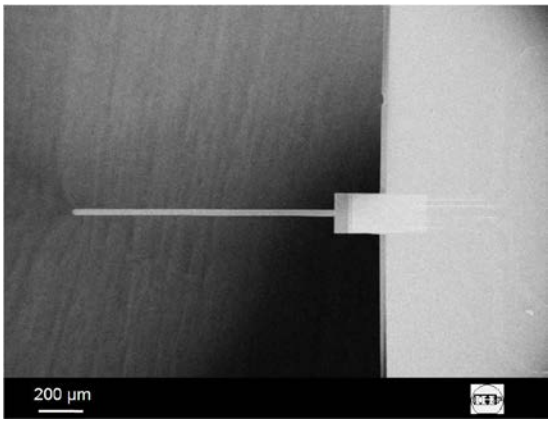

Figure 1. The cantilever sensor.

A slender geometry (Figure 1) allows for a very sensitive detection of particles impacting on the cantilever. After manufacturing the first prototypes of the sensor, and providing proof-of-principle measurements, work is on-going to further improve the sensitivity of the microbalance, to integrate part of the excitation and sensing electronics, and to construct a sampler case with defined flow field around the sensing cantilever.

The following section highlights a number of achievements of the project at the current state.

Results

Cantilevers of different sizes and geometries were tested in regard to their particle collection and sensing efficiencies. Current experiments are carried out with silicon-based cantilever-type resonators with fully integrated Wheatstone bridge piezo-resistors for signal read out.

To test the microbalances, test aerosols were generated in a 1 m³ environmental test chamber by nebulizing a suspension of e.g. carbon nanoparticles (< 30 nm) in water/butanol using a constant output atomizer (TSI 3076), followed by a dryer. Particle number concentration and size distribution is controlled by a fast mobility particle sizer (FMPS, TSI 3091). To improve the collection efficiency, the sensor was mounted on a nanometer aerosol sampler (TSI 3089) – at later stages, the collection voltage will be supplied by the sampler electronics.

Using the second resonant mode, a mass sensitivity of 32.7 Hz/ng was found. Detection limits of less than 1 ng can be achieved with current prototypes under climatic standard conditions and normal pressure.

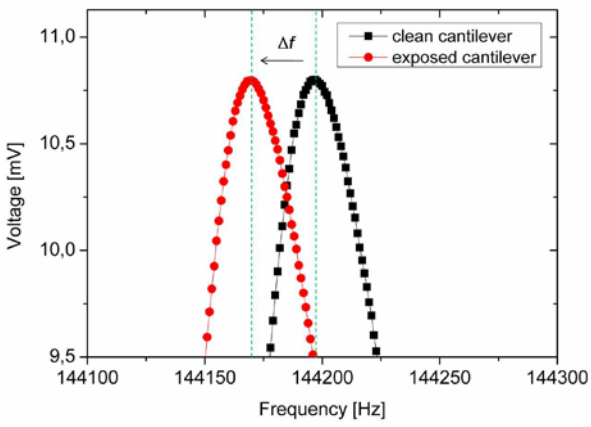

Figure 2. Frequency shift measured with a prototype cantilever (black line: clean cantilever; red line: exposed to carbon aerosol (5000 #/cm³) for 15 min.

Particles were collected predominantly at the tip and along the edges of the cantilever (Figure 3). An improved design of the field around the cantilever will be used to increase the sampling efficiency and to focus the particles deposition to the tip of the cantilever.

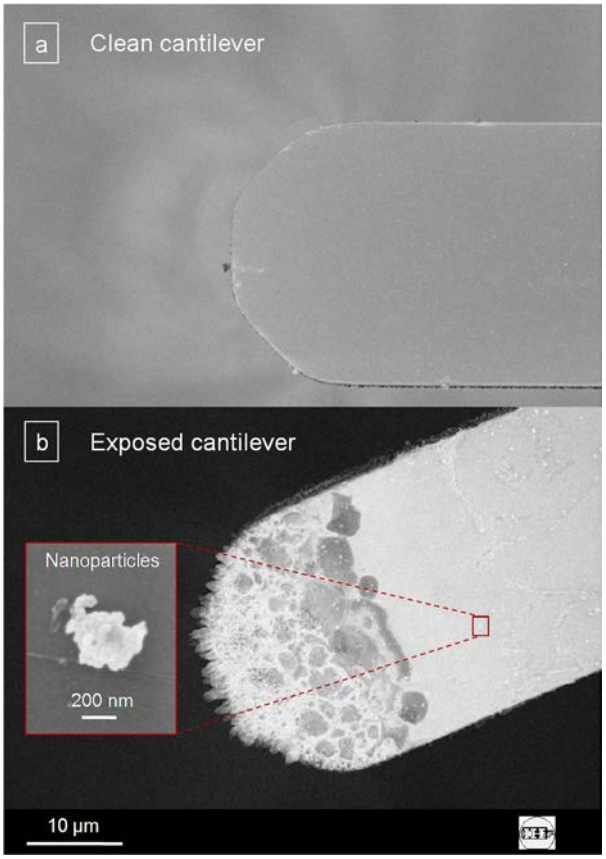

Figure 3. Cantilever tip (a) before and (b) after exposure to airborne carbon particles.

In a next step possible climatic interferences on particle sensing were studied: Temperature and relative humidity were expected to impact on the performance of the sensor. Variation of pressure, temperature and relative humidity during operation of the sensor revealed a minor cross sensitivity: Temperature changes of 2 K, pressure changes of 20 kPa, and relative humidity changes of 10 % during the measurement cycle would lead to an uncertainty of 15% with the current prototypes (Wasisto et al., 2012). Slower climatic changes that extend over several measurement cycles are less critical. Considering a measurement cycle time of only 15 to 30 min, the cross sensitivity is not critical for the workplace environment.

Currently, a sensor case with integrated fan is designed and tested. The main development targets are an optimized air supply to the sensor and a defined electrical field to improve particle collection (Figure 4).

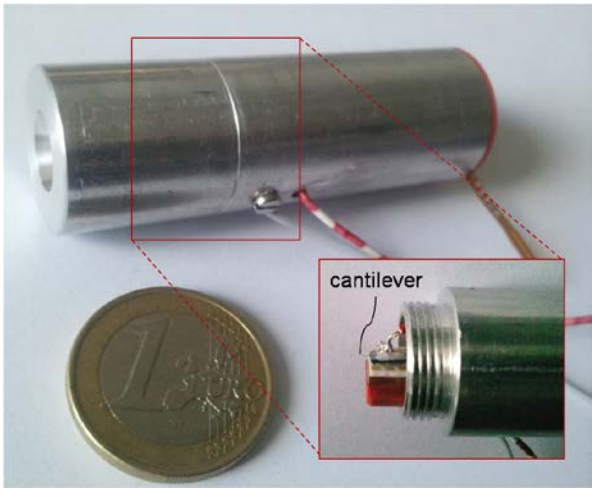

Figure 4. The sensor case with integrated fan.

Conclusion

At the current development stage the microbalance-detector prototypes show a mass-sensitivity sufficient to allow for 15-minute measurement cycles if the (preferred) second resonant mode is used for sensing. A mass resolution below 1 ng can be reached under typical indoor conditions, and the cross-sensitivity in regard to environmental changes is in an acceptable range. Evaluation the performance of the sensor towards a selection of industrially relevant nanoparticles (TiO_2, Silver, Carbon, SiO_2, PTFE) is still on-going, and a number of integration steps have to be finished before the sensor/sampler can be tested under more realistic conditions.

In a collaboration of the University of Minnesota, TSI Inc. and BASF, the Universal NanoParticle Analyzer (UNPA) was recently developed (Zhun et al., 2012) with the goal of providing an instrument for the analysis of the structure of nano-sized particles. In order to obtain information about the morphology of gas-born particles, the dependence of diffusion charging on the particle structure is utilized. According to Chang's theory for non-spherical particles (1981), the mean charge per particle can be calculated and compared to the mean charge of a spherical particle. This comparison gives evidence about the particle structure. The UNPA contains a DMA classifying particles according to their mobility diameter. The screened aerosol is split into two flows which pass a CPC and a NSAM in parallel. Therefore the particle number concentration and a current, depending on the particle charge which is linked to the particle structure, are measured. The ratio of both is termed "sensitivity" and allows conclusions regarding the particle morphology. Once the sensitivity and size is known, the theories of Lall and Friedlander (2006) and Wang et al. (2010) can be applied to calculate the primary particle size of loose agglomerates. Potential s of the UNPA are accelerating new ENP product development process monitoring. Due to its short measurement time, sensitivity data can be obtained quasi-online.

The aim of the studies was to test UNPA's structure detecting capability. The test particles were made of SiO_2 synthesized by chemical vapor synthesis which would optionally be followed by chemical vapor deposition in tube furnaces.

Three experimental setups were utilized. The purpose of the first approach was the investigation of the primary particle size of agglomerates. For this agglomerates were generated and fed into the UNPA. From the sensitivity data of differently sized agglomerates, the UNPA software was able to calculate the primary particle size. In order to verify the results delivered by the UNPA, small angle x-ray scattering measurements on filter-collected agglomerates were carried out. Furthermore TEM images were analyzed. Good agreement between the three independently determined values was found. In a second approach, spherical particles and agglomerates were mixed and analyzed with UNPA to examine the impact of mixed structures on the sensitivity. To get an idea of the measured particles and to support the interpretation of the sensitivity data, TEM images of sampled particle were taken. Since the sensitivity data of a mixture of particles can be distinguished from those of spheres and agglomerates, an effect of mixture on sensitivity was detected. In a third set of experiments Pt-coated SiO_2 spheres were analyzed to investigate whether the UNPA is able to detect even small surface textures, indicating that particles are not completely spherical. Here different degrees of coating were compared, starting from pure spheres, to lightly and heavily coated supports. Again TEM pictures of the coated particles were consulted. The measurements allow for a correlation between the sensitivity and the degree of coating. The flow patterns of the second and third experimental setups are shown in figure 1.

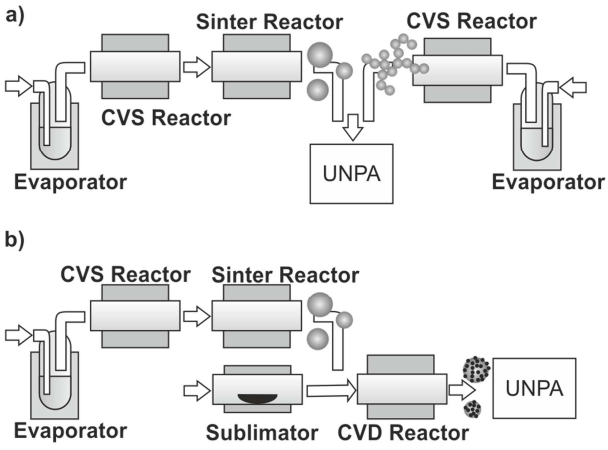

Figure 1: a) Flow pattern of the spherical particles and agglomerates mixing experiment b) Flow pattern of the coating experiment

Gas-borne nanoparticles generated at high temperatures undergo coagulation forming agglomerates (physically-bound particles) and aggregates (chemically- or sinter-bound particles). The structure of such particles influences their transport, light scattering, effective surface area and density. Significant advances have been made in characterization of agglomerates (physically – bonded particles) by employing fractal theory and relating agglomerate structure to its generation pattern through the mass fractal dimension, D_f. The D_f values have been developed for agglomerates of *monodisperse* primary particles. For coagulating aerosols, however, this needs to be carefully examined as Brownian coagulation leads to polydisperse particles (Eggersdorfer and Pratsinis, 2012). Furthermore, once coalescence or sintering starts between these primary particles, sinter necks are formed between them converting the agglomerates to aggregates.

Real-time characterization of nanoparticles is necessary for continuous monitoring of aerosol manufacturing and airborne pollutant particle concentrations, but is still challenging (Scheckman *et al.*, 2009). Mostly ex-situ methods have been used to characterize such structures in terms of agglomerate mass, mobility and radius of gyration, D_f, primary particle diameter and number and specific surface area (SSA). Figure 1 shows a sphere, an aggregate (Eggersdorfer *et al.*, 2011) and agglomerate (Eggersdorfer and Pratsinis, 2012) having the same mobility diameter, d_m, but different mass and surface area. So measuring only one particle property is not sufficient to characterize those structures.

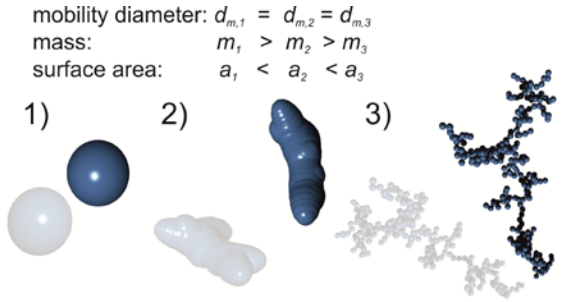

Figure 1. Snapshots of simulated nanoparticle structures: 1) sphere, 2) aggregate & 3) agglomerate.

Here, zirconia nanoparticles are generated by a scalable flame spray process and are characterized in almost real-time with their mass and mobility diameter. The mobility diameter is measured by a differential mobility analyser (DMA) and the mass by an aerosol particle mass (APM) analyser to determine the mass-mobility exponent (D_{fm}). Additionally, a new relation (Eggersdorfer *et al.*, 2012) between surface area mean primary particle diameter, aggregate/agglomerate mass and mobility diameter is used to extract the surface area mean primary particle diameter or SSA from these data. The effect of oxygen flow (Fig. 2) and precursor feed rate as well as precursor concentration on agglomerate/aggregate structure and primary particle diameter are investigated. Good agreement between ex-situ nitrogen adsorption (BET), transmission electron microscopy (TEM) and on-line DMA-APM is found for all investigated process conditions.

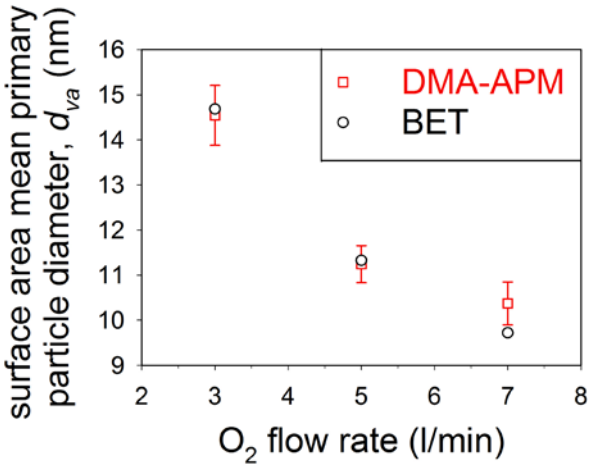

Figure 2. Effect of oxygen flow rate on the surface area mean primary particle diameter measured by ex-situ BET and on-line DMA-APM measurements using a new correlation (Eggersdorfer *et al.*, 2012b).

Determination of soot size distributions from spectra extinction measurements: a feasibility study

C. Caumont-Prim[1], J. Yon[1], A. Coppalle[1] and K.F. Ren[1]

[1]UMR 6614 CORIA, Avenue de l'université, BP 8, 76801 Saint Etienne du Rouvray, France
Keywords: soot particles, fractals, soot size distribution, extinction.
Presenting author email: chloe.caumont@coria.fr

The size of nanoparticles in aerosol is currently monitored by using low pressure impactor (ELPI) or differential mobility analysis (SMPS / DMS…). These techniques are expensive and need an aerosol's sampling. Optical techniques under development can also be used to infer size distribution in situ by interpreting scattered light (DLS or SLS). These techniques are generally difficult to implement in industrial applications (car exhaust, control of nanomaterial processes of production…).

A simple and cheap method consists in analyzing measurements of the spectrally resolved extinction of the light by particles. This last method has been successfully used for determining size distributions for polystyrene spherical particles using a commercial spectrometer and a white light source in the visible range (Ren, et al., 2009). For non-spherical particles, extinction spectrum must be interpreted thanks to an adapted light-particle interaction theory. For example, in case of soot particles (which are fractal aggregates (Jullien and Botet, 1987)), the Rayleigh Debye-Gans theory for Fractal Aggregates (RDG-FA (Dobbins and Megaridis, 1991)) can be used. This has been done to determine the soot optical properties (Yon, et al., 2011) knowing the soot size distribution. We propose to test the potential of extinction spectral measurements as a mean to determine soot size distributions.

The RDG-FA theory uncouples absorption and scattering effects for the calculation of light extinction by soot particles:

$$K_{ext} = C_{abs} M_{abs} E(m) + C_{sca} M_{sca} F(m), \qquad \text{(Eq. 1)}$$

Where $M_{abs} = \int_0^\infty N_p N^{agg}(D_g) dD_g$

And $M_{sca} = \int_0^\infty N_p^2 g(R_g, \lambda, D_f) N^{agg}(D_g) dD_g$.

In these expressions, the research size distribution is expressed by $N^{agg}(D_g)$; *E(m)* and *F(m)* are respectively absorption and scattered functions, which depend on *m*, the optical index of soot ($m = n(\lambda) - ik(\lambda)$). D_g, N_p and D_f are parameters which describe size and morphology of the soot; finally C_{abs} and C_{sca} are functions of the primary sphere diameter and wavelength.

The RDG-FA model is incorporated into the inversion procedure developed by Ren (Ren, et al., 2009) in order to find size distribution of non-spherical particles. Spectra extinction measurements have been done on an ethylene diffusion flame, at different height above the burner. The measured extinction spectral was determined applying the Beer-Lambert law on measured transmitted light, $K_{ext} = -\frac{1}{L}\ln\frac{I}{I_0}$ (where L is the length of the extinction bench, I_0 the reference intensity without particles, and *I* the measured light intensity with particles). From these measured extinction spectra, the new inversion procedure is applied allowing determination of a soot size distribution. Figure 1 presents soot size distributions at 8 cm above the burner determined by two ways: inversion of spectrum extinction measurements and Transmission Electron Microscopy pictures analysis (TEM analysis).

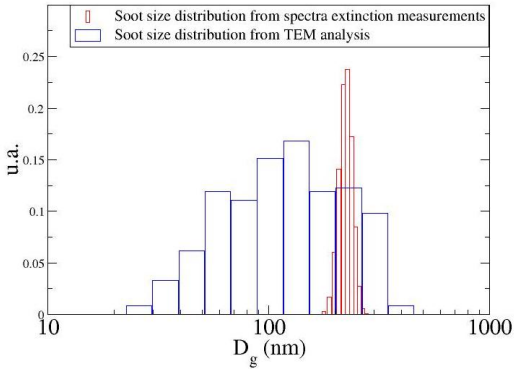

Figure 1 Soot size distributions at 8 cm above the burner in an ethylene diffusion flame

The two results seem very different especially for standard deviation. Soot size distribution found by inversion of the extinction signal is very thin in comparison with the one found by TEM analysis. As shown in Eq. 1, interpretation of extinction spectra needs the knowledge of morphological parameters and spectral optical index. Literature gives a lot of different values and expressions for *E(m)* and *F(m)* (Yon, et al., 2011). Furthermore, information about size distribution is contained in scattering contribution whereas absorption is devoted to the global volume fraction of the aerosol and the absorption term is often more important than the scattered term. That could explain the difficulty to invert and so the difference between the two soot size distributions.

So, a parametric study on optical index and morphological parameters will be presented in order to show if aggregates soot size distributions found from the extinction spectra measurements are reliable.

Conductivity for Soot Sensing: Possibilities and Limitations

B. Grob[1], J. Schmid[1], N. P. Ivleva[1] and R. Niessner[1]
[1]Chair for Analytical Chemistry, Technical University of Munich, Munich, Bavaria, 81377, Germany
Keywords: electrical conductivity, raman microscopy, soot reactivity, real-time detection

It is a matter of common knowledge that aerosol particles have a significant influence on the climate, environment and human health. Especially in urban areas soot particles emitted by diesel engines, pose a health risk. Current and upcoming limits require a removal of diesel soot particles, which is mainly accomplished by ceramic wall-flow diesel particle filters (DPF). Due to increasing back-pressure the DPF has to be regenerated periodically by gasification of the deposited soot. Thereby the efficiency of the regeneration step is affected by the oxidation reactivity of the deposited soot, which mainly depends on the microstructure of the soot particles. Since the DPF has to be controlled to avoid malfunctions, cheap and reliable tools are demanded for an on-board diagnostic system (OBD). A very promising attempt is the detection of particles by a conductometric sensor (Malik, 2010). Moreover, the conductance is strongly affected by the microstructure, which opens the possibility to use the conductometric sensor method also as a simple cheap and rapid analytical tool for characterization of soot structure.

In our study we want to give a perspective about the possibilities and the limitations of the electrical conductivity measurement for soot sensing. The sensor principle is based on measuring the electrical resistance of deposited particles between interdigitated electrodes. Therefore we developed a thermophoretic precipitator to deposit the particles on an oxidized silicon substrate with a structured 1µm thick AlSiCu layer (Figure 1). The thermophoretic precipitation system could be already tested under real-world conditions in a serial car with a Euro VI diesel engine. Thereby the sensor was validated by a AVL Micro Soot Sensor (photoacoustic aerosol sensor), which has been installed parallel in the car. As shown in Figure 2 the signals of the Micro Soot Sensor and the interdigitated electrodes agreed very well.

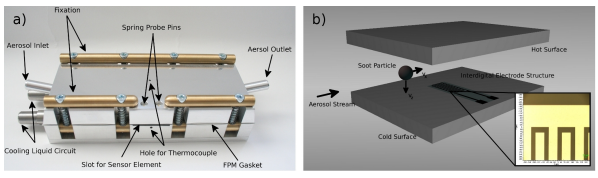

Figure 1: Thermophoretic precipitator with a cooled and heated plate (a) and a slot for a conductometric sensor with interdigitated electrodes (b).

Beside the on-road tests various basic laboratory experiments have been performed. Different commercial available carbon blacks and spark discharge soot were pressed into pellets and the electrical conductivity was determined by a van der Pauw arrangement (van der Pauw, 1958). The results were compared with the standard methods for structural (Raman microspectroscopy) and reactivity (temperature programmed oxidation) analysis (Sadezky, 2005, Schmid, 2011, Grob, 2012). It was shown that the conductivity of carbon materials varies over four orders of magnitude and is strongly influenced by the microstructure.

Moreover the influence of inorganic impurities in the soot matrix was investigated by mixing different materials (which can be found probably in the emitted particles of a combustion engine, i.e. $Fe_2O_3, TiO_2, SiO_2, (NH_4)SO_4, CaO, CaSO_4, MgSO_4, ZnO$) with graphite powder. The samples with varying mass concentrations were milled and compressed to get a thinly dispersed mixture. The composites showed a percolation behaviour with a sharp increase of the conductivity at a critical mass fraction of several orders of magnitude.

With this study we open the way for further research to use a conductometric sensor as a cheap, simple and rapid analytical tool for soot real-time detection and soot structure and reactivity characterization.

Concentrations of particles emitted during spraying of product with silver nanoparticles

Jankowska E. and Łukaszewska J.

Department of Chemical and Aerosol Hazards, Central Institute for Labour Protection – National Research Institute, Czerniakowska 16, 00-701 Warsaw, Poland
Keywords: silver nanoparticles, emission, number and surface concentrations, mass concentration.
Presenting author email: joluk@ciop.pl

The aim of the investigation was to determine the parameters of particles emitted to the air during spraying commercially available Product for Glass Cleaning (PGC) from Nano SILVER.

Investigation were done in the chamber with diameters 3x4,7x2,3m with ventilation switch-off. Before measurements ventilation was switch-on (from 12:25 to 12:37) for the time in which quite stabile background concentrations of particles were received. Spraying of PGC were conducted (from 12:38 to 15:34) seven times for the 10s on the surface located in the distance 52cm from the sampling points. After spraying of PGC ventilation was switch-on (from 15:35 to 15:53) for removing from the chamber air particles emitted during spraying PGC.

A following parameters of particles were determined: number concentrations (P-TRAK and GRIMM), surface concentration (AERO-TRAK) and mass concentration (DUST-TRAK).

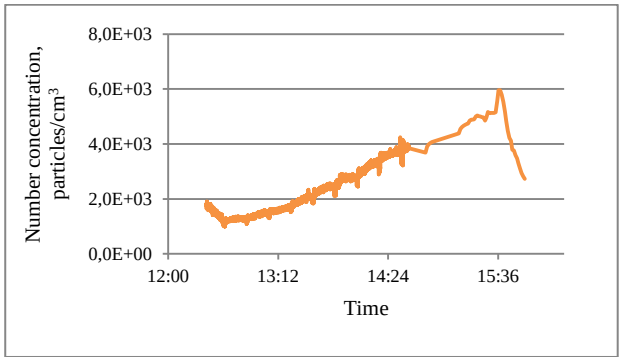

Figure 1. Number concentration of particles 20-1000nm (P-TRAK results).

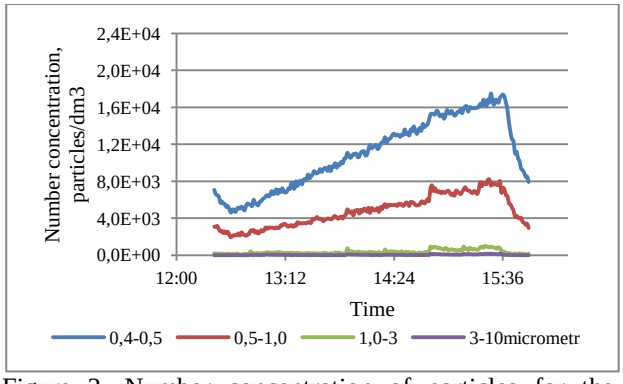

Figure 2. Number concentration of particles for the ranges 0,4-0,5µm, 0,5-1,0µm, 1,0-3µm and 3-10µm (GRIMM results).

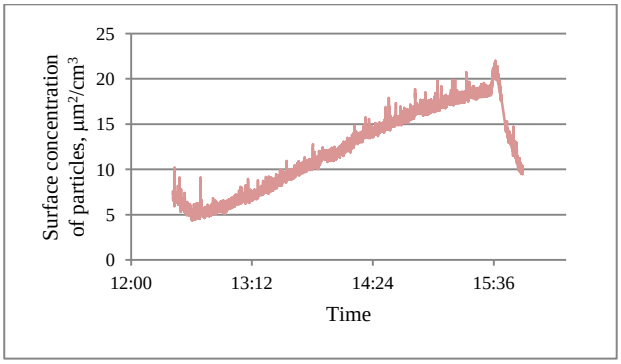

Figure 3. Surface concentration of particles 10-1000nm (AERO-TRAK results – fraction "A" alveolar).

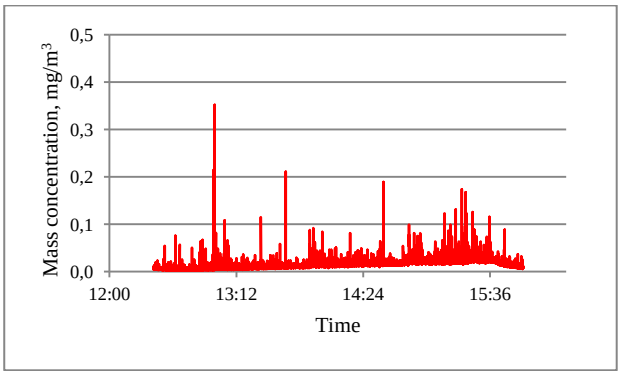

Figure 4. Mass concentration of particles 0,1-10µm (DUST-TRAK results).

It results from the analysis of data presented on Figures 1-3 that number and surface concentrations of particles increased evenly and the visible maxima of the concentration associated with the spraying products didn't appear. Switch-on of ventilation before spraying (from 12:25 to 12:37) an after spraying (from 15:35 to 15:53) with airflow 2000m^3/h significantly influenced on the decrease of number and surface concentrations. Above discussed changes weren't observed in case of mass concentrations determined with DUST-TRAK for particles 0,1-10µm (Figure 4).

This study has been prepared within RP CIOP-PIB (No. I-30) and NANODEVICE project (number FFP7 211464). The views and opinions expressed in this presentation do not necessarily reflect those of the European Commission.

Continuous tandem DMA determination of the mass and charge distribution of electrosprayed nanometer polystyrene particles

M. Attoui[1], J. Fernandez-García[2], J. Cuevas[3], G. Vidal[3] and J. Fernandez de la Mora[2]
[1]M. Attoui, Universty de Paris 12, 94010 Creteil, Paris, France; Presenting author: attoui@univ-paris12.fr
[2]Department of Mechanical Engineering, Yale University, New Haven, CT 06520-8286, USA
[3] SEADM, Parque Tecnológico de Boecillo, 205; 47151 Boecillo, Valladolid, Spain.
Keywords: nanoparticle, size, charge, tandem DMA.

Nanoparticle studies based on a differential mobility analyzer followed by a mass spectrometer (DMA-MS) produce informative two-dimensional (2D) maps which have revealed unusual transitions such as shape changes at critical sizes and charges (Larriba et al. 2012), single molecule evaporation activated by the Kelvin effect on presumably involatile materials (Hogan et al 2010), charge loss transitions of apparently stable clusters (Rus et al, 2010), etc. However, these transitions are difficult to study quantitatively by DMA-MS due to uncontrolled heating of the particles by confining radiofrequency fields as they enter the MS. In order to investigate these phenomena controlling temperature and residence time during the transit between two analyzers we have assembled a tandem DMA (DMA^2) system (Rader & McMurry 1986) where the voltages V_1, V_2 of both DMAs are scanned in an effectively continuous fashion.

Experimental. The two nano-DMAs used were of the Half-Mini type (Fernandez de la Mora 2011). The computer control program was developed at SEADM. It scans the two DMAs over a 2-dimensional (2D) grid of voltages and measures the corresponding nanoparticle current I exiting the second DMA. The resulting 3D data set (V_1, V_2, I) is stored as a single file and can be represented via 2D graphics

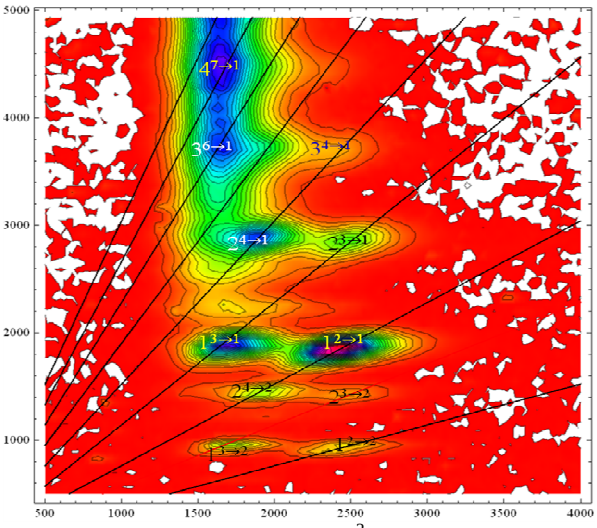

Figure 1: 2D continuous DMA^2 spectrum of multiply charged polystyrene particles 4.7 to 7.5 nm in diameter.

The system has been tested by studying aerosols of nanoparticles electrosprayed from a 1 mM solution of polystyrene (Psty) dissolved in l-methyl-2-pyrrolidone (NMP) seeded with 10% (vol) dimethylammonium formate (Ude *et al*, 2006). DMA_1 analyzes the Psty particles in their natural charge state, as electrosprayed. The aerosol is then charge-reduced on its way to DMA_2 by flowing through a tube internally coated with Ni^{63} (10 mCi).

Results. Figure 1 shows the 2D mobility spectrum from a spray of Psty with a relatively narrow size distribution and average molecular weight M_w=34.5 kDa. The line labelled 1 corresponds to particles having the same mobility (same charge state) on both DMAs. Its slope will be denoted k. Lines labelled 2, 3, .. have slopes 2k, 3k,... The peaks labelled $n^{z\to z'}$ correspond to aggregates of n chains (n-mer) of Psty 34.5 kDa having passed with z and z' charges through DMA_1 and DMA_2, respectively. They can be identified unambiguously (i) because they lie over lines of slope k(z/z'); (ii) Because the charge reduction process is relatively efficient, the most abundant peaks correspond to z'=1, so that peaks $n^{z\to 1}$ of given n fall on horizontal lines whose abscissa give the (known) mobility of the singly charged n-mer. The monomer, dimer, trimer and tetramer carry primarily 2, 4, 6 and 7 charges, respectively. The larger aggregates are less efficiently discharged, whence the greater number of surviving charge states crowd together on the upper left region of the plot, precluding clear peak assignment. The present approach is limited by the poor transmission of high mobility multiply charged particles through the tandem DMA, particularly due to space charge losses from the ES chamber to the inlet of the first DMA. These losses are moderated at the relatively large sample flow rates used here, though this reduces the efficiency of the neutralizer and the resolving power of the DMA. The acquisition (typically 10^4 points) is also slow due to the ~1s response time of most aerosol instruments. These limitations will hopefully be alleviated by use of a planar DMA on the first stage, whose high transmission will permit moderate sample flow rates and the use of a faster electrometer.

New materials based on nanotechnology are reaching the market in a wide variety of consumer products. Since these nanostructured materials can be in powder form, a suspending powder system is essential for many purposes:

- For in vivo inhalation toxicological studies
- For dustiness evaluation

Different powders suspending systems have been developed like the rotating drum or the single drop. They are used as a reference method to evaluate bulk materials dustiness. Usually cumbersome, these systems need a huge amount of powder (a few hundred grams) and require time-consuming cleaning processes which could be even more tedious when a nanostructured material and/or a toxic powder is used. The vortex shaker is proposed as a solution. Quite easy to handle, this system requires a very small amount of powder (a few grams) in a tube. It has been set up to study the dustiness of any type of powder under controlled and reproducible conditions.

The aim of this work is to aerosolize Multiwalled carbon nanotubes Graphistreght C100 and characterise the generated aerosol. The set up is designed to aerosolize, observe and quantify the carbon nanotubes mass.

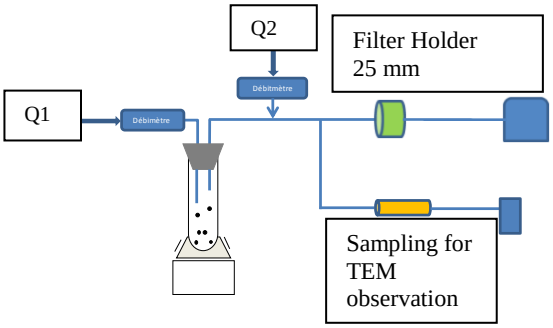

Figure 1 : Set up
Q1,Q2: Respectively clean and dry air in the tube and for dilution

In order to observe the generated particles with a Transmission Electronic Microscope giving information on size distribution, particle shape and composition, a TEM grid sampler was operated. This sampler, coupled with a Gilian LFS-113DC pump, allows the aerosol trapping through a copper grid whose pictures are shown on figure 2. The observed aerosol display different type of shape: agglomerate on the left picture, single nanotube on the right.

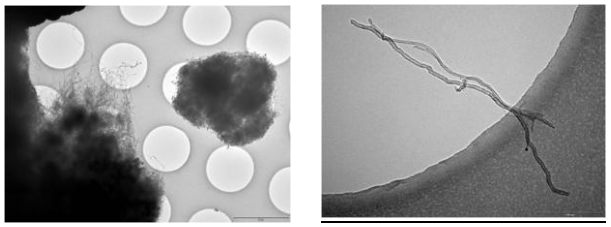

Figure 1:TEM picture at two different scales

In parallel, to measure the aerosol mass, samples have been performed on a 25 mm quartz filter. The carbon nanotubes deposited on the filter are oxidized by combustion at 980°C in the module SSM 5000A (Solid Sample Modul). The melting point is lowered by addition of V_2O_5. Platinum is used as catalyzer. The carbon is then released in CO_2 measured by non dispersive infrared analysis by a Shimadzu detector. To lower the quantification limit, a second infrared detector, the MIR6000 was added in series to the first one. This assembly allows to obtain a limit of quantification of 5 µg / filter.

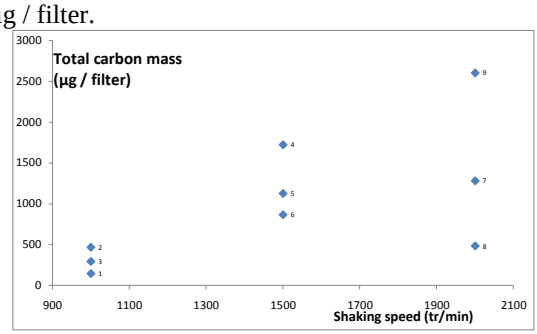

Figure 2: Correlation between the total carbon mass and the shaking speed.

An hour sampling time was repeated three times at three different shaking speeds. The mass and the standard deviation increase with the shaking speed.

A continuous mass measurement with TEOM will be added in the set up in order to determine the stability of the aerosols concentrations.

Influences on nanoparticle size distributions generated by the spark principle

J. Spielvogel, R. Joachim, M. Schmidt

Palas GmbH, Karlsruhe, 76229, Germany
Keywords: aerosol generation, nanoparticles, agglomerates, particle size distribution
Presenting author email: spielvogel@palas.de

In various fields of study a defined and well characterized nano particle source is essential to creating precise and reproducible measurements. The Palas defined nano particle (DNP) generators that generate aerosol particles by electrode atomization in a spark discharge are widely used in the fields of toxicology and automotive. In the latter the particle generators are used to calibrate the emission measurement systems that were defined in the framework of the particle measurement programme (PMP) and put into regulation in the EURO 5b emission standard.

These types of aerosol generators have unique advantages. They can generate a steady stream of high concentrations of particles over a wide mobility range. When this is used in combination with a differential electrical mobility classifier (DEMC) a very well defined calibration aerosol is obtained. By changing the electrode material a large number of materials can be aerosolized.

In this presentation we will present a thorough comparison of submicron particle size distributions resulting from the use of different aerosol materials e.g. carbon, gold, copper, stainless steel and the use of different carrier gases e.g. nitrogen, argon. By adjusting instrument parameters such as the spark frequency the sizes of the formed agglomerates can be tuned to the region of interest (see figure 1). These particle size distributions are measured and characterized using the U-SMPS.

Figure 1 shows an example of the influence of spark frequency on the generated size distribution.

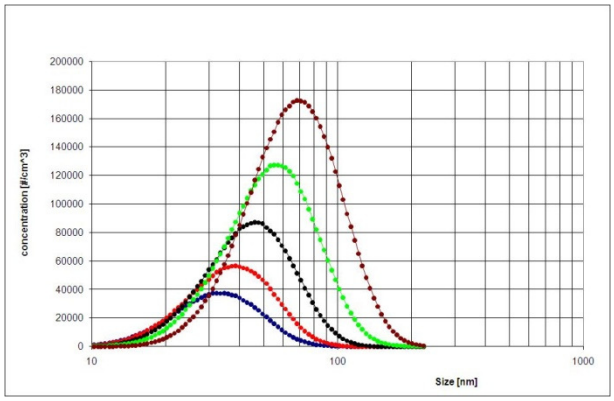

Figure 1. Size distributions of particle agglomerates at different spark frequencies.

In the second part of the presentation the underlying process will be examined theoretically. Correlations between spark frequency, evaporation temperature, and particle size and number concentration are examined and presented.

Pilot melt spin-tester has been widely used in the research of polymer composites for years, due to its capability of producing bi- and tri-component composite fibres, and relatively small requirement of materials. Recently, this technique is frequently applied in many fields such as the development of carbon fibre composites (Shaffer *et al*, 2004) and biodegradable materials (Hufenus *et al*, 2012). The safety assessment of the operating environment, however, has not been conducted extensively. The effect of the potential nano-scale bi-products generated by the heating extruding procedure is still unclear while researchers and operators have been working in this environment for long time-durations without suitable protective equipment. Based on the known damage by micro-particles to human being, the increasing interest about nanotoxicology, and potential work-place nanoparticle emission (Wang *et al*, 2011, 2012, and Walser *et al*, 2012), safety in melt spinning plants could be a serious topic.

We measured the emitted aerosol particles in the working environment of a fibre melt spinning production, which features mixing of polyester (PET) and P25 TiO_2 nanoparticles. The setup was built under a ventilation hood for isolating workers from the emissive particles. Measurement was performed in both the case of pure PET extrusion and the case of extrusion of the mixture of PET and nanoparticles. A fast mobility particle sizer (FMPS) and a nano-micro-orifice uniform-deposit impactor (MOUDI) were employed to measure aerosol particle distribution. Samples for SEM and TEM were prepared in order to directly measure the structural properties. The usage of a thermo-denuder (TD) enabled separation of the volatile components of the particles and further characterization of the chemical composition was performed by a GC-MS with a Thermal Desorption Unit (TDU) using impactor samples.

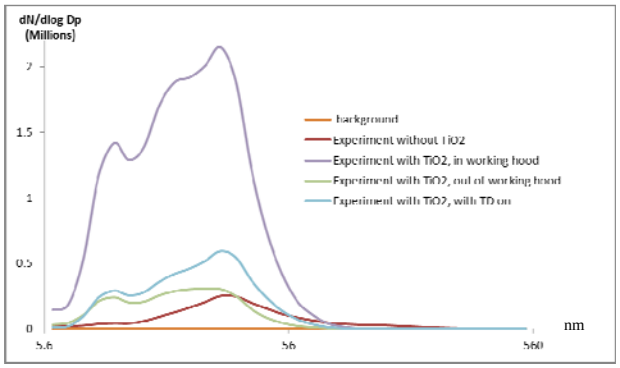

Figure 1. Size distribution of particles analysed in different experiments based on FMPS.

Based on the measurements in the hood by FMPS, the total concentration was $3*10^5$ #/cm^3, ten times as the background value in the experiment without TiO_2. The concentration increased up to around $6*10^5$ #/cm^3 when TiO_2 was added but then down to 10^5 #/cm^3 when it was sampling outside of the ventilation hood. Even the total concentration fluctuated, the size distribution did not change substantially, not even with the change of mixing ratio between the polymer and nanoparticle material. The particle sizes were in the range of 10-100 nm in all tests and the majority were smaller than 30 nm (Fig 1).

With the operation of the TD, the total concentration dropped to 150,000 #/cm^3 in TiO_2 experiment. This indicates that non-volatile particles existed since the heating of air stream in the TD removed volatile particles. SEM and TEM images (Fig 2) showed both polymer and TiO_2 particles. Agglomerates of TiO_2 nanoparticles were observed in the size range from 200 nm to a few microns. The analysis by GC-MS provided further information about the composition in both particle and gas phases. Fragments of broken PET chain, the terephthalate esters, were found in the full-field scanning analysis.

Dissociation rates of Fe_2^+, Fe_2^-, and Fe_2

M. Noppel

Institute of Physics, University of Tartu, Ülikooli 18, 50090 Tartu, Estonia
Keywords: iron dimers, dissociation rate.
madis.noppel@ut.ee

Iron nanoparticles have a wide field of technical applications due to their magnetic, electronic and catalyst properties. They are extensively used in synthesis of carbon nanotubes, where the uniformity and controllable size of particles plays essential role. One way for the generation of particles is their gas-phase synthesis. For a better understanding and description of gas-phase formation processes, kinetic data are necessary. Giesen et al (2003) found that the major initial reactions for the understanding of the condensation of iron vapour are the formation and the decomposition of Fe_2. In the following we present the preliminary results of calculations of the dissociation rate coefficients of ionic and neutral iron dimers.

Dissociation rate coefficients are calculated by RRKM theory. Experimental dissociation energies, vibration frequencies, equilibrium bond lengths of dimers and electronic level values of iron atoms and atomic cations are taken from literature as well as the density functional theory values of higher electronic energy levels of dimers. As ab initio calculation results are still uncertain, experimental dissociation energies are used to estimate energy barrier value for dissociation reactions. Available experimental and theoretical results refer that there is an energy barrier for reverse association reaction of neutral iron atoms. Therefore, in calculations, the moments of inertia of activated complex and dimer are taken approximately equal. For the activated complex of ionic dimers the "apparent" moment of inertia is used (Waage *et al*, 1970).

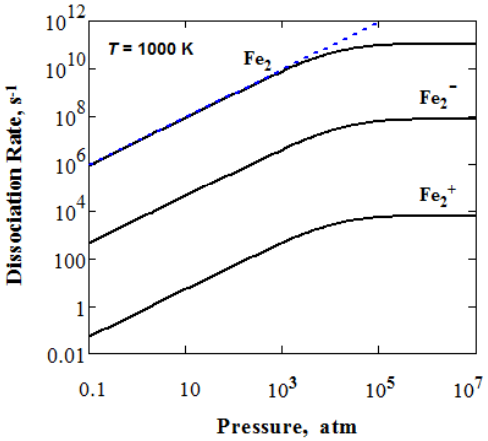

Figure 1. The pressure dependence of dissociation rates of Fe_2^+, Fe_2^-, and Fe_2 at temperature T=1000 K. Dashed curve represents rate of Fe_2 by Giesen *et al* (2003).

Figure 1 shows that at common experimental pressures calculated dissociation rates are located in the fall-off regime. In Figure 2 the temperature dependence of dissociation rates in low-pressure region are presented.

The obtained dissociation rate of Fe_2 is close to the result by Giesen *et al* (2003) at temperatures of their experiments, but the dependence on temperature is weaker. Ionic dimers, especially cations, are remarkably more stable than neutral dimers Fe_2.

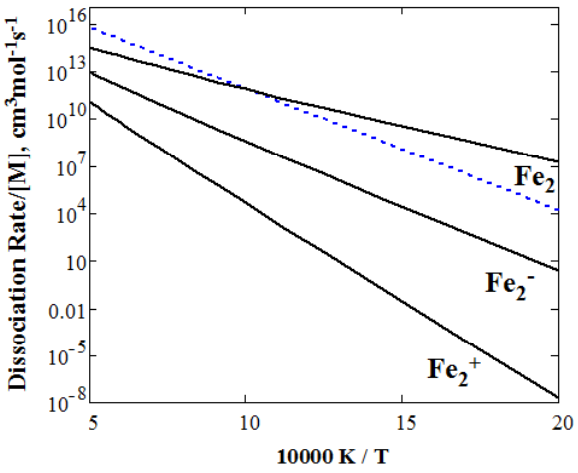

Figure 2. Arrhenius plot of the dissociation rate coefficients. Dashed curve represents rate of Fe_2 by Giesen et al (2003). At low pressure unimolecular reaction rates become proportional to buffer gas concentration [M].

Surface concentration of particles emitted during burning of foams with nano-objects

Jankowska E., Sobiech P., Łukaszewska J. and Zatorski W.

Department of Chemical and Aerosol Hazards, Central Institute for Labour Protection – National Research Institute, Czerniakowska 16, 00-701 Warsaw, Poland
Keywords: nano-objects, foams, emission, surface concentration.
Presenting author email: pisob@ciop.pl

The aim of the investigation was to determined surface concentration of particles emitted during burning of two types of foams with ca. 9% of nano-objects: foam (TT) with titanium dioxide and foam (MMT) with Nanomer I.34TCN nanoclay which is a surface modified montmorillonite.

Investigation were done during burning of each foam for 30s. Surface concentrations of particles with size 10-1000nm were measured with AERO-TRAK for the scenarios described in Table 1.

Table 1. Scenarios of measuring surface concentration of emitted particles.

Abbreviations	Description of scenarios/time(s)
1. BB-TT/4800	Before burning of TT foam/4800s
2. JBB-TT/30	Just before burning of TT foam/30s
3. DB-TT/30	During burning of TT foam/30s
4. JAB-TT/30	Just after burning of TT foam/30s
5. BB-TT/MMT /6240	Between burning of TT and MMT foams/6240s
6. JBB-MMT/30	Just before burning of MMT foam/30s
7. DB-MMT/30	During burning of MMT foam/30s
8. JAB-MMT/30	Just after burning of MMT foam/30s
9. AB-MMT/7380	After burning of MMT foam/7380s

Table 2. Surface concentration of particles presented in the air during different scenarios.

Scenarios	Surface concentration of particles ($\mu m^2/cm^3$)			
	Min	Max	Median	ArMean
1. BB-TT/4800	26	33	30	29
2. JBB-TT/30	27	28	28	28
3. DB-TT/30	35	13422	1370	2943
4. JAB-TT/30	1281	5105	2682	2712
5. BB-TT/MMT /6240	166	5105	331	375
6. JBB-MMT/30	166	174	169	170
7. DB-MMT/30	320	2632	757	1111
8. JAB-MMT/30	506	1867	737	975
9. AB-MMT/7380	27	1867	175	182

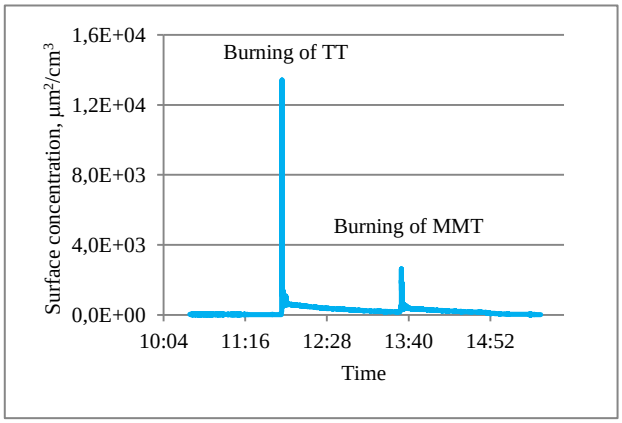

Figure 1. Surface concentration of particles 10-1000nm (AERO-TRAK results for fraction "A").

It results from the analysis of data presented in Table 2 and Figure 1 that depending of the type of foam during burning can be emitted particles with different surface concentrations: higher for TT foam with mean concentration 2943$\mu m^2/cm^3$ and lower for MMT foam 1111$\mu m^2/cm^3$. Maximum value of surface concentration of particles emitted during burning of TT foam was 13422$\mu m^2/cm^3$, when during burning of MMT foam 2632$\mu m^2/cm^3$. Measured values of surface concentrations were higher than that recommended to measured with AERO-TRAK for the fraction "A" (alveolar).

Process of burning can significantly influenced on the increase of surface concentration of particles presented in the air, especially just after burning. During the period of 30s after burning of foams mean surface concentrations of particles were very high (2712$\mu m^2/cm^3$ for TT foam and 975$\mu m^2/cm^3$ for MMT foam).

Particles emitted during burning can presented in the air log time. In the period of 6240s mean surface concentration after the burning of TT foam was 375$\mu m^2/cm^3$, when in the period of 7380s after burning of MMT foam 182$\mu m^2/cm^3$. The surface concentration of particles achieved the value similar to the mean concentration obtained before burning (28-29$\mu m^2/cm^3$) only 7380s after burning of MMT foam.

Keywords: Aerosol generation, aerosol measurement, filtration, nanoparticles.
Presenting author email: ikammenou@ethz.ch

Nowadays there is an intense concern about the health hazard posed to humans exposed to inhalation of toxic nanoparticles [1]. It is supported that engineered nanomaterials are released at high mass and/or number concentrations only under unusual circumstances and the particles are also present in air as agglomerates of several hundred nm [2, 3, 4].

Airborne nanoparticles are released to the windtunnel located at EMPA Dübendorf and a series of experiments are performed to measure them. Specifically, the nanoparticles are released via a nozzle into a DIN EN 779 windtunnel at different injection flow rates and carried downstream by controlled air flow. The nanoparticles are monitored at two different sampling points, upstream and downstream of the filter. Sampling probes capable of isokinetic sampling are used to transport nanoparticles from the windtunnel to the measuring instruments, with the aim to obtain information on nanoparticle size and number concentrations. The filtration efficiency is also studied under different experimental conditions based on DIN EN 779.

Standard aerosol instruments, including SMPS, OPC, and FMPS are used for the measurement of generated airborne nanoparticles. The particle concentration can be controlled by adjusting the flow rates of the aerosol and the windtunnel flow. An Atomizer Aerosol Generator (TSI 3079), a 6-Jet-Atomizer (TSI Model 9306A) and a furnace have been adopted for generation of the aerosols in various experiments. The temperature and humidity of the clean air can be controlled using a heater and a humidifier upstream of the flow straightener. NaCl and KCl solutions in different concentrations (% w/t) and silver powder purchased from Sigma Aldrich are experimented for the aerosol generation.

The following figure (figure 1) depicts the filter efficiency in all the cases studied. It is observed that the initial efficiency for 0.35 μm is generally higher than 72.2 % (observed at 1000 m^3/h) and the maximum level of efficiency achieved is 100% under all windtunnel flow rates. The standard airflow rate for F7 filter used in these studies is 3400m^3/h. In figure 2, it is observed that the higher the temperature, the bigger the peak of the particle number-size distribution. Furthermore, the nanoparticle size is increased at elevated aerosol flow rate when the temperature remains the same.

Future studies will be oriented in analyzing the transport characteristics of nanomaterials after their release, as well as their morphology and structural properties.

Structure deformation of Ag nanoparticle clusters induced by deposition onto carbon nanotubes

T. Shinohara, N. Nishida, H. Tanaka

Institute of Science and Engineering, Chuo Univ. 1-13-27 Kasuga, Bunkyo-ku, Tokyo, 112-8551, Japan

Keywords: Ag nanoparticle cluster, carbon nanotube, size selection, deformation

Presenting author email: hnznshubiduba1354@yahoo.co.jp

Nanoparticles have been considered to be expected as building blocks to construct nanocomposites with surprisingly unique properties. Especially, Ag nanoparticles are good candidates for this purpose because they have specific chemical and optical properties. While it is relatively easy to produce these nanoparticles in the gas phase using gas-aggregation technique, it is not easy to avoid aggregation each other because of their surface activity. In this regard, we have synthesized Ag nanoparticle clusters previously, which are composed of surface-active Ag nanoparticles and surface-inactive C_{60} nanoparticles [1]. In this study, we have investigated the deposition of the Ag nanoparticle clusters onto carbon nanotubes. Structure changes of the deposited clusters were analyzed by scanning transmission electron microscope (STEM).

Ag nanoparticles were produced by a gas aggregation method and were passed through C_{60} vapor. The nanoparticles thus produced were admitted into an ionizer equipped with a radioactive ^{241}Am and were size-selected at 20 nm by a differential mobility analyzer (DMA). The selected nanoparticles were electrically collected onto CNT deposited on a Cu grid, and were analyzed by STEM.

Fig.1 shows STEM image for size-selected Ag nanoparticle cluster deposited on a CNT. The deposited cluster is observed to be composed of 9 Ag nanoparticles with high contrast. In addition, these nanoparticles are superposed on areas with low contrast. Because these high- and low-contrast features resemble those for the nanoparticle clusters observed previously [1], the cluster produced in the gas phase is considered to be deposited on the CNT.

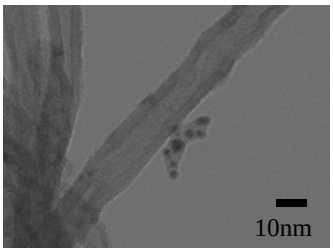

Fig.1. STEM image for
Ag nanoparticle cluster size-selected at 20 nm on a CNT

The number of Ag nanoparticles is found to be quite close to that for the previous report. This indicates that the no fission occurs on the deposition process.

On the other hand, although the shape of the cluster seems drastically deformed, the constituent Ag nanoparticles are well isolated each other. The deformation implies shape conversion induced by the impact energy. The isolation suggests that aggregation of the Ag nanoparticles is probably restricted by existence of C_{60} molecules. In fact, the distance between adjacent Ag nanoparticles was estimated to be approximately 2.2 nm, and this distance is close to the diameter of a few C_{60} molecules. In other words, C_{60} molecules work as effective isolator for Ag nanoparticles.

Reactant depletion in chemical reactions inside nanoscale particles

V.V. Levdansky[1], J. Smolik[2], V. Zdimal[2] and P. Moravec[2]

[1]Heat and Mass Transfer Institute NASB, 15 P. Brovka Str., 220072 Minsk, Belarus
[2]Institute of Chemical Process Fundamentals AS CR, v.v.i., Rozvojova 135, 165 02 Prague 6, Czech Republic
Keywords: nanoparticles, chemistry, size effect.
Presenting author email: vlev5@yahoo.com

It is known that physicochemical processes occurring in aerosol systems with nanoscale particles and in the particles themselves can depend on the particle size. Some problems related to phase transitions in aerosol systems with nanoparticles in the dependence of the condensation coefficient on the particle size were studied in (Levdansky *et al*., 2010). Here we consider the influence of the size effect on reactant depletion in nanoparticles due to a chemical reaction.

The rates of chemical reactions in nanoparticles can be higher than in a bulk matter. This is related to the size dependence of activation energies for diffusion of reactants in nanoparticles and intrinsic activation energies of chemical reactions. The size dependence of the mentioned activation energies leads to the size dependence of rate constants of chemical reactions as well as the size dependence of reactant depletion. Let us consider a decrease in the number density of the reactant component A in the nanoparticle n_A with time due to a bimolecular chemical reaction of components A and B inside the particle. For simplicity, we assume further that concentrations of reactants are uniform throughout the nanoparticle, the diffusivity of the component A in the particle D_A is much greater than the diffusivity of the component B (D_B) and the number density of the component B in the particle n_B is much greater than n_A. Under the above-mentioned assumptions, we can suppose that the value of n_B is independent of time t and $n_B = n_B(t = 0) = n_{B0}$ (Connors, 1990). In this case the value of n_A in a diffusion-controlled chemical reaction can be found from the equation

$$\frac{dn_A}{dt} = -4\pi D_A R_0 n_A n_{B0}, \qquad (1)$$

where R_0 is the effective radius at which a reaction can occure.

It is known that the cohesive energy decreases with a reduction in the nanoparticle size (Vanithakumari and Nanda, 2008). In turn, it leads to a decrease in the activation energy for diffusion of reactants inside the particle and to an increase in the rate of a chemical reaction.

Taking into account the relation between the activation energy for diffusion of components in nanoscale particles and their melting temperature by analogy with (Vanithakumari and Nanda, 2008) and allowing for the size dependence of the nanoparticle melting temperature according to (Rekhviashvili and Kishtikova, 2006), we can obtain the following equation for n_A:

$$n_A = n_{A0} \exp\left\{-t^* \exp\left[\frac{E_{A\infty}}{kT}\left(1-\exp\left(-\frac{4\delta}{\delta+d}\right)\right)\right]\right\}, \qquad (2)$$

where $n_{A0} = n_A(t = 0)$, $t^* = 4\pi R_0 n_{B0} D_{A\infty} t$, $E_{A\infty}$ and $D_{A\infty}$ are respectively the activation energy for diffusion and the the diffusivity of the component A without considering the size effect, k is the Boltzmann constant, T is the temperature, d is the particle diameter, δ is the Tolman length.

Figure 1 shows the dependence of the dimensionless number density of the component A in the nanoscale particle $n^* = n_A/n_{A0}$ on t^* for different values of $d^* = d/\delta$.

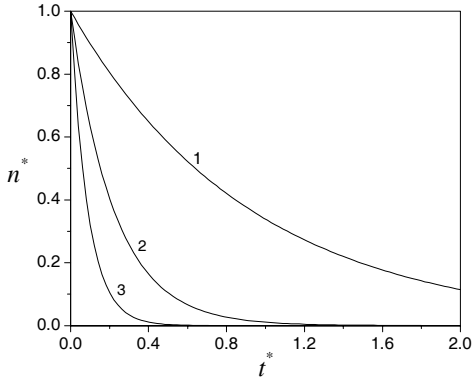

Figure 1. Dependence of n^* on t^* at $E_{A\infty}/kT = 20$. 1: $d^* = 1000$, 2: $d^* = 50$, 3: $d^* = 30$.

It follows from Fig. 1 that the value of n^* decreases with an increase in t^* and in a decrease in d^*.

Monitoring a CVD process for the synthesis of nanostructured particles by means of low-pressure impaction

F.Weis, M. Seipenbusch and G. Kasper

Institute for Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology (KIT), Karlsruhe, 76131, Germany
Keywords: aerosol coating, impactor, nanoparticle, CVD.
Presenting author email: frederik.weis@kit.edu

Nanoparticles synthesized by gas phase processes like flame spray pyrolysis, spark discharge generation or chemical vapour synthesis (CVS) show great potential in gas sensing, catalytic or electrical applications. In order to optimize and simplify screening for the required synthesis parameters online monitoring of the process is desirable. In this work an integrated CVS/CVD aerosol process[1] at atmospheric pressure was adapted to synthesize core-shell structured nanoparticles composed of SiO_2 support particles coated with a bismuth and molybdenum oxide shell. These nanoparticles are active catalysts for selective oxidation of hydrocarbons like methanol or propene. The whole process can be monitored online by the use of a single stage low pressure impactor (LPI) in the pressure scanning mode in combination with a differential mobility analyzer (DMA). The SiO_2 support particles were synthesized by thermally activated Chemical Vapour Synthesis (CVS) in a hot wall reactor using tetraethyl(ortho)silicate (TEOS) as precursor and a nitrogen-oxygen mixture as carrier gas. A sintering furnace was used to adjust particle morphology and the resulting change in effective particle density was measured by the use of the LPI. The values given in table 1 for a particle with a mobility diameter of 130nm show that after the CVS reactor agglomerates with a low effective density are formed. After the sintering furnace a density close to the bulk value of silica (2200 kg/m^3) is determined, indicating complete coalescence of the particle. This is in agreement with TEM images, showing the spherical shape of the particles.

Table 1 Effective particle density of SiO_2 particles measured by low pressure impaction.

	ρ_{eff} (kg/m^3)
CVS reactor (1000°C)	310
Sintering furnace (1500°C)	2145

In a second step the support particles were directly coated downstream in the aerosol state with Mo- and Bi-oxide by Chemical Vapour Deposition (CVD) using molybdenum hexacarbonyl and bismuthtriphenyl as precursors and oxygen as reactive gas. Since the resulting shells of molybdenum and bismuthoxide have a higher density, the coating of the particles can be monitored online. If the particles are coated successfully, the penetration curves of the LPI for a constant mobility diameter shift to higher pressures as shown in figure 1 for a subsequently coated particle. From this shift the coating thickness in the nanometer range can also be determined online. Figure 2 shows the growth of the molybdenum oxide shell with increasing residence time in the CVD reactor. Since the density of the film is not exactly known the values resulting from the LPI measurements are given by the grey band, showing good agreement with the coating thickness determined by TEM-image analysis. The presentation will show how a low pressure impactor can be used to study the coating step online and possibilities to increase the resolution for the determination of coating thickness will be discussed.

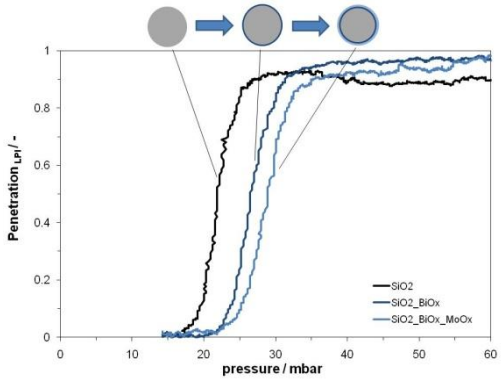

Figure 1 Penetration curves of LPI for coated silica

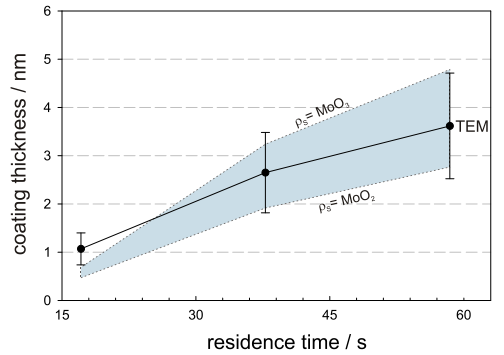

Figure 2 Coating thickness of silica particles coated with molybdenum oxide as function of residence time

Electro-hydrodynamic atomization of solutions with strongly electrolytic behaviour – governing parameters and applications

A. Maißer[1], M.B. Attoui[2], A.M. Ganan-Calvo[3] and W.W. Szymanski[1]

[1]Faculty of Physics, University of Vienna, Vienna, 1090, Austria
[2]LISA, UPEC-Diderot, Créteil, 94010 ,France,
[3]ESI, Universidad de Sevilla, Sevilla, 41092, Spain
Keywords: electrospray, aerosol generation, nanoparticles, salt aerosol.
Presenting author email: anne.maisser@univie.ac.at

Electro-hydrodynamic atomization (EHDA) is a widely applied tool for aerosol generation and can be applied to produce aerosols of various sizes and chemical composition.

In this work EHDA has been applied to produce airborne sub 10 nm nanoparticles from salt solutions of strongly electrolytic behaviour (sodium chloride NaCl and potassium chloride KCl). The goal of the investigation was to find the relationship between molar concentration and solution conductivity to the particle size produced. The results have been compared to existing scaling laws under the assumption that the chemical composition is preserved during the spraying process. The quality of the generated aerosol and their possible applications have been investigated.

For EHDA a commercial TSI electrospray aerosol generator (EAG, 3480 TSI Inc.) has been used. This device includes a ^{210}Po radioactive alpha radiation to produce a high concentration bipolar ion cloud for neutralization of the highly charged droplets emerging from the tip of the electrospray capillary.

The generated aerosol has been investigated using a custom-made differential mobility analyzer (Vienna type nanoDMA) in combination with a Faraday cup electrometer for particle detection. For investigations of the charge state and monodispersity of the generated particles a tandem DMA experiment has been performed using two identical Vienna type nanoDMAs in series. The applications of the monodisperse particles for further investigations has been tested by measuring the detection efficiency of the sub 10 nm particles with a commercial ultrafine water condensation particle counter (WCPC, 3786 TSI Inc.).

Experimental Results

NaCl and KCl salts have been dissolved in various concentrations in either pure water or in an aqueous ammonium acetate buffer liquid of varying molarities. The solutions have been sprayed in stable cone-jet mode.

Because of the strongly electrolytic behaviour of the salts used the change in concentration strongly affects the conductivity of the solutions.

Figure 1 shows the compiled results for NaCl sprayed from solutions in pure water and for constant electrical fields applied to the liquid at the capillary tip and constant liquid flow rates through the capillary. It can be seen that there is a linear relationship between the concentration of salt in solution and the conductivity. The dry particle diameter has been measured and the droplet diameter has been derived from the particle diameter under the assumption that the residue particles consist of pure NaCl or KCl, respectively.

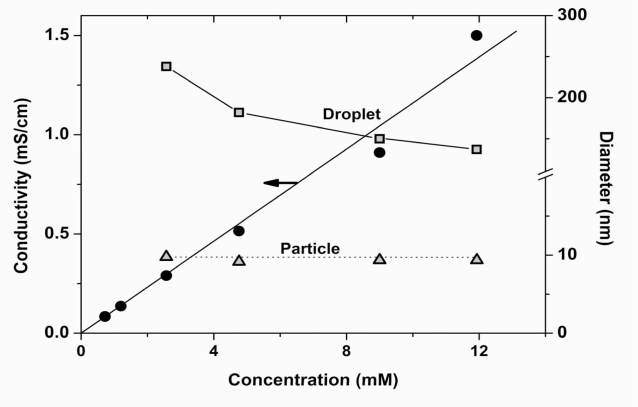

Figure 1. Measured dependency of particle and droplet diameter to the molar concentration and conductivity of the solution for NaCl.

It can be seen that the variation of the dry particle size is small for solutions in pure water and thus strong variations of conductivity.

The experimental results have been compared to two different theoretical approaches so called scaling laws introduced by Fernandez de la Mora and Loscertales (1994) and Ganan-Calvo (1997), respectively.

It has been found that the electrolytic behaviour of the solutions needs to be taken into account for scaling the droplet diameter and particle size. Apparently, the particle size can be scaled solely by the 1/3rd power of the liquid flow rate as far as the hypothesis of non-altered chemical composition holds (Maißer *et al.* 2012). However, the experimental results and comparison to the scaling law by Ganan-Calvo indicate a possibility of some electrochemical effects that could affect the chemical composition; this issue still requires some further experimental studies.

University of Salzburg, 5020 Salzburg, Austria
Keywords: ultrafine particles, charged particles, lung deposition.
Presenting author email: l.guo@student.qut.edu.au

Eepidemiological studies have linked exposure to ultrafine particles (UFPs, <100 nm) to a variety of adverse health effects. To understand the mechanisms behind these effects, it is essential to measure aerosol deposition in the human respiratory tract. Electrical charge is a very important property as it may increase the particle deposition in human respiratory tract (Melanderi et al., 1983). However, the effect of charge on UFP deposition has seldom been investigated. The aim of this study is to investigate the effect of charge on UFP deposition in human lung, by conducting a pilot study using a tube-based experimental system.

A nebuliser (Model CN241, BGI Inc., US) was used to generate polydisperse diethyl-hexyl-sebacate (DEHS) particles. A Scanning Mobility Particle Sizer (SMPS) was used to measure particle size distribution and particle number concentration (PNC) was measured by both an SMPS and a TSI 3010 Condensation Particle Counter (CPC). The SMPS is comprised of a CPC and a 3071 Electrostatic Classifier (EC). An ioniser (AH-202, Aironic, US) inside the chamber was used to charge the DEHS particles, and an Aerosol Electrometer (AE, TSI Model 3068) was used to measure particle charge. In order to investigate the effect of charge on particle deposition in the tube, three aerosols were compared: charged (generated by nebuliser, then charged by an ioniser), non-charged (generated by nebuliser), charge neutralised (generated by nebuliser and then passed through an ^{85}Kr bi-polar charger). A sampling box (9 L) was connected to the end of the tube (L: 85 cm; D: 1.7 cm), which acted as a reservoir to avoid measuring the artefacts produced by flow fluctuation. The aerosols were drawn through the tube from the large chamber ($1m^3$) into the sampling box at a flow rate of 7.5 L/min. Particle number concentration and charge were measured by the CPC and AE, respectively, both before and after the aerosols were drawn through the tube. For each of the three aerosols, particle deposition was determined by comparing the particle number concentration difference before and after the aerosol passed through the tube. The average of three to five measurements was taken as the final deposition value.

Only the comparison between the deposition fraction of charged and non-charged particles is reported here. As can be seen form Table 1, the deposition fraction of charged particles increased 78% compared with non-charged particles. The increase in deposition for UFPs was generally higher than those of submicron particles. However, it is too early to conclude that charge has a greater effect on lung deposition for UFPs than for larger particles, since the difference could be a result of conducting in vitro experiments (i.e. the plastic tube used this study or the metal cast used by Cohen et al., 1998) versus in vivo experiments (i.e. the rats studies in Ferin et al., 1983 and the humans studied in Melandri et al., 1983). Further in vivo experiments are needed to confirm this hypothesis and therefore, the focus of our future work will be to measure the deposition of charged UFPs directly in the human lung.

Table 1. Comparison of deposition increase

Keywords: bouncing, charge transfer, nanoparticles, ELPI
Presenting author email: heino.kuuluvainen@tut.fi

Introduction

Bouncing and charge transfer has previously been studied mainly for aerosol particles larger than one micrometer. Furthermore, studying particle bounce in impactors has often focused on means to reduce the bounce, not to explore the phenomenon itself. Recently, however, a new method was established in which the particle bounce in an electrical low pressure impactor (ELPI) was used to verify the physical phase state of newly formed SOA particles (Virtanen et al., 2010). To be able to use the method for more accurate and quantitative analysis in the future, both modelling and laboratory measurements are required.

Methods

A new model for bouncing particles and charge transfer in the ELPI is presented. The model is based on previous theories of Dahneke (1971) and John et al. (1980), which were originally developed and verified for larger particles. Along with these theories, it is very important to know the impact velocities of the particles at different impactor stages. For the estimation of these velocities, a recently published flow field model of the ELPI by Arffman et al. (2011) is used.

The bounce and charge transfer model covers the process in the ELPI stage by stage starting from the top and ending finally to the filter stage. At a single stage, the size distribution and the charge distribution of incoming aerosol change through impaction, bouncing and charge transfer. The modelled ELPI current distribution is calculated as a result of impacted particles and charge transfer from bouncing particles. In the model, there are basically three parameters describing the properties of the aerosol: material coefficient of bouncing, contact charge and effective density.

Laboratory measurements were conducted for sodium chloride and levoglucosan particles with polydisperse distributions and average mobility sizes below 100 nm. The ELPI current distribution was measured both charger on and charger off. In addition, as an approximation of the bounced fraction and bounced particles without charge transfer, so called bounce current can be defined, which is the difference of the two measured current distributions.

Finally, the model was fitted into the two measured currents and the bounce current for each measured aerosol distribution. Three parameter values were defined for each distribution minimizing the difference between the modelled and measured currents. The results are seen in Fig. 1 as a function of particle size distribution GMD. Substrate roughness and particle size seem to have only minor effect on the results. In the case of contact charge, substrate loading during the measurement is a problem and, for material coefficient, the theoretical size dependence may require further studies.

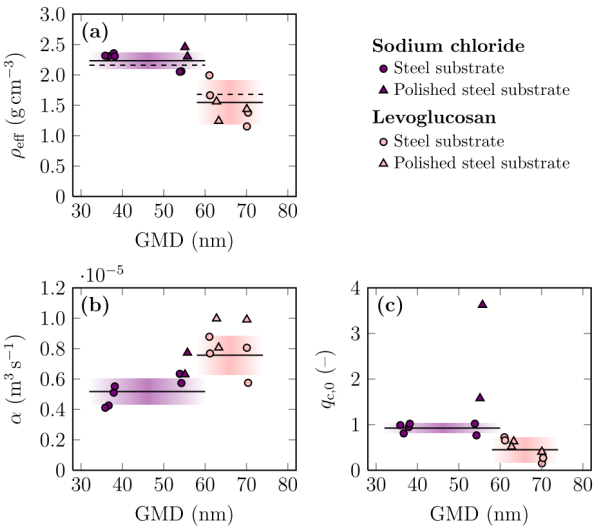

Figure 1: The values of (a) effective density, (b) material coefficient of bouncing and (c) contact charge as a function of particle size distribution GMD. In the subfigure (a), the dashed lines represent bulk densities.

Conclusions

The new method based on the bouncing and charge transfer model in the ELPI is shown to be a promising tool for measuring bounce and charge transfer properties of nanoparticles. The good agreement between the model and the experiment also shows that the previous theories for larger particles are to some extent relevant for particles below 100 nm.

Influence of flow conditions and process parameters on the production rate and characteristics of nanoparticles produced by spark discharging

M. Wagner[1], M. Wild[1], F. Weis[1] and M. Seipenbusch[1]

Spark discharge generators are widely used for the synthesis of metallic, mixed-metallic and oxidic nanoparticles at the laboratory scale. They are flexible with respect to electrode material and enable the production of high purity particles without employing hazardous precursors.

During particle production, the electrodes are being consumed since they constitute the particle feedstock, thus constantly increasing the width of the inter-electrode gap. As the electrode distance influences the production process, it is necessary to continuously readjust the gap width. This is especially important for the high production rates necessary for an industrial-scope application of the spark discharge generator. Consequently, two manual or automatic electrode feed mechanisms are usually employed to keep the electrodes at a constant distance (Helsper, Mölter et al. 1993), as can be seen in figure 1.

However, as ablation rates are dependent on polarity, the electrode gap is prone to displacement even if held at constant width (Tabrizi, Ullmann et al. 2009). This leads to a change in flow conditions in the vicinity of the gap, which in turn influences the removal of particles and residual ions from the gap as well as the dilution in the electrode wake (Schwyn, Garwin et al. 1988).

In order to allow for stable flow conditions even in case of high electrode ablation, we constructed a spark discharge generator with coaxial configuration as shown in figure 2. In contrast to the conventional setup, the gas flows alongside the electrodes, thus reducing the influence of spark gap displacement. As a side effect, it is possible to operate the coaxial spark discharge generator using only one feed mechanism by fixing one electrode to the housing. The failure rate in comparison to the conventional setup is therefore lower, as the number of moving parts is essentially halved.

We investigated the influence of the spark gap position on the production rate and properties of particles from spark discharge generators both with coaxial and traditional configuration. An SMPS was used to determine the size distributions of the aerosol, while the mass production rate was examined by gravimetric analysis. The measurements were conducted with different parameter constellations, including a variation of the gas flow rate.

Presenting author email: purmahia@udc.es

Size distribution measurements have been a recent focus of field campaign studies at several places around the world including urban, rural and remote sites (Zdímal *et al*., 2011).

Atmospheric particles are the object of a rising concern from environmental agencies, public opinion and scientific community. Excessive concentration of airborne particles is known to have detrimental effects on human health on global heat balance and possibly on precipitation patterns (Bigi and Ghermandi, 2011).

Measurements of number size distributions of submicron aerosols during summer 2011 have been performed at the Western part of Spain as part of an extensive measurement campaign to study volatile organic compounds and aerosols (NANOVOC Project). The measurements were made at the Institute of Environment station in Galicia.

This area is characterized by an Atlantic climate, with an accumulated precipitation of 33 l/m^2, 85 l/m^2 and 26 l/m^2 and a relatively humidity of 65%, 67% and 64% for July, August and September, respectively. Average temperature was around 22ºC during the measurements.

The data collection system used was a scanning mobility particle sizer with particle distributions measured in the range between 7,37 < Dp < 289 nm, where dp is the mobility particle diameter. The SMPS consisted of TSI 3081 Electrostatic Classsifier and TSI 3785 Water Condensation Particle Counter. The SMPS was set to the sheath and polydisperse aerosol flow rates of 10.0 and 1 l/min, respectively, to scan the size range 7,37–289 nm. A pre-impactor with nozzle 0,457 cm was used. The SMPS sampled periodically every 10 minutes with two scans per sample and 120 seconds scan up. The distributions were corrected for multiple charging and diffusion.

Particle size distributions during three months were different. The highest monthly average concentrations in all size distributions occur in August. July showed a bimodal distribution with two maximum, between 17,5-25 nm and 44,5-59,4 nm respectively. On the other hand, August showed only one maximum between 31,1 and 44,5 nm. September showed a bimodal distribution as occurs in July but particle number concentration with diameter between 17,5-25 nm was higher (figure 1).

The full range of the SMPS (N_{SMPS}, 7,37-289 nm) was integrated and the total particle number concentration showed different weekly patterns between different months: in July and September, number concentration was the lowest during weekend days but in August no differences were observed between weekdays due to an increase in the traffic flow generated by the proximity of the sampling point to the beach (figure 2).

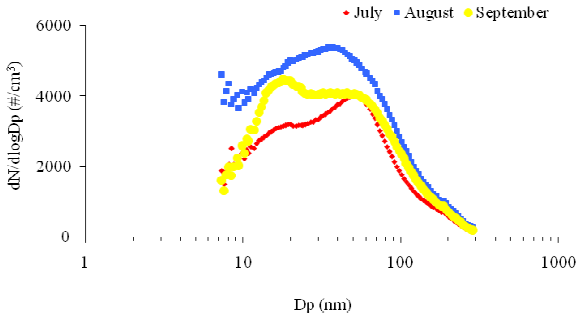

Figure 1. Average number size distributions during the measurements.

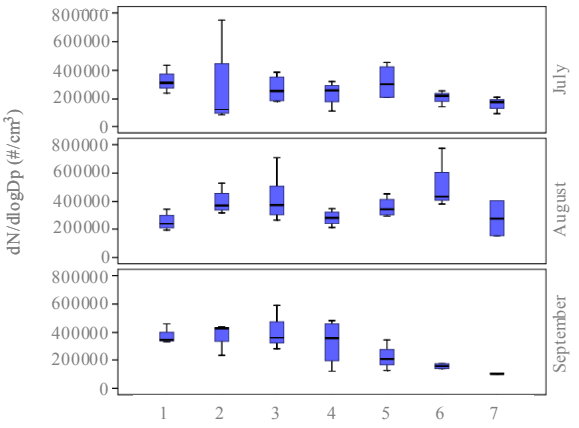

Figure 2. Weekly variations of total number concentrations during sampling months (1: Monday; 2: Tuesday; 3: Wednesday; 4: Thursday; 5: Friday; 6: Saturday; 7: Sunday).

Characterization of different CNT using a thermo-optical elemental carbon / organic carbon analyzer in view of workplace aerosol measurements

A.C. John[1], M. Renker[1] and T.A.J. Kuhlbusch[1]

[1]Air Quality & Sustainable Nanotechnology Unit, IUTA e.V., 47229 Duisburg, Germany
Keywords: nanotubes, CNT, nanoparticles (characterization), occupational exposures.
Presenting author email: johnas@iuta.de

Introduction

In the last few years, applications involving carbon nanotubes (CNT) have been experiencing enormous growth because of the material's unique properties. Besides these promising opportunities, however, potential risks of these new materials for human health and the environment have to be assessed. In view of exposure assessment during CNT production and the processing of CNT-containing products, a method for the detection and quantification of carbon nanotubes in ambient and workplace air is needed.

Methods and Materials

Thermo-optical carbon analysis is a standard to determine exposure to soot at workplaces (NIOSH method 5040). This method determines total carbon (TC=OC+EC) and uses a specific thermal protocol to fractionate different types of "organic carbon" (OC) during a first analysis step in pure helium. Similarly, "elemental carbon" (EC) is analyzed in a second step in a helium/oxygen atmosphere. An optical correction can be applied to account for artefact formation during analysis.

In our study, 13 different CNT (SWCNT= single walled CNT, MWCNT= multi-walled CNT, functionalised MWCNT) having different lengths and diameters were analyzed to determine similarities and differences in their thermal behaviour. In addition to the above mentioned NIOSH protocol, other generally applied methods for ambient air analyses (EUSAAR 2, IMPROVE A, quartz.par) were tested. These protocols last between about 10 and 30 minutes and apply different temperatures in the OC and EC analysis step.

Results and discussion

The results of the 13 different CNT showed that they could be successfully analyzed with the thermo-optical EC/OC analyzer. However, only 11 CNT were analysed with all 4 above mentioned "standard protocols", whereas two out of the 13 CNT showed higher thermal stability and needed a modification of the helium/oxygen step for all 4 protocols (increase of last temperature step, extension of analysis time) to be converted completely.

As expected, the carbon nanotubes were mostly analyzed as elemental carbon, with an EC/TC- ratio ranging from 85% to 100%. However, differences in the fractionation into organic and elemental carbon did not only depend on the type of CNT, but also on the applied temperature protocol. The latter ones can be (amongst others) explained by the different temperatures in the helium step. Protocols with high temperatures in this first step (NIOSH 850°C, quartz.par 870°C) convert some of the material that is only released in the second step in the other protocols (EUSAAR2 650°C, IMPROVE A 580°C in the first step).

When looking for the "best protocol" to analyze CNT, we did not only pay attention to the OC/EC fractionation, but also to the possible distinction of CNT from other carbonaceous substances. Figure 1 and figure 2 show the thermograms of the different materials using the NIOSH protocol and the quartz.par protocol, respectively. Whereas in the first example most of the thermograms overlap, the thermograms of the second figure are better separated, and three groups of CNT can be distinguished.

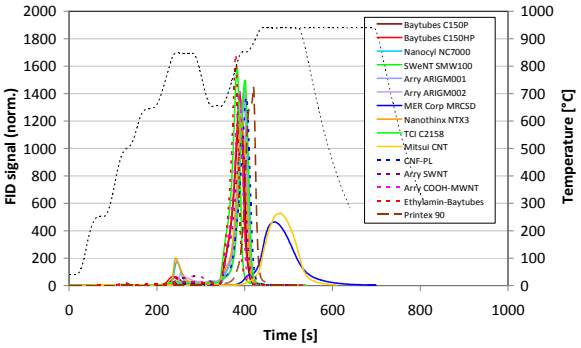

Figure 1. Thermograms of different CNT and carbonaceous materials using the NIOSH protocol.

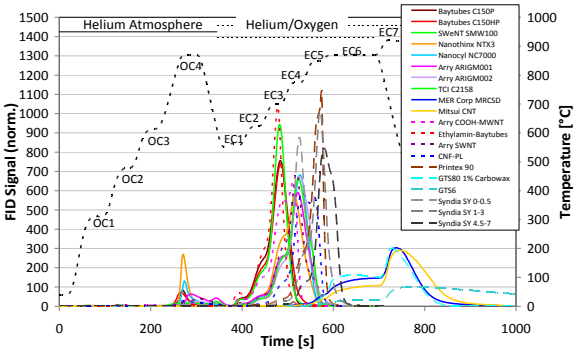

Figure 2. Thermograms using the quartz.par protocol.

The thermograms indicate that CNT seem to be distinguishable from other carbonaceous materials, but that the established temperature protocols might not be suitable for this purpose.
Based on these findings, we currently investigate methods to specifically detect CNT for workplace and environmental measurements.

(Quasi) Real-time detection of catalytically active nanoparticles in presence of a background aerosol

N. Neubauer[1], M. Seipenbusch[1] and G. Kasper[1]

[1]Institut für Mechanische Verfahrenstechnik und Mechanik, Karlsruhe Institute of Technology (KIT), 76131 Karlsruhe, Germany

Keywords: background distinction, catalytically active nanoparticles, (quasi) real-time detection

Presenting author email: nicole.neubauer@kit.edu

Introduction

Workers involved in the production or handling of engineered nanoparticles are likely to be at a high exposure risk. The isolation of this additional contribution to the total background particle concentration at the workplace still remains a challenge. Especially small particles can quickly attach to the background aerosol of the workplace due to coagulation (Seipenbusch, 2008). Because of the resulting disappearance in the size distribution, the on-line measurement devices currently used during exposure studies are not capable to discriminate them from the background particles of the workplace. In a recent publication (Neubauer, 2011) we introduced a new measurement technique based on catalysis for the material-specific detection of nanoparticles with a high sensitivity. We now present further details of this method, especially with regard to the discrimination of catalytically active nanoparticles from a non-active background aerosol.

Experimental

To investigate the specificity of our method, the detection of palladium nanoparticles both directly after their production by spark discharge and after mixing them with SiO_2 background particles was studied. At first the particles were sampled onto a filter for a fixed time interval. Afterwards they were exposed to gaseous reaction educts which initiate the catalytic reaction. The hydrogenation of ethene was chosen as a specific catalytic test reaction for the detection of palladium. The conversion of ethene to ethane due to the catalytic activity of the palladium nanoparticles is measured online by infrared spectroscopy.

In addition, the palladium and the background particles as well as their mixture were characterized by an electrical mobility spectrometer and by electron microscopy. The specific surface area of the catalytically active palladium nanoparticles was determined by nitrogen BET.

Results

Electron microscopy analysis resulted in a median primary particle size of 3.2 nm for the palladium nanoparticles. They are arranged in agglomerates with a mode of the mobility equivalent diameter of 74 nm. The SiO_2 background particles also form agglomerates ($x_{mob,mod}$ 163 nm) of primary particles with a median size of 48 nm. The nitrogen BET analysis of the palladium nanoparticles gave a specific surface area of 87 g/m^2.

The catalytic experiments showed a proportional dependence of the catalytic activity of the pure palladium nanoparticles on their BET surface. In addition, the influence of the temperature and the contact time between the reaction gases and the particles were studied in order to find ideal conditions for the substance-specific detection of palladium.

After the addition of the background aerosol, the smaller palladium agglomerates attach to the SiO_2 particles due to coagulation (cf. Figure 1) and disappear from the particle size distribution. Nevertheless, it was possible to detect them via their catalytic behaviour – even in the attached state.

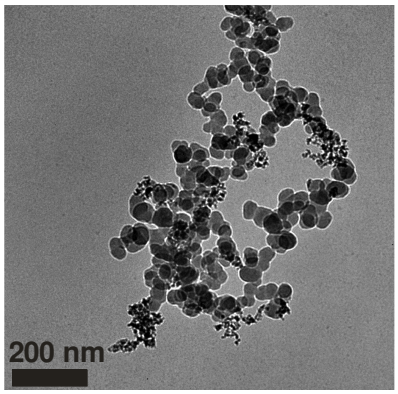

Figure 1: Palladium agglomerates attached to a background agglomerate of SiO_2

Conclusion

The presented measurement technique enables the detection and quantification of palladium nanoparticles based on their catalytic activity. Besides, the method is suitable for a discrimination of catalytically active particles from a non-active background aerosol in (quasi) real-time. The used setup is already a compact and portable version which allows measurements directly at workplaces.

The research leading to these results has received funding from the European Commission's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 211464-2 (Nanodevice).

Epoxy /carbon nanotubes (CNTs) nanocomposites exhibit excellent mechanical properties. Compared to the pure epoxy, they have additional properties like electrical conductivity and thermal conductivity. They are used for applications where low weight, high strength, and high conductivity are required. The potential hazard of such materials has become a significant concern to researchers, manufacturing industries and customers. The exact environmental and health impact of nanoparticles released into the ambient either during manufacturing or in applications is still unknown and a matter of debate. Most of the literature on the toxicity related to CNTs has so far focused on raw CNTs in a finely granulated form to assess their potential health and environmental risks (Helland et al. 2007, Pulskamp et al. 2007). However few studies report on the toxicology of CNT reinforced nanocomposites (Wohlleben et al. 2011).

This study investigated the release of CNTs from the nanocomposite during abrasion. Therefore, three samples containing 0 wt%, 0.1 wt%, and 1 wt% of CNTs were produced and an experimental set-up has been established to perform abrasion, particle measurement, and collection all in one. The particle size distribution of the abraded particles was measured in the size range from 10 nm to 20 µm by a scanning mobility particle sizer (SMPS) and an aerosol particle sizer (APS). Additionally, collected particles were investigated by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX), and transmission electron microscopy (TEM).

The measured particle size distributions showed four size modes for all measured samples. The mode corresponding to the smallest particle sizes of 300-400 nm showed a trend of increasing size with increasing nanofiller content. The three measured modes with particle sizes from 0.6 to 2.5 µm were similar for all samples. In contrary to other release studies, the imaging by TEM revealed that free standing individual CNTs and agglomerates were emitted during abrasion as is shown in Fig. 1.

To our knowledge, the present study is the first to show release of free standing individual CNTs from CNT-embedded composites. The discovery indicates that in environmental, and safety studies, single CNTs should be considered as well as CNT bundles and agglomerates.

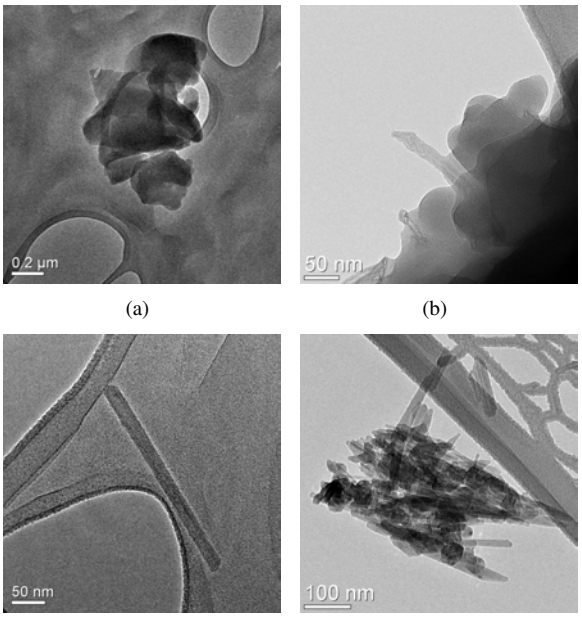

Figure 1: TEM images of abraded particles. a) Agglomerated particles from the pure epoxy sample; b) protruding CNTs from abraded particles of the 1 w% CNT composite; c)-e) free standing individual CNTs; f) an agglomerate of CNTs with a couple of individual CNTs scattered nearby.

The increasing penetration of products containing engineered nanoparticles (ENPs) has raised many concerns with respect to their environmental impacts (Scown et al, 2010). Due to the high variability of ENPs (i.e., in size, morphology, and composition), attempting such an assessment requires standardized methods for measuring potential nanoparticle spills in the environment, as well as techniques for assessing their toxicity on living cells. With respect to the latter, to date there is lack of universal technique for assessing nanoparticle toxicity (Oberdörster, 2005). This is reflected by the vast number of works which in many cases report measurements that are contradicting with one another (Hamouda et al, 2000; Sondi and Salopek-Sondi, 2004).

In this paper we demonstrate the use of aerosol-based techniques for assessing the toxicity of ENPs on living cells. Compared to wet-chemistry techniques, generating test nanoparticles by aerosol-based methods has the advantage of higher purity, as well as of better control over their size, morphology and composition. For our study we generated Ag nanoparticles with mobility diameter of 15, 22, 30 and 50 nm using vaporization condensation. The particles were then collected on filters and were placed on Columbia ANC + 5% sheep's blood (CAN) dishes containing the tested cells. After 3 hours of incubation inhibition zones were evident as a result of the absorption of the ENPs by the cells and their subsequent death. After the growth of the inhibition zones was stabilized, the test plates were held in front of a desk lamp and the zones were measured using a ruler held against the back of the Petri dish. The diameter was measured to the nearest millimeter.

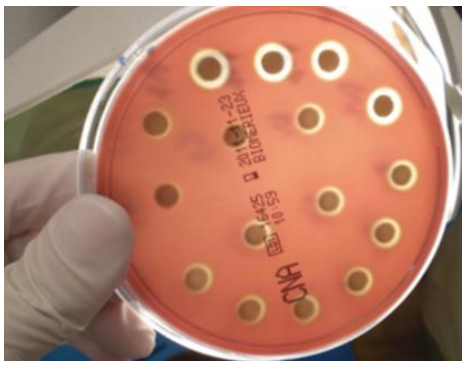

Figure 1: Inhbition zones observed around the nanoparticle-laden filters (brown spots) placed on Columbia ANC + 5% sheep's blood (CAN) medium.

The size of the inhibition zones increased progressively from the start of the experiment until they became stable after ca. 48 hours of incubation. Fig. 2 shows the growth of the inhibition zones (expressed as the diameter of the zone over the diameter of the filter) for the different particle size tested. As expected, increasing the concentration of nanoparticles, the inhibition zone was greater, indicating that the technique provides meaningful results with respect to nanoparticle toxicity. Although no apparent nanosize effect is observed with particle diameters investigated, the method can be easily extended for testing particles of other diameters and morphologies.

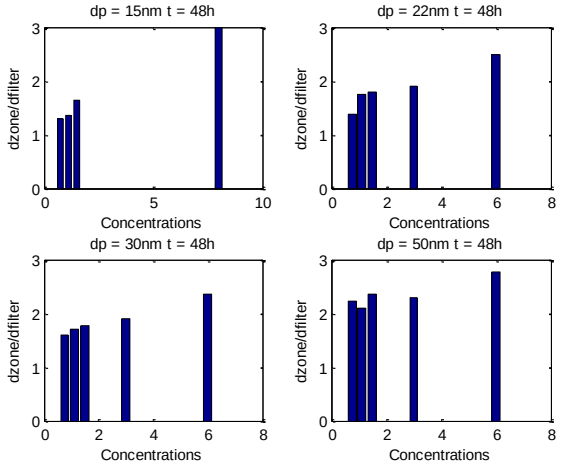

Figure 2: Normalized size of the inhibition zone's with respect to the diameter of the filter as a function of ENP surface concentration expressed in 10^{14} #/m^2.

Nanoparticle Balancing from Release to Dose

H. Fissan[1,2], B. Stahlmecke[1], C. Asbach[1], T.A.J. Kuhlbusch[1,2]

[1]Institute of Energy and Environmental Technology, 47229 Duisburg, Germany
[2]Center for NanoIntergration Duisburg-Essen, 47057 Duisburg, Germany
Keywords: nanoparticle release, exposure pathway, nanoparticle concentration balances, dose estimation
Presenting author email: heinz.fissan@uni-due.de

The production and use of nanomaterials in form of products has risen over the recent years. Besides the expected beneficial properties of nanomaterials, they have also been reported to potentially cause adverse (health) effects, especially if engineered nanoobjects are released into the air and cause exposure of humans. Inhalation is seen as the major uptake route. The starting point for balancing is the amount of released nanoparticles per mass unit of nanostructured material. It can be considered to be a material property. Techniques that have the capability of being standardized, based on different stress (energy input) situations have to be developed (Fissan and Horn, 2012) to reduce the tremendous variability of stress cases. Besides defined stress cases, measurement techniques allowing for quantitative determination of nanoparticle release have to be used. The measures of interest (number, surface area, volume (mass)) depend on the physical and chemical processes occurring during the transport of the nanoparticles in the environment (air) and in the effect system, and the kind of effect considered to be risky. Release is followed by the changes occurring during transport, described by the nanoparticle release-exposure relationship (mainly dilution), then followed by the description of the changes during transport in the effect system (lung deposition), described by the exposure-dose relationship. Balancing should finally allow the determination or at least the estimation of the dose. These processes can be modeled taking into account different exposure scenarios. From thereon it is the task of, for instance toxicologists, to determine the possible hazard for different health endpoints.

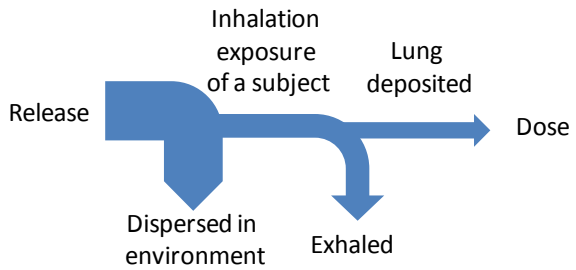

Figure 1. Balancing a metric from release to dose

Modeled balances can be evaluated or controlled by measurements at different points of the exposure pathway. For aerosol balancing, measurement techniques for number size distributions of spherical particles and loose agglomerates are available (SMPS, UNPA). For aggregates correction procedures for multiple charge effects still have to be developed. For transformation into number, surface area and volume distributions as function of volume per aggregate, calibration methods are developed (Fissan et al., 2012).

Another difficult problem for measurements is the in the real world especially in the environment always existing background of nanoscale particles.

We will report about first steps towards measuring nanoparticle release properties of nanostructured materials. We will set up a balance for number, surface area and volume concentration in an exposure scenario for inhalation to determine the expected dose. We will describe the possible control measurements along the exposure pathway.

Cytotoxicity of nanosilver with different sizes: Effect of Ag^+ ion release

A.Pratsinis[1], P. Hervella[2], S. E. Pratsinis[1], J-C. Leroux[2] and G. A. Sotiriou[1]

[1]Particle Technology Laboratory, Institute of Process Engineering, Department of Mechanical and Process Engineering, ETH Zurich, Sonneggstrasse 3, CH-8092, Zurich, Switzerland
[2]Drug Formulation and Delivery Laboratory, Department of Chemical and Applied Biosciences, ETH Zurich
Keywords: silver nanoparticles, toxicity, surface area concentration, dissolution.
Presenting author email: panna@student.ethz.ch

Nanosilver is used in heterogeneous catalysis and has promising applications in textiles [1], biomedical applications, biodegradable polymer films for food packaging [2], biological labeling [3], photonics, coloristic (plasmon)[4], optoelectronics and surface enhanced Raman scattering (SERS). At the same time, the use of nanosilver raises concerns for its toxicity against aquatic micro-organisms when disposed and therefore draws public attention. In fact, nanosilver is one of the first nanomaterials to be regarded toxic and petitions had been filed to the U. S. Environmental Protection Agency (EPA) to regulate it as pesticide. Therefore to safely employ nanosilver, correct risk and dose relations assessments need to be made.

There are several studies on the antibacterial activity of nanosilver made by wet-methods, co-condensation, and flame spray pyrolysis. Smaller nanosilver particles are more toxic than larger ones [5] especially when oxidized. Additionally, even though silver metal is practically insoluble in water, when present in nanometer size range Ag^+ ions are released (leached) [6-8] from its surface. It has been shown recently [9] that the antibacterial activity of small (<10 nm) nanosilver particles is dominated by Ag^+ ions, while for larger ones (>15 nm) the antibacterial contribution by Ag^+ ions and particles is comparable. Such a behavior implies a surface area dependency of the antibacterial activity especially for small nanosilver sizes since the Ag^+ ion release is proportional to the exposed nanosilver surface area [9]. Additionally, when a nanothin silica coating on the surface of nanosilver is applied, this antibacterial activity can be minimized [10].

Here, the toxicity of nanosilver against mammalian cells is investigated by immobilizing nanosilver on nanostructured silica particles and closely controlling Ag content and size. These Ag/SiO_2 nanoparticles were characterized by S/TEM, EDX spectroscopy, X-ray diffraction, N_2 adsorption. Furthermore, the fraction of dissolved nanosilver was determined by measuring the released (leached) Ag^+ ion concentration in aqueous suspensions of such Ag/SiO_2 particles. The toxicity of Ag^+ ions was distinguished from that of nanosilver particles by monitoring the growth of cell populations in the presence and absence of Ag/SiO_2 particles. The toxicity of nanosilver was dominated by Ag^+ ions when fine Ag nanoparticles (less than about 10 nm in average diameter) were employed that release high concentrations of Ag^+ ions. In contrast, when relatively larger Ag nanoparticles were used, the concentration of the released Ag^+ ions was lower. Then the toxicity of the released Ag^+ ions and nanosilver particles was comparable.

Investigations on nanoparticle release from artificially weathered coatings and composites that experience different treatment processes

D. Göhler, A. Nogowski, P. Fiala and M. Stintz

Research Group Mechanical Process Engineering, Institute of Process Engineering and Environmental Technology, Technische Universität Dresden, 01062 Dresden, Germany

Presenting author email: daniel.goehler@tu-dresden.de

Possible risk to health, safety and environment, associated with the use of engineered nanomaterial, is determined by whose hazard potential and exposure level. Exposure studies in laboratory as a consequence of the tiered approach of exposure measurements (Kuhlbusch *et al.*, 2011) can provide basic data about the ability and/or the quantity of nanoparticle release due to simulated treatment processes.

Currently, only few studies have analyzed the release of engineered nano-objects (ENO) from composites and coatings in the air. Vorbau *et al.* (2009), Guiot *el al.* (2009) and Wohlleben *et al.* (2011) simulated weak, but long-term abrasion processes and found only a slight release of coarse particles containing embedded ENO. Total abrasion by sunlight, wind and human contact (Hsu & Chein, 2007) led to similar results. The nanoparticle release from coatings due to sanding were studied by Koponen *et al.* (2011), Göhler *et al.* (2010) and Wohlleben *et al.* (2011), while cutting and drill processes on composite material were simulated by Bello *et al.* (2009 & 2010). Sanding, cutting and drilling based on high energy input, that led in each case to a considerable generation of nanoparticles, whether ENO were added to the matrix material or not. Free ENO were only observed by Bello *et al.* (2010), which can maybe explained by thermal degradation of the matrix material.

External impacts like sunlight, moisture or temperature fluctuations can destruct the matrix material of coatings and composites, what can lead to an open laying of ENO and is probably associated with a higher release risk.

Based on an extended test apparatus (Göhler *et al.*, 2010) artificially weathered samples of numerous coatings and composites with and without nanoscaled pigments were exposed to different treatment processes (wind erosion, dynamic friction and sanding). Concerning the process-specific amount of released particles different experimental setups with suitable aerosol measurement devices (e.g. EEPS, APS, CPC) were chosen to determine particle size distributions and particle number concentrations. Additionally, electrostatic precipitation was used for preparing samples analyzed by scanning electron microscopy, transmission electron microscopy and energy dispersive X-ray spectroscopy.

Results based on the sanding of artificially weathered coatings show an increase of the nanoparticle release in comparison to the non-weathered samples, while the weathering of the composites led to a decrease in the particle release. In some cases the addition of nanoscaled pigments to the matrix material results in a decrease of released particles, for both non-weathered and weathered coatings. Some coatings based on non-nanoscaled pigments show a higher release of nanoparticles in comparison to the non-doped ones.

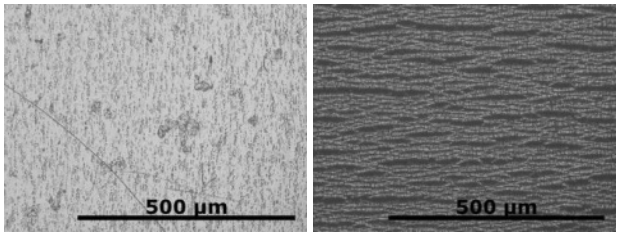

Figure 1: Example of changes on the sample surface due to artificial weathering (initial state left)

In addition to the results of particle release, the presentation will also show the process simulations, the evaluation of measurement data for the quantification of the particle release and the possibility to determine emission factors for the comparison of different treatment processes.

The number of nanotechnological products, particularly those using nanoparticles has risen constantly over the recent years. Besides the tremendous advantages these products provide over conventional products, a discussion about possible adverse effects especially to human health has been initiated. Since a risk may only arise from nanoparticles if an exposure coexists with a potential hazard of the substance, exposure assessment is a substantial element of risk analysis. The highest probability for release of and consecutive exposure to engineered nanomaterials exists in workplaces where these materials are produced, handled or used. The assessment of exposure to nanoparticles requires a differentiation of the engineered nanomaterials from ubiquitous background particles. While a definitive online differentiation of engineered nanomaterials from other background particles is usually impossible, we here present a more pragmatic approach, used in the German project nanoGEM. The approach is tiered and based on a suggestion by the German Chemical Industry Association (VCI). The first tier comprises data gathering for the considered workplace to obtain information if nanomaterials may be released. If exposure to nanomaterials cannot be excluded from tier 1, the second tier comes into play, which foresees a simplified assessment of the particle concentrations in the workplace and comparison with the common average background concentration. Tier 2 assessment can either be carried out as a short term measurement or as a long-term monitoring. Monitoring instruments can either permanently be installed in workplaces to allow for a continuous monitoring of the particle concentrations in the workplace, or only temporarily, e.g. if a first assessment revealed indications for a potential particle release. If the assessment in the second tier provides evidence that particles may be released, tier 3 needs to be followed that foresees a detailed analysis of the workplace aerosol. In tier 3 the particle size distributions are measured in a wide size range and particle samples taken for consecutive chemical and morphological analysis. Two sets of measurements are conducted to differentiate between background particles from those stemming from nanomaterials. This can be achieved by either measuring with two sets of equipment simultaneously in a background location and a workplace location or by using a single set and measuring during periods before/after and during the use of nanomaterials. Consecutive electron microscopic analysis of the sampled particles can provide clear evidence for the presence or absence of engineered nanomaterials. All measurements within nanoGEM are conducted in accordance to standard operation procedures (SOPs). The strategy and SOPs will be presented along with first measurement results.

Aerosol particle emissions from sanding coated plates: effect of the sanding paper and filtering method to the human exposure.

I.K. koponen[1], M. Levin[2] and K.A. Jensen[2]

[1]National Research Centre of Working Environment, Copenhagen, Denmark
Keywords: Occupational exposures, Occupational health
Presenting author email: ikk@ikkopone.fi

There are several safety concerns with consumer products were engineered nano materials (ENM) have been used. However, there is a vast amount of products in the everyday use which have embedded ENMs. Production lines where ENMs are handled are usually controlled; therefore exposure to nanoparticles is more likely to happen after the manufacturing process itself. One common product group where ENMs have been used for decades are e.g. paints and lacquers.

Studies of dust released performing sanding to coated plates have been published by e.g. Koponen et al, 2010; Gohler et al., 2010. Both studies were focused on investigating differences in dust emission depending what kind of ENMs were used in the coating. On this study aim is to investigate what could be the real exposure for the worker or end user when sanding coated plates.

Exposure experiments were conducted inside a 20.6 m3 human exposure chamber made with an inner wall of stainless steel (a nominal air exchange rate of 9.2 ± 0.8 h-1). HEPA-filtering of the supply air to exposure chamber assured low total background particle concentrations (<300 cm-3).

To compare emission rates we made an attempt to measure emission source strength more precisely. These experiments were performed in the small 0.66 m^3 stainless steel chamber.

Number size distribution measurements were conducted using a TSI Fast Mobility Particle Sizer (FMPS; 5.6-560 nm) and a GRIMM Dust monitor Model 1.109 (0.28-30µm) for the aerosol size and number distribution. For background measurements, we used a TSI Condensation Particle Counter (CPC) Model 2022 and GRIMM Dust monitor Model 1.109 (0.28-30µm). The particulate mass of particles smaller than 1 µm (PM1) was sampled with Triplex cyclones Model SC.1.106 mounted with cellulose-filters for electron microscopy and Teflon filters for gravimetric analysis. Humidity and temperature were monitored using Gemini sensors.

Test plates were coated with paints, fillers and lacquers. Paints were manufactured for indoor, outdoor and metal use. Some of them had ENM embedded like e.g. Nano-Silicasol (SiO2; 7 nm). One of the filler were with CaCO3 and other one with CaCO3+perlite. We had two types of lacquers; UV-hardcoat and another with 5% Nano-SiO2 (SiO2; <50 nm) added.

Previously in our study Koponen et al.,2011, we presented aerosol particle emission data for sanding different paint products. Main focus was to compare the difference between the products where ENMs have been used to enhance paint quality and paints were ENMs were not used. In that study we used closed system to make sure that we would characterize released dust as good as possible.

Here focus was to estimate real exposure risk while using sanding machine to sand coated plates. We compared different paint products using two different kind of filter paper with grin sizes 120 and 240. In addition three different kind of filtering methods were used to estimate possible exposure.

Figure 1 presents aerosol number size distribution spectra measured from human exposure chamber during sanding indoor wall paint without ENPs added. Small particles under 50 nm are originating from the sanding machine electrical motor as reported in our previous study. Figure 1 illustrates how filtering is effecting the particle emissions and the possible exposure to the user.

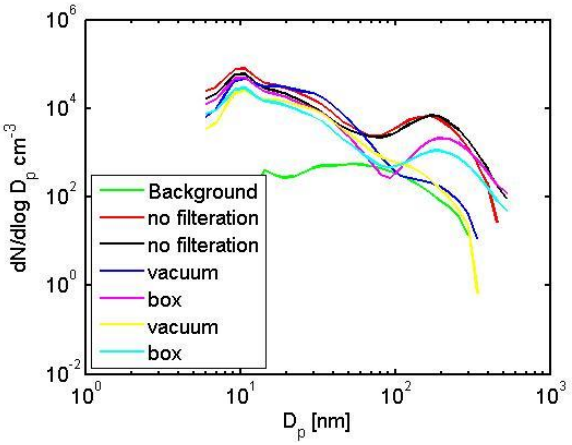

Figure 1. Measured size distribution spectra during sanding experiment.

Environmental health and safety of nanomaterials are of growing concern as it becomes more common for consumer goods to utilize nanomaterials. For a risk to be posed by nanomaterials both hazard and exposure need to be present. The hazard is determined by toxicology studies, whereas the exposure is determined by exposure assessments.

The few reports (Wang et al. 2011, Walser et al. 2012) of workplace exposures suggest that engineered nanomaterials are released at high mass and/or number concentrations only under unusual circumstances. However, there still exists the need for study of exposure levels to different engineered nanomaterial types in occupational and environmental settings. Herein we present emission measurements of airborne nanoparticles performed at EMPA Thun, during the process of nanoparticle production.

Assessments of potential occupational exposure to nanoparticles were conducted at a pilot facility where nanoparticles were synthesized by inductively coupled plasma (ICP) (Leparoux, et al. 2005, 2010). The nanoparticles plasma synthesis is based on rapid condensation, also called quenching, of a supersaturated gas phase. The quenching dynamics influence the nanoparticles properties such as size, size distribution and eventually the final chemical composition. The synthesis procedure is taking place in the plasma reactor and the process itself is based on the evaporation-condensation method. Numerous view ports for process observation, monitoring, and in-situ characterization were analysed.

Regarding the emission studies, the filtration unit was used to collect small quantities of nanoparticles on the surface of a filter. The filter cartridge contained metal filters which were backpulsed to removed caked nanoparticles. This system was used to collect larger quantities of nanoparticles.

Further on, real-time aerosol instruments were used to monitor particle concentration and size distribution. By looking for relative changes in size and concentration, while also considering particle sources, it was possible to monitor a nanoparticle release. Instrumentation that was included was: fast mobility particle sizer (FMPS), handheld condensation particle counter (CPC), nanoparticle surface area monitor (NSAM) and aerodynamic particle sizer (APS). Area sampling with track-etched polycarbonate filters was done for particle identification by scanning electron microscopy (SEM).

The P-Trak and DustTrak were placed in front of the ventilation exhaust. This placement likely resulted in elevated concentrations. Dust was visible when filter was blown with compressed air. The cleaning of the cartridge resulted in a significant increase in particle concentrations. During this process the particle concentrations increased by 20 times. The blowing of the cartridge with compressed air resulted in elevated particle concentrations which subsided after approximately five minutes. The particle concentration returned to that which was present before cleaning began (background level).

A particle release was not detected during the synthesis of SiC nanoparticles. Particles were released when nanoparticles or nanoparticle contaminated equipment were handled in the open air. Compressed air was found to resuspend nanoparticles when it was used in inadequately ventilated areas. The use of compressed air in workplaces containing nanoparticles should be avoided or methods recommended by ASTM and NIOSH standards should be used instead.

Analysis of aerosol solid nanoparticles produced during soldering using metal alloys

Virginia Gómez, Silvia Irusta, Francisco Balas and Jesús Santamaría
Instituto de Nanociencia de Aragón (INA), Edificio I+D, c/ Mariano Esquillor s/n, 50018 Zaragoza (Spain)
Keywords: Nanoparticles ;Soldering ; Occupational exposure
virgomez@unizar.es

In the recent years, there has been an increasing concern about the toxicological effect of airborne particles. Several factors as size, shape, charge, aggregation state and material have capital importance in the toxicological effects of particles with diameters below 100 nm. Among the different exposure routes to particles, the most worrying are inhalation and ingestion. In order to prevent worker exposure to harmful aerosols, different industrial processes has been studied as welding, sanding and grinding.

Soldering is a broadly used process in electronica industry and also in investigation process. This process involved join two electronic components by using a filler tin-based metal alloy. Moreover, solder wires also contains a small amount of flux based in colophony rosins in order to prevent solder oxidation. Continuous exposure to colophony fumes can lead in harmful effects as bronchial asthma [1-3] and dermatitis [4]. Another concern about soldering is the use of lead bases solders. Despite the development in latest years of lead-free solders, soldering with lead alloys is still common in a wide variety of occupational environments.

In the present work, aerosol particles generated during soldering process has been characterized. Two solder wires have been chosen one lead-free (SnAgCu) and the other with lead (SnPbCu). The soldering wires have been characterized by X-ray photoelectron spectroscopy (Axis Ultra DLD, Kratos Tech.) and scanning electron spectroscopy, secondary electron image and energy dispersive X-ray spectroscopy (FESEM, Inspect form FEI).

Experiments have been performed inside an especially-designed globe box chamber in order to avoid the presence of background nanoparticles. The aerosol formation is alternatively online monitored with a condensation particle counter (CPC, Grimm) and an optical particle counter (OPC, Grimm). As the CPC and OPC take the aerosol from the chamber at 0.3 and 1.2 l/min, the same flow of HEPA-filtered clean air is added during the experiment to keep constant air pressure. Offline analysis of the aerosol particles has been performed using transmission electron microscopy (T20 – FEI), scanning transmission electron microscopy (STEM) and energy dispersive X-ray spectroscopy (TEM-EDX) (F30 – FEI) using holey-carbon coated copper grids placed in a stainless steel filter holder. Aerosol nanoparticles have been also filtered through polycarbonate filters and subsequently observed by scanning electron microscopy (SEM) and SEM-EDX

Figure 1 shows the SEM image of nanoparticles and aggregates collected on the surface of polycarbonate filters. Online aerosol analysis shows also the generation of primary nanoparticles with average diameters below 100 nm and aggregates with diameters below 1 μm consisting of metallic nanoparticles in a flux matrix. The EDX analysis of the particles and aggregates show lead and tin signals.

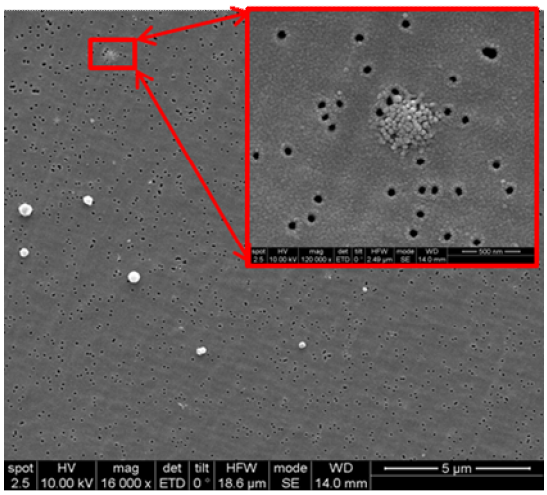

Figure 1. SEM image of aggregates and some nanoparticles collected on the surface of a polycarbonate filter after soldering with SnPbCu at 250 ºC.

The chemical analysis soldering fumes show the presence of tin and lead-containing nanoparticles. This study points to the possible harmful impact of soldering due to the presence of nanoparticle-laden aerosols with variable contains of metals.

Presenting author email: jussi.lyyranen@vtt.fi

The increased use of nanoparticles and nanomaterials to produce different kind of products has increased concern on the possible health effects of these products. Also the processes used to manufacture these products have raised interest. In this study Cu and carbon nanotube (CNT) like containing Cu-particles produced by hydrogen reduction reaction from copper chloride precursor vapour and H_2O + ethene (for CNT production) in nitrogen carrier gas (Forsman, et al., 2008) were studied. The aim was to characterise the produced particles with aerosol measurement devices to help to design the scale-up of the Cl-process as well as possible both technically and occupationally safe. In addition, a custom-made electrostatic precipitator (ESP) was installed to the measurement system to determine its particle removal efficiency.

The particle number concentration was measured with a TSI 3775 CPC and the number size distribution with a TSI 3080 electrostatic classifier with a TSI 3081 DMA connected with a TSI 3775 CPC and controlled by the SMPS software. The mass concentration was measured with a TEOM 1400a. The gas composition was monitored with a Fourier-Transform Infrared spectrometer (FTIR). Individual particle samples for electron microscopy (EM) analyses were collected with an aspiration EM sampler.

The particle number concentration with CuCl and H_2 feed only varied between 0.4-1.0·10^9 1/cm^3 and the CMD 35-47 nm. The average mass concentration was 450 mg/m^3. When the ESP was switched on the number concentration dropped down to 1.0-2.0·10^3 1/cm^3 producing particle removal efficiency of 99.999 %. The produced particles were almost smooth spherical particles up to about 150 nm in diameter (Fig. 1a). The HCl concentration measured by FTIR indicating the reduction of CuCl to Cu was approximately 200 ppm.

With CuCl and H_2 feed together with and H_2O + ethane (for CNT production) the particle number concentration varied between 0.2-0.6·10^9 1/cm^3 and the CMD 66-74 nm. The average mass concentration was 370 mg/m^3. When the ESP was switched on the number concentration dropped down to a few hundred particles 1/cm^3 producing particle removal efficiency of 99.99999 %. The produced particles were carbon nanotube like cords or wires with very small spherical Cu particles at the end of the wires (Fig. 1b). The width of the wires was approximately 25 nm or less. The HCl concentration measured by FTIR indicating the reduction of CuCl to Cu was approximately 100 ppm.

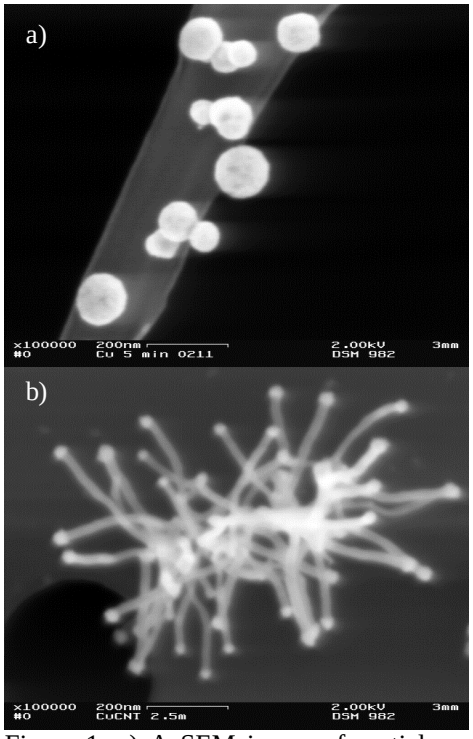

Figure 1. a) A SEM image of particles produced with CuCl and H_2 feed only.
b) A SEM image of particles produced with CuCl and H_2 together with H_2O + ethene (for CNT production).

The results indicated that even in very aggressive environments, i.e. reducing and HCl containing atmospheres, the ESP was able to remove practically all the produced particles. For the final scale-up a large enough back-up filter after the ESP would be recommended to remove the particles possible penetrating the ESP.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement 24789 (NanoSustain).

Presenting author email: jussi.lyyranen@vtt.fi

The increased use of nanoparticles and nanomaterials may set new demands for the recycling of the products containing these materials. In this study the possibly emitting nanoparticles during heating and melting of window glass coated with pro.Glass Barrier 401 (containing ZnO nanoparticles) and only with sol-gel binder matrix were investigated. As a reference, a plain window glass sample without any surface treatment was heated/melted. The glass sheets were provided by Nanogate. The particle number and mass concentration as well as the number size distribution were measured during the heating/melting, i.e. mimicking the established recycling process of the product. The heating/melting was carried out in an induction furnace and the temperature range studied was 700-1500 °C.

The particle number concentration was measured with a TSI 3775 CPC and the number size distribution with a TSI 3080 electrostatic classifier with a TSI 3081 DMA connected with a TSI 3775 CPC and controlled by the SMPS software. The mass concentration was measured with a TEOM 1400a. Individual particle samples for electron microscopy (EM) analyses were collected with an aspiration EM sampler.

The first traces of particles appeared in the number concentration for coated window glass at approximately 700 °C, but the mass concentration was very low, close to 0 (MC≈0-5 mg/m^3). The primary particles from sol-gel binder matrix coated glass were almost perfect spheres, with a diameter of approximately 50 nm or smaller. The primary spheres had not formed aggregates by adhering to each other. For pro.Glass Barrier 401 coated glass the primary particles were also almost perfectly shaped single spheres at 700 °C, but the diameter was much smaller, less than 15 nm.

At the highest temperature of 1500 °C the number of the primary spheres and nanoparticles seemed to have decreased, and the number of larger particles (>100 nm) increased. This indicated the further growth of the nanoparticles by condensation and aggregation. At 1500 °C the number concentration for sol-gel binder matrix coated glass was somewhat lower than for pro.Glass Barrier 401 coated glass, 1.0-1.6·10^9 1/cm^3 and 1.4-2.0·10^9 1/cm^3, respectively. However, the mass concentration for the sol-gel binder matrix coated glass was clearly higher than for the pro.Glass barrier 401 coated glass, 135-150 mg/m^3 and 84-93 mg/m^3, respectively. The particles emitted from the plain window glass were mainly rod-like and asymmetrical (Fig. 1a) compared to almost spherical ones for coated glass (Fig. 1b).

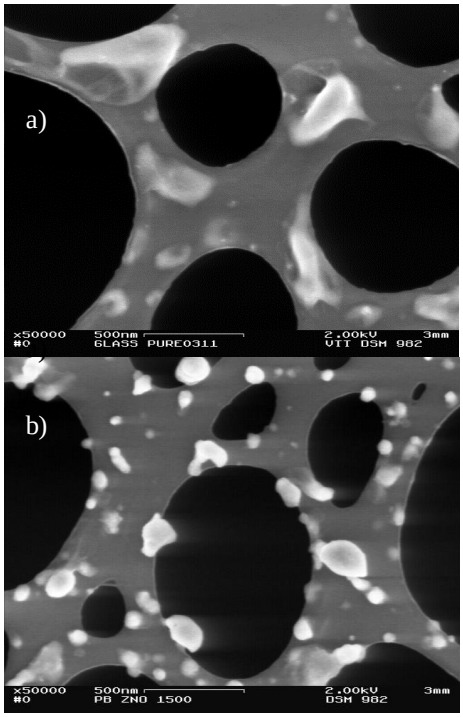

Figure 1. a) A SEM image for particles emitted at 1500 °C for plain window glass.
b) A SEM image for particles emitted at 1500 °C for pro.Glass Barrier 401 coated glass.

The number and mass concentration of the emitted particles from the glass samples did not depend on whether coating was applied or not, nor on the type of coating. A relatively larger amount of the particles emitted from plain window glass seemed to be larger than nanoparticles (>100 nm) than the ones emitted from coated glass samples. A notable increase in the number concentration begun at > 1000 °C and in the mass concentration > 1300 °C for all samples. In the emitted particles Na was enriched whereas the amount of Si was decreased in all of the glass samples. Zn was found only in particles emitted from the pro.Glass Barrier 401 coated glass.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement 24789 (NanoSustain).

Atmospheric new particle formation in the Central European boundary layer: A long-term study using Neutral Cluster Air Ion Spectrometer (NAIS) data

Keywords: Nucleation, New Particle, Sulphuric acid, Formation and Growth

New particle formation (NPF) from supersaturated vapors (nucleation) has been show to occur almost everywhere in the atmosphere. According to current understanding, NPF is controlled mainly by gaseous sulphuric acid (H_2SO_4), a species that has a low vapor pressure and is therefore easily condensable. However, there numerous observations in the literature imply that ambient H_2SO_4 concentrations are not sufficient to explain the observed nucleation rates and subsequent particle growth by H_2SO_4 alone. Organic compounds represent a large fraction of secondary aerosol mass and are therefore considered to play an important role for the growth of the freshly formed particles.

NPF events were experimentally detected at the research station Melpitz (Germany) for the time period 2008-2011 using the following instruments:

- NAIS (Neutral Cluster Air Ion Spectrometer), measurement range 2-20 nm
- TDMPS (Twin Differential Mobility Particle), measurement range 3-800 nm
- APS (Aerodynamic Particle Sizer), measurement range 0.5-10 µm

A new method has been devised to identify and classify NPF events. It is based on the convolution integral (CI) of time series of freshly nucleated particles (2-20 nm). First, outstanding NPF events, which amounted to about 20% of all measurement days, were selected manually from the data set. An average diurnal cycle $N^*_{[2\text{-}20nm]}$, in which time series were normalised relatively to the beginning of the NPF event, was computed for those days. $N^*_{[2\text{-}20nm]}$ represents the "idealistic" behaviour of a new particle formation event. In a second step, the time series of the convolution function between $N^*_{[2\text{-}20nm]}(t)$ (defined for a 15 hour interval) and $N_{[2\text{-}20nm]}(t)$ was calculated. This time series is illustrated in Fig. 1a. Next, the peak values of the convolution integral were evaluated. High values in CI indicate an objective measure of significant particle formation. Fig. 1b illustrates the classification of NPF events into three classes. The CI method was also compared against the widely used method by Dal Maso et al. (2005). The comparison shows basically a good agreement between the methods for the strongest NPF events. However, the new CI method was, at least for this data set, able to detect weak NPF days more accurately than based on a visual inspection of contour diagrams of particle size distributions.

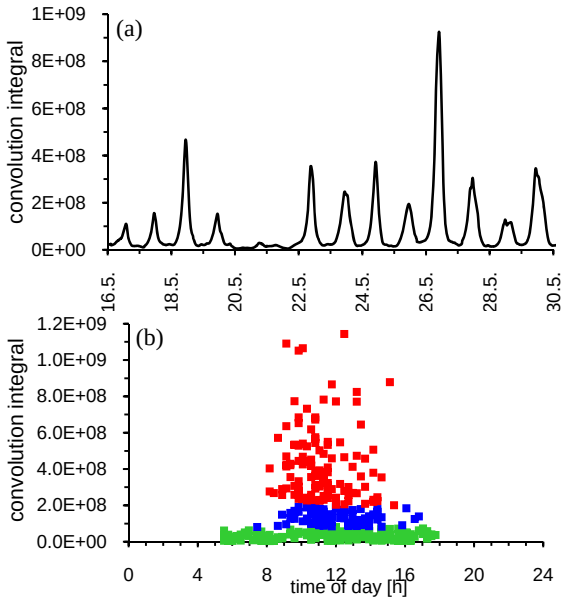

Fig. 1. (a) time diagram of the convolution integral from 16th to 30th May 2011, (b) daytime diagram of the daily maximum of the convolution integral for all observation days. Event classes are as follows: red: class I (intense new particle formation), blue: class II (new particle formation occurs but at low intensity), green: class III (NPF below significance level).

The presentation will conclude with the analysis of the relationship between NPF events and precursor concentrations, such as a H_2SO_4 proxy and a calculated ternary nucleation rate.

Nanostructured catalytic layers for fuel cell electrodes prepared by electrospray

S. Martin, B. Martinez-Vazquez, P.L. Garcia-Ybarra and J.L. Castillo

Dept. Fisica Matematica y de Fluidos, Facultad de Ciencias UNED, Madrid, Spain
Keywords: Electrospray, Deposit morphology, Nanoparticles, Fuel cell
Presenting author email: smartin@dfmf.uned.es

The electrohydrodinamic atomization or electrospray has demonstrated to be a suitable technique for micro- and nano-thin-film deposition (Martin *et al*., 2005; Jaworek and Sobczyk, 2008). In our laboratory, the electrospraying of liquid suspensions containing catalytic nanoparticles is being successfully used in the production of porous catalytic layers for proton exchange membrane fuel cell (PEMFC) electrodes (Martin *et al*., 2010a, 2010b). One of the factors limiting the wide use of PEMFCs is the cost of the catalyst (platinum) in the electrodes. The goal of this study is to determine the electrospraying working conditions for obtaining electrodes with a low catalyst loading without compromising the fuel cell performance.

The electrospray deposition method enables the generation of nanostructured catalytic layers whose building blocks are clusters (of a few catalyst particles each) with a characteristic size of approximately 100 nm disposed in a dendritic arrangement (see Fig. 1).

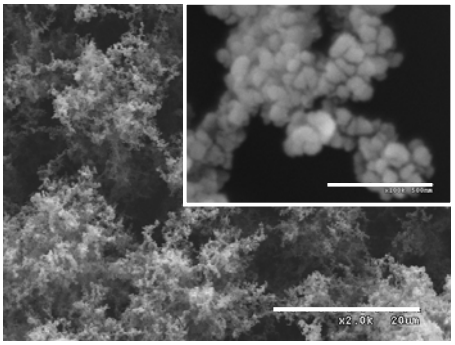

Figure 1. Dendritic structure of a catalyst layer with 0.01 $mg_{Pt}cm^{-2}$ Pt loading. The micron bar is 20 μm long for the main image and 500 nm for the inset.

This arrangement produces catalytic deposits with the appropriated morphology for PEMFC electrode preparation. On the one hand, the small size of the catalyst clusters leads to a high dispersion of the catalyst. On the other hand, the dendritic arrangement of the catalyst clusters results in a highly porous deposit with an enhanced permeability and increased electrochemical active surface area (Castillo *et al*., 2012).

The electrospray technique allows the preparation of efficient PEMFC electrodes with ultra-low platinum loadings (0.01 $mg_{Pt}cm^{-2}$). The conditions for achieving uniformly thin layers with the electrospray working in a stable cone-jet mode will be discussed. Figure 2 shows the fuel cell performance for several electrodes prepared under the same electrospraying parameters. The catalyst utilization (power per gram of platinum) delivered by these electrodes lies in the interval 30-35 kW g_{Pt}^{-1} what, to the best of our knowledge, represents the maximum platinum utilization reported up to now for any catalyst deposition method. Indeed, these results overcome in more than 50% the highest utilization achieved by sputtering (Cavarroc *et al*., 2009) and it is 3 times the Pt-utilization in our previous work (Martin *et al*., 2010b).

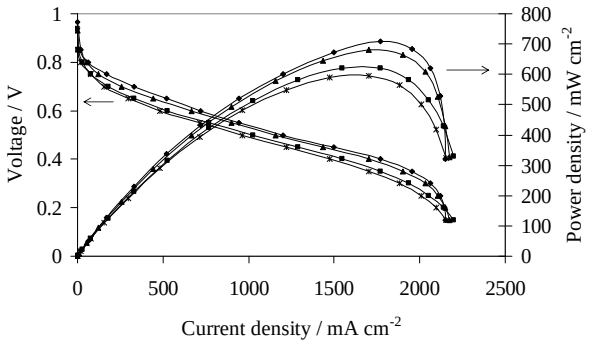

Figure 2. Fuel cell current-voltage and power density curves for electrodes with a Pt loading of 0.01 $mg_{Pt}cm^{-2}$.

The latter results were achieved using a fuel cell with small (5 cm^2) square electrodes. The scaling up to get 50 cm^2 square electrodes (delivering the same power density) will be discussed. In this way, the electrospray deposition method may be used to cover the entire range of required electrode sizes: from automotive or stationary applications down to portable units.

Presenting author email: anna.lahde@uef.fi

The structure of global energy supply is changing rapidly towards sustainable energy solutions. However, all forms of sustainable and intermittent energy production (e.g. wind power, photovoltaics) and sustainable transportation (e.g. hybrid and full electric vehicles) require excellent energy storage systems in order to increase their effectiveness (Hall and Bain 2008). Li-ion secondary cells are one of the most advanced battery energy storage systems currently available due to their high energy density. However, new higher capacity materials are urgently required in order to address the need for greater energy density, cycle life, lower cost and charge lifespan, among other issues faced by Li-ion batteries.

Iron-based cathode materials are ideal for future Li-ion batteries in terms of cost and environmental friendliness. In particular, olivine phase $LiFePO_4$ is an attractive material due to its high cycle stability, low toxicity and affordable precursor materials. However, $FePO_4$ is known to crystallize at least in four different polymorphs in addition to olivine that could also be electrochemically active (Voβ et al. 2012, Arroyo-de Dompablo et al. 2005).

In this paper, we present the preparation of $LiFePO_4$ with controlled phase composition using a spray pyrolysis. The precursors were dissolved in water and atomized using an ultrasonic nebulizer (RBI Pyrosol 7901). The produced droplets were then carried to the heated zone of the reactor. Experiments were carried out at temperatures between 200 and 800 ºC. The aerosol exiting the heat zone was rapidly cooled with a large volume of dilution gas (air or N_2) at ambient temperature. The particle size was controlled by precursor solution concentration. The particle properties were analyzed with electron microscopy, XRD and Raman.

The particles were spherical, soft agglomerates, see Figure 1. The particle size was around 0.5 µm based on SEM images.

Figure 2 shows the XRD patterns of particles produced at 800 ºC. Based on the XRD the particles contained two different crystalline phases, i.e. high pressure and olivine polymorphs. By controlling the conditions, the desired crystalline phase can be obtained.

Introduction

Liquid Flame Spray (LFS) is an aerosol synthesis method for nanoparticles. LFS generated nanoparticles are deposited onto paperboard surface on roll-to-roll process. Functional nanoparticle coating is produced on paperboard surface in order to modify the surface properties. Main focus is to modify paperboard wetting properties. Coating is applied in laboratory conditions, demonstrating roll-to-roll process with line speed of 50 m/min. Functional properties like hydropohobicity and hydrophilicity are demonstrated. (Mäkelä et al. 2011, Stepien et al. 2011 and Teisala et al. 2010) In this study, different mass ratios of Ti/Si on the coatings were analysed.

Methods

In LFS method, liquid precursor is sprayed into a turbulent H_2/O_2-flame. The material evaporates, reacts, nucleates and grows inside the flame. Liquid precursors were prepared by solving titanium(IV) i-propoxide (TTIP) and tetraethoxysilane (TEOS) to isopropanol. All liquid precursors contained total concentration of 50 mg/ml of Ti+Si combined. Produced nanoparticles are mixture of TiO_2 and SiO_2. Coating of the paperboard can be carried out in laboratory scale with the coating track, demonstrating the roll-to-roll process or in a pilot scale roll-to-roll process. Line speed can be varied between 0-200 m/min. Coated paperboard surfaces were analysed using water contact angle (WCA) measurement and mean mobility particle sizes were measured with SMPS.

Results

WCA measurements (Figure 1) show that Ti/Si ratio in the used precursor has a significant effect on the water contact angle. Coatings with high Ti/Si ratio are superhydrophopic, water contact angles exceeding 160°. Coatings with low Ti/Si ratio are superhydrophilic with contact angle below 10°. Water contact angle of the non-coated reference paperboard is around 90°. Ti/Si ratio has a clear effect on mean mobility particle size, as shown in Figure 2.

Further studies will focus on the composition of the nanocoating as well as morphology and deposited size of the nanoparticles.

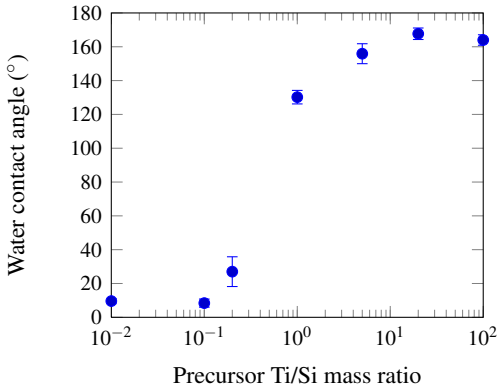

Figure 1. WCA with different Ti/Si mass ratios.

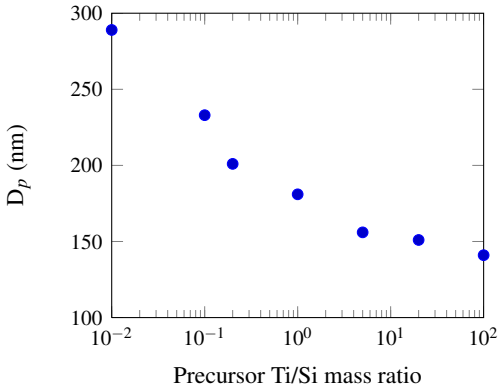

Figure 2. Mean mobility particle size (D_p) measured with SMPS with different Ti/Si mass ratios.

Keywords: aerosol synthesis, silver nanoparticle, localized surface plasmon resonance.
Presenting author email: juha.harra@tut.fi

Introduction

Optical properties of noble metal nanoparticles are dominated by coherent oscillations of conduction electrons which give rise to localized surface plasmon resonances (LSPR). The wavelength of the resonance depends on the particle size, shape and dielectric environment. Materials with plasmonic properties can be utilized in, e.g., biosensors and plasmonic solar cells.

Plasmonic materials containing silver or gold nanoparticles can be prepared with, e.g., ion implantation, sputtering or wet chemical techniques. These techniques usually offer rather restricted size control of spherical nanoparticles. However, the size range of spherical silver particles generated with aerosol techniques extends from a few nanometers to over 100 nm. Thus, aerosol synthesis gives the opportunity to tune the wavelength of the LSPR more extensively.

In this study (Harra *et al*, 2011), size-controlled aerosol synthesis was used to prepare plasmonic samples consisting of spherical and monodisperse silver nanoparticles deposited on a glass substrate. The particle coverage was varied between approximately 2 and 8 %.

Experimental

Silver agglomerates were generated in a tube furnace using an evaporation-condensation technique. The generation was followed by a size selection with a differential mobility analyzer and a sintering step with an additional tube furnace to obtain spherical particles. Finally, the nanoparticles were collected on a glass substrate with an electrostatic precipitator. The optical extinction spectra of the prepared samples were measured with a UV-VIS spectrophotometer, and the measured spectra were compared to a simple theoretical model.

Results and conclusions

Figure 1 shows high extinction near 400 nm for 90 nm particles, which is typical for silver. The spectrum also displays some fine structure: the peaks 1 and 2 near 400 nm and the peak 3 at longer wavelength. In order to analyze the spectrum, theoretical calculations were carried out using refractive indices of 1.0 and 1.3 for the dielectric environment. The calculations suggest that the peak 1 is caused by a dipolar resonance and the peak 2 is at least contributed by a quadrupolar resonance. The peak 3 is most likely caused by dimer particles formed during the collection process.

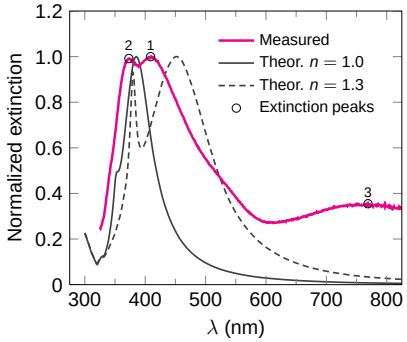

Figure 1: Extinction spectrum of 90 nm silver particles.

In Figure 2, the wavelengths of the peaks 1 and 2 are presented as a function of the particle size and compared to the theoretical peak wavelengths of dipolar and quadrupolar resonances. Some discrepancies occur most likely because the theoretical model neglects, e.g., effects caused by the dielectric substrate.

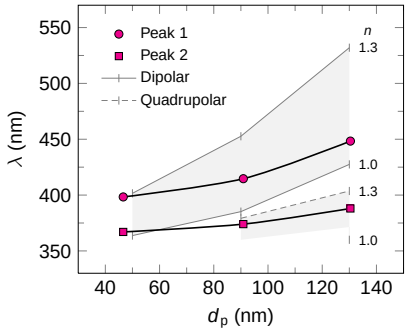

Figure 2: The wavelenghts of the extinction peaks as a function of the particle size.

All in all, aerosol techniques can be successfully used to prepare plasmonic nanoparticle samples for optical studies. Furthermore, the wavelength of the LSPR can be tuned by controlling the size of the deposited particles.

Synthesis of germanium nanoparticles in an aerosol reactor

C. Mehringer[1], R. Körmer[1], B. Butz[2], E. Spiecker[2] and W. Peukert[1]

[1]Institute of Particle Technology, Friedrich-Alexander-University Erlangen-Nuremberg, Cauerstr. 4, 91058 Erlangen, Germany
[2]Center for Nanoanalysis and Electron Microscopy (CENEM), Friedrich-Alexander-University Erlangen-Nuremberg, Cauerstr. 6, 91058 Erlangen, Germany
Keywords: nanoparticles, material synthesis, silicon, germanium.
Presenting author email: c.mehringer@lfg.uni-erlangen.de

Nanocrystalline germanium (Ge) is a promising material for the application in printable electronics. Dispersed in organic liquids and deposited as thin functional film, e.g. as a thin film transistor, the electronic properties of the nanocrystals (NCs) can be investigated (Holman et al, 2010). The synthesis of freestanding Ge NCs is challenging and can for example be achieved in a nonthermal plasma reactor (Gresback et al, 2007). We report on our progress in synthesizing Ge NCs in a reactor system with two consecutive hot-wall reactors.

In this setup the first reactor is used to produce, silicon nanoparticle (Si NP) seeds from monosilane pyrolysis in argon atmosphere. Those seeds influence the particle growth in the subsequent reactor, as known from literature (Alam et. al, 1986). After the first reactor stage the aerosol is quenched by additional argon. Prior to the second reactor stage, monogermane is fed into the system. In the second reactor stage the Si seeds serve as nuclei for Ge NP growth at temperatures of 700°C to 900°C. At the reactor exit the aerosol is quenched by nitrogen. The particles are collected with a membrane filter or sampled via a low pressure impactor by deposition on TEM grids or silicon wafers.

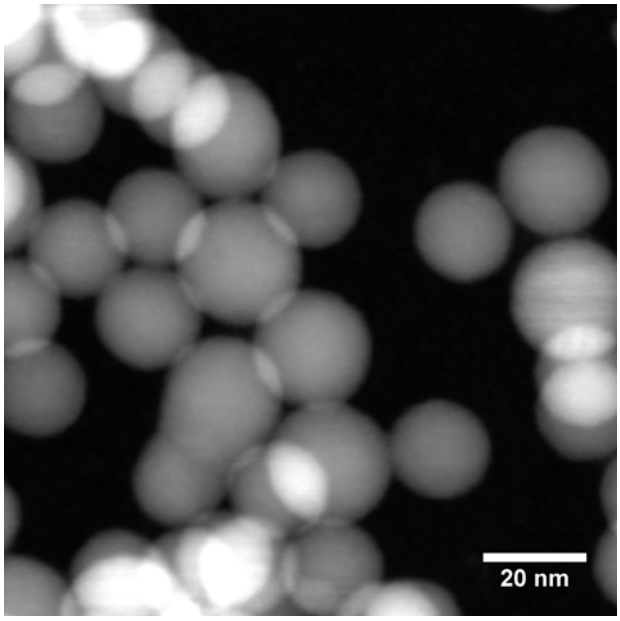

Figure 1. STEM image of Ge NPs

It is found, that monogermane pyrolysis in the absence of any seed particles leads to too high nucleation rates and subsequently to a growth mechanism, which is dominated by agglomeration and sintering. Therefore undesired particle structures are obtained, meaning strongly branched hard aggregates of very small primary particles around 9 nm in size. By addition of small amounts of monosilane however, nanoparticles with a mean particle size of 26 nm are accessible. The geometric standard deviation of their number density distribution is 1.25. Analysis with XRD and EDX shows almost pure germanium particles. STEM images prove, that the initial Si seed is completely dissolving in the evolving particle, as can be seen in figure 1. The monocrystallinity is also proven by HRTEM analysis (figure 2). The influence of monosilane addition and process parameters on particle formation, morphology and composition will be discussed.

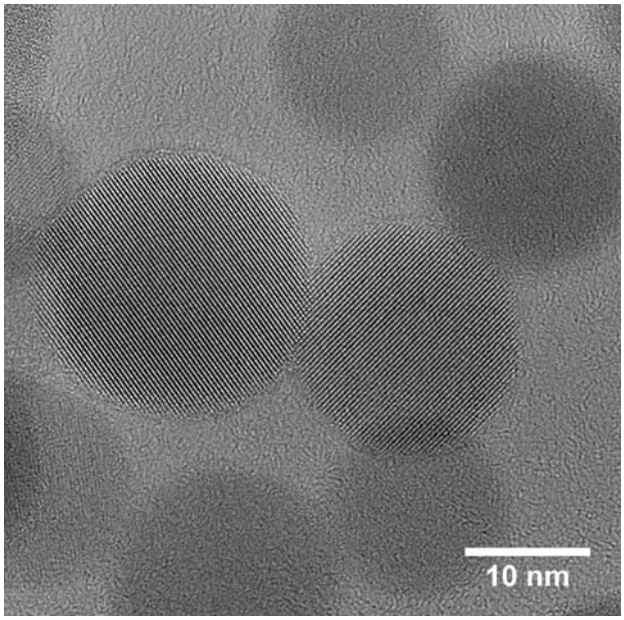

Figure 2. HRTEM image of Ge NPs

Gas-Phase Synthesis of Metal-Decorated Titanium Dioxide Nanoparticles

N. Alam[1] and A.M. Boies[1]
[1]Department of Engineering, University of Cambridge, Cambridge, UK, CB2 1PZ
Keywords: catalyst, particle synthesis, self assembly and particle charge
Presenting author email: a.boies@eng.cam.ac.uk

Metallic catalysts are critical components in technologies for renewable energy generation and pollution mitigation. As catalysts are often the most costly and rate-limiting components in many devices, advances in catalytic performance have the potential to make technologies such as fuel cells viable for widespread use. In order for nanoparticles to be viable for devices, methods must be developed to control their surface properties and assembly. In particular, the controlled spatial orientation of nanoparticles composed of different metals allows for the design of materials with better performance and increased durability. Studies of bimetallic nanoparticle combinations of gold (Au), platinum (Pt) and palladium (Pd) have demonstrated that each material catalyzes different reactions and when located in close proximity can lead to significant reductions of carbon monoxide, a harmful pollutant and fouling agent in fuel cells.

Research on the effects of substrates has shown that titanium dioxide (TiO_2) enhances the activity of catalytic oxidation reactions of carbon monoxide. Gas-phase processes offer practical benefits for catalytic nanoparticle synthesis as they allow for production in inert or non-reacting environments where particle size and charge can be manipulated. These continuous throughput processes can achieve high production rates at low cost, and are "green" as they do not require the use of environmentally hazardous solvents. Recent work has shown that nanoparticle surface properties can be controlled in the gas phase through both coating [1] and decoration [2].

This study demonstrates the production of TiO_2 nanoparticles decorated with catalytically active metals collocated on the surface. A conceptual schematic of the gas-phase synthesis system is shown in Figure 1. Core TiO_2 particles were synthesized by thermally decomposing a gas-phase precursor, titanium tetraisopropoxide ($C_{12}H_{28}O_4Ti$) in a temperature-controlled (~700°C) reaction chamber at atmospheric pressure. Titanium particle size and morphology were controlled by varying the temperature, precursor concentration and residence time within the reaction chamber. In-situ monitoring of the nanoparticle size and concentration were conducted using tandem differential mobility analysis (TDMA).

Metallic nanoparticles (<5 nm) were synthesized concurrently with TiO_2 particles in parallel hot-wire evaporators. Hot-wire evaporators produce metal vapors by resistively heating a metallic wire in an inert gas flow. Upon cooling the vapor nucleates forming particles. The size, morphology and charge state of the metallic nanoparticles were controlled by selecting the gas velocity, applied voltage, and voltage bias of the hot-wire generator. As depicted in Figure 1, the charge state of the two metallic nanoparticle aerosols was modified to ensure that they are charged to opposite polarities. By setting the particle charges to opposite polarities, the assembly of the agglomerates composed of different metals is encouraged while like-particle collisions are suppressed. Modification of the metallic particle charge state using corona and x-ray sources was used to ensure unipolar charge distribution. Preferential agglomeration between the opposite-charged materials occurs as the two flow streams are joined. The metallic agglomerates were then mixed with the larger (~30 nm) TiO_2 particles where the collision frequency between particles of different sizes dominates like-sized collisions.

The change in nanoparticle size and charge as a result of the surface decoration was monitored using a DMA, CPC and an electrometer. We measured and controlled the charge state of the nanoparticles to direct their synthesis. The fundamental dynamics of small particle charging and agglomeration were experimentally measured and compared to theoretical calculations. Ex-situ analysis of the particles was conducted by collecting the particles on TEM substrates for microscopy and elemental analysis. Further catalytic analysis of the particles was conducted using infrared spectroscopy analysis.

Metal hydrides are one of the most promising materials for hydrogen storage given their high volumetric capacity when compared to gas or liquid storage, and their high hydrogen content when compared to carbon materials (Sakintuna, Lamari-Darkrim, & Hirscher, 2007). Nanostructured magnesium is one of the most promising materials for creating these metal hydrides. It has also been shown that 20-40 at.% of titanium can enhance the sorption kinetics of magnesium (Danaie, Mauer, Mitlin, & Huot, 2011).

Instead of ball milling or roll-bonding, we chose to use the techniques described by Tabrizi *et al* (2010) to create intermetallic Ti-Mg nanoparticles. We used two metal rods as electrodes, one made from magnesium and the other from titanium. By creating a spark the metals vaporize and later condense to form nanoparticles. Non-alloyed intermetallic nanostructures are formed by the rapid co-condensation of both vapour species. In this study, we attempt to control the composition of the nanoparticles by varying the polarity and distance of the rods.

The resulting nanoparticles were analysed using XRD, STEM/EDX and ICP-OES to determine the composition of the samples, their structure and the distribution of elements. Tests were also made regarding the hydrogen absorption and desorption capabilities.

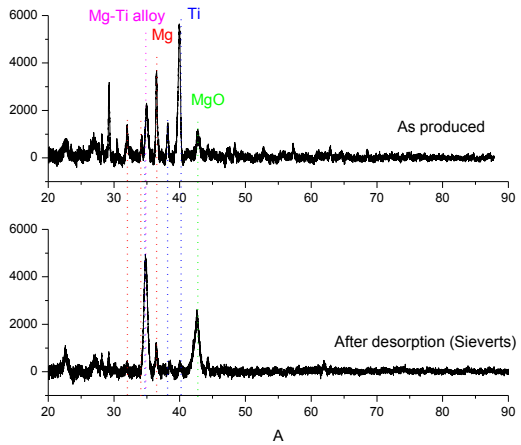

Figure 1. XRD before and after cycling.

Samples produced with a titanium anode (+) and a gap spacing of 2 mm show a Ti content of 33 at.%, as measured by ICP. XRD shows the existence of an intermetallic Mg-Ti phase, in addition to MgO and metallic Mg and Ti. STEM elemental mapping shows primary particles with nanometer sized Mg and Ti domains, as expected from the results of Tabrizi (2010) for non-alloying metals.

The hydrogen absorption and desorption isotherms were used to create Van't Hoff plots for two samples of $Mg_{0.67}Ti_{0.33}$. Significantly lower enthalpies of formation were found, lower than reported in previous studies (Gross, Spatz, Züttel, & Schlapbach, 1996). 2.5 %wt of H_2 was reversibly ab- and desorbed at 473K.

By using a spark discharge generator it was possible to synthesize Mg-Ti nanoparticles of the desired composition. These nanoparticles were not mixed on an atomic level, but rather showed distinct domains but nevertheless showed good hydrogen storage properties.

We thank Q. Xu and U. Lafont for STEM analyses. Funding by Agentschap NL, grant EOSLT07052.

Generation of sub 10 nm self charged particles with a spark generator in positive and negative mode

Michel ATTOUI
University Paris Est Creteil France
attoui@univ-paris12.fr
Keywords : nanoparticles, spark, generation, mobility,

Schwyn et al., (1988) introduced the spark method between 2 electrodes as generator of metallic particles. The spark generator (SPG) is made mostly of standard stainless steel ultra high vacuum (UHV) parts. The electrodes are mounted in a five way cross by a high voltage feedthrough with an embedded gas inlet. One of the remaining flanges of the SS cross is equipped with a viewport. All the parts of the generator are in SS to avoid desorption of surface contaminants inside the generator. Cylindrical electrodes of 6 mm diameter of Al, Cu, Ag are used. The mounting enables precise adjustment of the spacing of 1 mm, used in this study, between the electrodes. A high voltage capacitors are continuously charged by a high voltage power supply mounted in constant current mode (+/- 5 kV – 10 mA). The accumulated energy in the capacitors is then sent to the spark during the discharge. The frequency of charge or discharge of the capacitors is measured with an oscilloscope through a high voltage divider.

Helium or argon is required to produce clean metallic aerosols. The inert shield is required to f1ow over the arcing region, removing the aerosol and ions produced by the previous spark.

The aerosol particle size distributions from the spark generator have been measured recently by Tabrizi et al. (2009) using a home made DMA-Electrometer system for different electrodes and flowrates values. They detected a minimum diameter of 3 nm. The DMA used in their study (short cylindrical TSI) is not designed for small particles in terms of minimum diameter nor for high resolution.

The present paper gives the size distributions in different conditions obtained with a high flow, high transmission and high resolution DMA. This DMA is designed for particles smaller than 10 nm with a very high resolution and very high transmission. Ions in positive and negative mode are produced by the spark when the flowrate is very high (> 10 lpm) in the chamber. These ions has been seen with different metals (Ag; Cu; Al; Ni etc…)

Figure 1 gives the size distribution of positive silver particles. The small peak on the left at 1.2 nm is given by the silver ions. Figure 2 gives the size distribution of the small ions seen in the fig 1 in positive mode. In the other hand the charge distribution of the particles with a tandem high resolution DMAs has been measured.

Morphology dependency of electrospray-generated polymer particles and coatings on ambient humidity

E. Bodnár[1], P. Kiselev[1], J. Grifoll[1] and J. Rosell-Llompart[1,2]

[1]Department of Chemical Engineering, Universitat Rovira i Virgili, Tarragona, Catalonia, E-43007, Spain

Keywords: electrospray, particle formation, relative humidity, microstructure.
Presenting author email: eszter.bodnar@urv.cat

The functionality of structures (particles, coatings) made from electrosprays of dilute polymer solutions depend critically on their morphology, which we have recently found to be strongly influenced by ambient relative humidity (RH). We have investigated the influence of RH on the morphology (shape and microstructure) of polymer particles from various polymer-solvent systems which differ in how strongly polymer solubility is lowered by the presence of water. The polymers studied include ethyl cellulose (EC), polystyrene (PS), and poly(methyl methacrylate) (PMMA). Water miscible solvents (isopropanol, acetone), one water soluble solvent (2-butanone) and one water-immiscible solvent (dichloromethane) were used.

At dry ambient conditions compact smooth particles are collected, which often carry single nanofilaments (as shown for PS in Figures 1a, 1b). The globular part of these particles is shaped as a deflated capsule, an indication that polymer precipitation starts near the surface of the droplet, producing a shell that grows in time from within. Nanofilaments are likely to be a signature of the last Coulomb explosions as the polymer solution was sufficiently concentrated to electrospin a fiber that dried up at the same time. However, at high ambient RH (Figures 1c, 1d) the filaments disappear and porous particles are obtained. In this case, water from the ambient is absorbed by the droplet and becomes a non-solvent, triggering the precipitation of the PS, which happens early on when the solution is still dilute, thus precluding the formation of filaments, leading to porous particles instead. The lower polymer concentration solution (Figure 1c) at high RH produced flat irregular particles on the collection substrate (see Figure 1c inset), which may be the relics of globular thin shell-like particles that have undergone compressive failure upon impingement with the collection surface (Hogan et al, 2007), but remain cohesive.

Under dry conditions, EC in isopropanol leads to collapsed capsules, whose wall is thicker at higher polymer concentration as expected. At 1.0 wt %, the effect of RH on EC in every solvent is to wrinkle the particle surface, which may reflect a partial loss of polymer chain entanglement and mechanical strength, and non uniform distribution of this effect. At low polymer concentration (0.1 wt %), the precipitation due to ambient water is delayed. Instead, droplets arrive wet at the collector surface giving rise to dense films, suggesting that ambient water slows down solvent evaporation from these droplets. The topography of these films is not flat, suggesting some fraction of precipitated polymer phase in the arriving droplets. Dense films were also obtained with PMMA in water miscible solvents. In these systems, water slows down solvent evaporation or increases the solvent fraction held by the polymer precipitate, or both.

In dry ambient, EC-dichloromethane solution at 1.0 wt % leads to disc shaped particles with a smooth-wall. At high humidity, a reticular structure on the surface of the particles is encountered, which resembles those found in some electrospinning systems, as well as "breath figure" patterns.

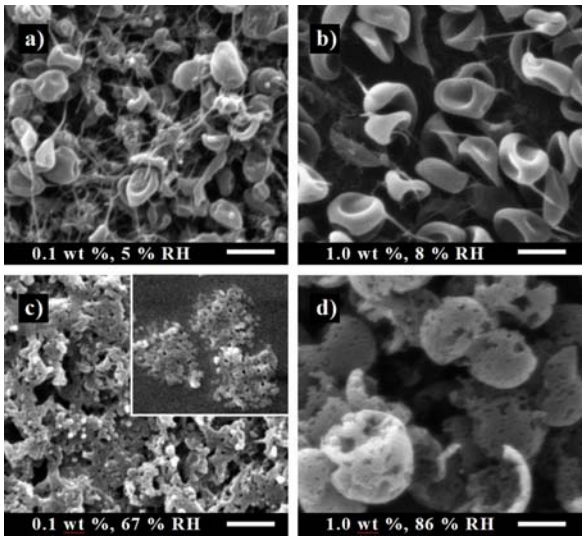

Figure 1. Particles formed from PS-butanone solutions at different initial concentrations (0.1 wt % left; 1.0 wt % right) and RH (dry at top; humid at bottom). Inset shows individual particles from a short collection time sample. Scale bar = 1 μm.

Formation of the condensed disperse phase (CDP) round a metal particle, with a size 10 - 100 microns, warmed up to temperature in some thousand degrees is one of ways to produce nanoparticles. Depending on a chemical compound, environment round a particle, it is possible to receive both nanoparticles of pure metal, and nanoparticle of metal oxides. We conduct researches on reception and studying of characteristics of rutile nanoparticles which are widely used in light protective structures, at influence on bacterial endospores, in semiconductors for creation of the forbidden zone in width 3,23 and 3,06 eV. Particles of the fused titanium with the size about one hundred micron produced by electrical discharge from the pure titanium. After formation the drop of the titanium was deposited in the rectangular cell which walls could be used as a condenser facing in the corresponding atmospheric environment. As results of the chemical analysis have shown, about 7 discrete phases of a rutile homological number were formed in the air. Only in the oxygen environment at pressure 101 kPa oxide nanoparticles (rutile) were formed.

As a result of thermionic emission from a particle surface, both the particle, and a CDP of nanoparticle get electric charges. Expected concentrations of nanochastic and electrons in resulted on pictures 1 and 2 (Lyalin *et el*, 2008). Research of

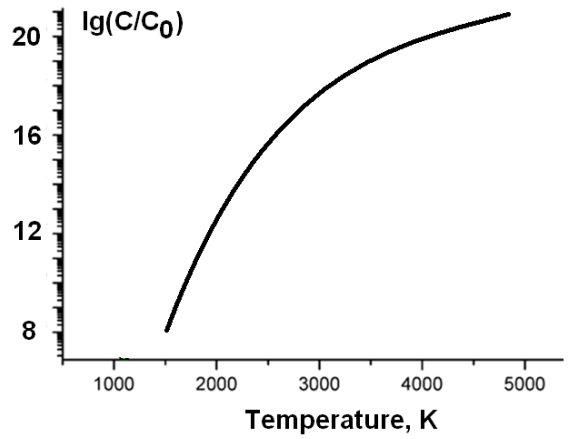

Figure 1. Dependence of logarithm of concentration C of nanoparticles of CDP near a particle from the temperature of particle ($C_0 = 1m^{-3}$).

parameters of the CDP was spent with application of x-ray diffractometer DRON - 3.0 which allowed us to

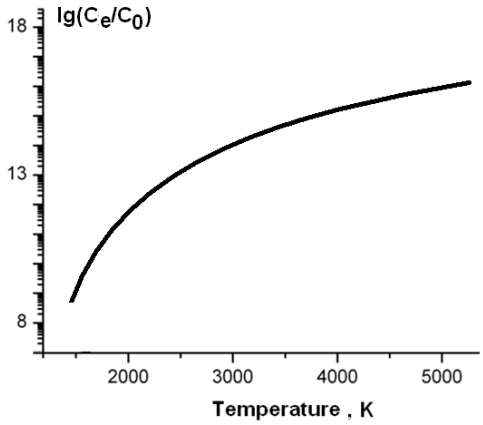

Рисунок 2. Dependence of logarithm of concentration of electrons C_e in CDP from the temperature of particle.

determine phase, chemical transformations and size intercalates crystals lattice constant. Photographing has shown that the nanoparticles representing the CDP around moving in environment metal particle have cylindrical symmetry. Sedimentation in an electrostatic field has revealed distinctions in signs on charges of nanoparticles depending on their distance from a parent particle. The density of nanoparticles in CDP "tail" falls in 3-6 times, concentration of nanoparticles depends on initial temperature of a parent particle. Researches of the nanoparticles deposited on a substrate have shown that their size lies in limits from 5 to 100 nanometers and depends on entry conditions.

The equation of thermionic emission charge of the parent particle surrounded with nanodisperses particles in the field of its positive and negative charges are received.

The equation of charging balance of a parent particle with a nanodisperse phase surrounding it in the field of its positive and negative charges is presented. It has allowed to receive the decision of system of the equations defining dependence of an equilibrium charge of a parent particle from its temperature.

Further development of nanoscience and nanotechnologies connected among the other factors with search of new methods of nanoparticles production, which can have new interesting properties based on specification of concrete method.

Existing methods and technologies, for example precipitation of vapor in vacuum, explosion of wire, et al., are carried out without presence of powerful electric fields. That's why organization of process of nanoparticles production in conditions of large temperature gradients and electric field is of interest as new direction of search. Such process can be carried out in vicinity of heated metallic particle using applied by us method of developed of monodisperse particles in impulse electric arch. Received heated particle in cold gas creates large gradient of temperature around itself. In addition, at the expense of thermoemission from the surface of particle, the particle itself gets certain electric charge in its vicinity. Intensive evaporation of metal goes on a surface of particle, vapors condense in certain vicinity of particle, react with active components of gas environment, creating nanoparticles.

The experimental arrangement consisted of monodisperse particle generator, airtight vessel, which could be filled with different gas. Movement of particle under the action of force of gravity took place in the vessel. Control of particle temperature was carried out with the help of digital method (Semenov, 2010). Measurement of charge was conducted by deviation of particle in external homogeneous electric field (Semenov K.I. *et al* , 2008). After some time of moving in gas, particle hit the surface of glass bottom layer. Herewith particle melted into the bottom layer, nanoparticles, consisting of chemical compounds of metal with components of employed gas, precipitated around the particle. Figure 1 shows a photograph of copper particle with precipitated around it nanoparticles. After removing the bottom layer with the particle from the airtight vessel, the analysis of obtained products was conducted. Figure 2 shows one of the photographs of nanoparticles of condensed phase at the distance 10 micrometers from the particle. Size of nanoparticles near the surface of the particle was about 10 nanometers, and at the distance – about 100 nanometers. Thereby, the increasing of particle size with the increasing of distance to the particle can be seen.

Particles from tungsten, molybdenum, copper, and tantalum were studied in air environment under normal conditions. The calculation scheme for evaluating the charge of particles was developed, the calculation of their charge and intensity of electric field was made. The analysis of possible mechanisms of electric (Lyalin L.A. *et al*, 2011) field influence on characteristics of nanoparticles, which are being generated, particularly on their agglomeration, was made. The formation of aerogel from linked nanoparticles was revealed experimentally for the particles of tungsten and molybdenum, oxides of which are prone to polymerization.

Figure 1. Photograph of particle with surrounding it nanoparticles on the bottom layer (diameter of the particle is 346 micrometers).

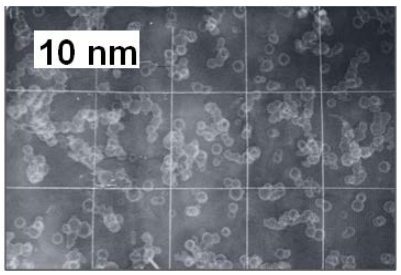

Figure 2. Photograph of nanoparticles of cupric oxide near the copper particle, made on transilluminate electron microscope.

As a result, it's shown that the proposed method can be used to obtain nanoparticles of sizes ranging from tens to hundreds of nanometers of different chemical composition which it is possible to vary.

Presenting author email: d.kilian@lfg.uni-erlangen.de

For the production of nanoparticles at a commercial scale flame spray processes are most frequently used [Kammler *et al*., 2001]. Despite the simplicity of the set-up, the process control is rather complex. Consequently, a profound knowledge of the particle formation mechanism during combustion is required. As minor changes of the process parameters may have a huge impact on the product, there is a huge demand for non-invasive advanced optical measurement tools to understand the local formation mechanisms and to quantify particle formation kinetics.

In this work, silica particles are made from Hexamethyldisiloxane (HMDSO) / ethanol precursor solutions. For the characterization of the flame spray process the following optical techniques are employed (Table 1).

Table 1. Optical techniques used for characterization of the silica synthesis by flame spray pyrolysis

Technique	Information
Mie scattering	Spatial droplet distribution
OH* chemiluminescence	Post reaction zone
CH* chemiluminescence	Reaction zone
SiO* chemiluminescence	Precursor decomposition / Nucleation regime
Coherent anti-Stokes Raman scattering (CARS)	Temperature, rel. N_2/O_2 gas concentration

By systematic combination of these techniques we can identify the predominant mechanisms in regions of the flame. Based on these results we are able to classify the flame into different regions and propose a particle formation mechanism.

Due to limited space we highlight in this abstract an extract of our results regarding the identification of the particle nucleation regime, which is linked to the work of Glumac 2001: On the right hand side of Fig. 1 the measured SiO* chemiluminescence intensity is depicted. As reaction rate constants for the formation of SiO_2 from SiO* are very high, up to 10^{15} mol/cm*s (Chagger *et al.*, 1996), this is the predominant region of particle formation.

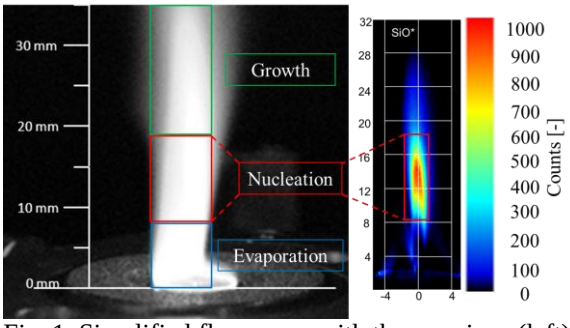

Fig. 1. Simplified flame map with three regions (left), SiO* chemiluminescence intensity (right)

The other zones in Fig. 1 (blue and green boxes) are determined by the combination and evaluation of the results from the other optical techniques. For example, combining the results of Mie scattering and OH* / CH* chemiluminescence measurements give an insight up to which height droplet evaporation is dominant before the early combustion reaction starts.

Based on the classification in different zones a particle formation mechanism is proposed in this work. By variation of process parameters the position of the regimes (evaporation, nucleation and growth) is shifted and the main influencing process parameters on particle formation are identified.

Formation of advanced SiC and carbon structures with controlled annealing of preceramic silicon-carbon nanoparticles

A. Lähde[1], M. Miettinen[1], J. Hokkinen[2] ,T. Karhunen[1], T. Torvela[1], U. Tapper[2]and J. Jokiniemi[1,2]

[1]Department of Environmental Science, University of Eastern Finland, Kuopio, 70211, Finland
[2]Fine Particles Team, Technical Research Center of Finland, Espoo, 02044 VTT, Finland
Keywords: preceramic silicon-carbon, induction heating, SiC and carbon structures
Presenting author email: anna.lahde@uef.fi

Silicon carbide (SiC) is an important high temperature structural material and high performance semiconductor, which can be operated at high temperatures, high power and high frequencies and in harsh environments (Legrand and Sénemaud 2003). Furthermore, SiC can be used as a precursor material for more advanced structures such as graphene layers (Emtsev et al. 2009).

The pre-ceramic Si/C synthesised with the aerosol method (Miettinen et al. 2011) was used as a precursor for induction heating, which enables the vaporization of metals at high temperatures. In this study, thermal treatments were performed on SiC nanoceramic particles in argon atmosphere at temperatures between 1900 and 2600 ^{o}C. The evolution of the particle structure and crystalline phases at different annealing temperatures was studied with SEM/EDS, XRD and Raman spectroscopy.

The annealing caused an increase in the crystallite size from few nanometers of the untreated precursor (Miettinen et al. 2011) to several micrometer crystals obtained in the annealed particles. In addition, the annealing temperature had an effect on the crystalline phase of the formed particles, see Figure 1. At lower temperature, i.e. below the melting temperature of amorphous silicon carbide (T_m = 2172 ºC, Baeri et al. 1999), the crystalline phase of SiC-3C was dominant (>96 w-%). Above the decomposition temperature (T_{dec} = 2577 ºC, Baer et al. 1999) a separation of carbon and silicon was observed, i.e. graphitic carbon (T=2600 ºC vessel) was formed in the sample vessel while SiC-3C and -6H was formed due to the cooling at the exit of the sample vessel (T=2600ºC exit), see Figure 1.

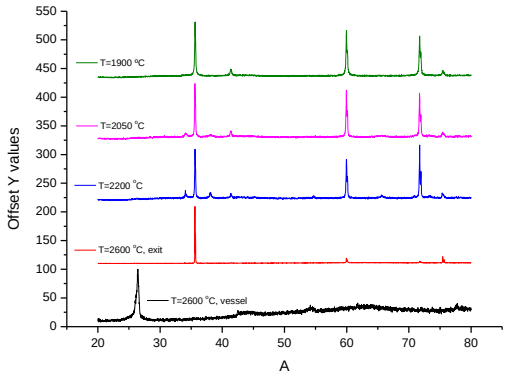

Figure 1. Normalized XRD diffraction patterns of crystalline phase of particles produced with induction heating of preceramic SiC

Figure 2 shows the SEM images of the particles produced at 2600 ºC. Leafy, graphitic carbon among the spherical particles was obtained in the sample vessel (Figure 2a) while silicon carbide was grown as large needles at the exit of the vessel (Figure 2b).

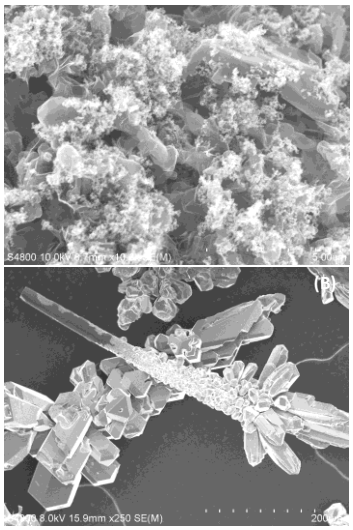

Figure 2. SEM image of Si/C particles formed with the induction heating at T=2600 ºC. The particles obtained from the sample vessel (A) and the exit of the vessel (B).

Induction heating of preceramic Si-C nanoparticles enables the preparation of advanced SiC and carbon structures. The preceramic precursor and high surface area of nanoparticles improve the formation of single layer graphenes by thermal decomposition of silicon carbide

This work was supported by the strategic funding of the University of Eastern Finland under the NAMBER spearhead project.

In situ observation of sintering behavior of Pt particles supported on silica nanoparticles

Kun Gao[1], Philipp Müller[2], Matthias Faust[1], Reinhard Schneider[2] and Martin Seipenbusch[1]

[1]Institute for Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany
[2]Laboratory for Electron Microscopy, Karlsruhe Institute of Technology, Karlsruhe, 76128, Germany
Keywords: in situ, TEM, contact angle, surface migration.
Presenting author email: kun.gao@kit.edu

Supported catalysts, such as Pt or Pd supported on different oxides, are widely used in chemical industry today, but sintering of the active phase, usually noble metal, is a serious mode of deactivation in this kind of catalysts. Therefore, it is significant to slow down the deactivation of them.

The present project deals with the stabilization of the noble metal supported nanoparticles. Three different mechanisms were proposed for this process (Binder and Seipenbusch 2011) and a theoretical description was developed by Wynblatt (Wynblatt 1975 and 1976). In order to study the sintering process, supported Pt nanoparticles were chosen as a model system. First of all, Pt/SiO_2 particles were prepared in the gas phase by a highly controlled chemical vapour synthesis (CVS) and metal organic chemical vapour deposition (MOCVD) process at atmospheric pressure. The size distribution and the number density of Pt nanoparticles can be controlled by the concentration of Pt precursor and O_2 in the gas phase in the CVD process.

The TEM grid, with Pt/SiO_2 nanoparticles on it by a low pressure impaction process, was heated up from the room temperature to 800°C at a constant rate of $5°C \cdot min^{-1}$ under ultra-high vacuum, and the surface migration, the collision and the sintering process of Pt nanoparticles on silica was observed in situ. Therefore, series of TEM images were taken at a frequency of approx. $1s^{-1}$ (Figure 1). The change of the Pt nanoparticle size distribution at different temperatures and the average surface migration velocity of Pt particle could be measured. Additionally, the contact angle between Pt and silica can also be measured in a high resolution TEM image.

The influence of the temperature on contact angle, surface migration velocity and the surface collision frequency of Pt nanoparticles will be investigated.

$$\beta = f(T, \alpha, v, n, d, x)$$

- β surface collision frequency
- T temperature
- α contact angle
- v average surface migration velocity
- n number density of Pt particle on carrier surface
- d size of supported nanoparticle
- x size of carrier nanoparticle

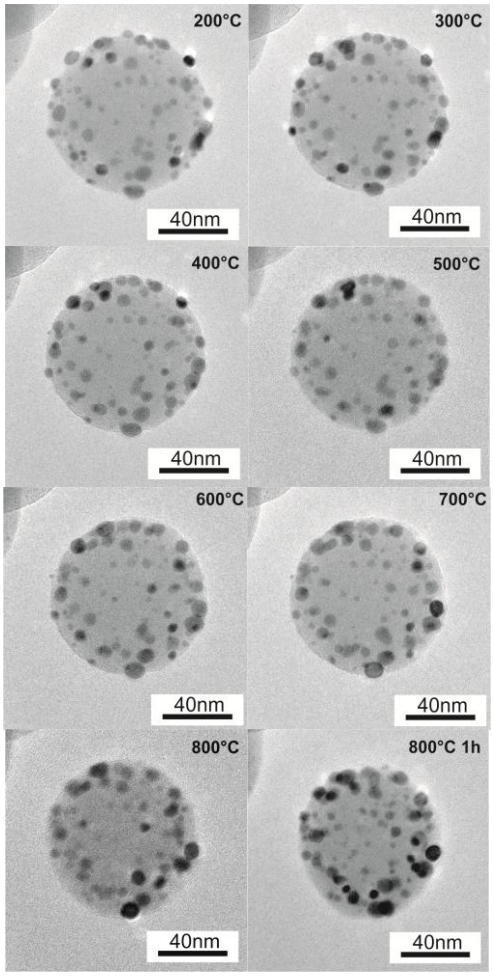

Figure 1. TEM photographs of the same spot of Pt/SiO_2 at different temperatures

Synthesis of copper nanoparticles formed on carbon nanotubes by photochemical process

N. Nishida, A. Miyashita, and H. Tanaka

Department of Applied Chemistry, Faculty of Science and Engineering, Chuo University,
1-13-27 Kasuga, Bunkyo-ku, 112-8551, Tokyo, Japan
Keywords: Copper nanoparticles, carbon nanotubes, photochemical process
Presenting author email: nnishida@kc.chuo-u.ac.jp

Metal nanoparticles have a variety of interesting spectroscopic, electronic, and chemical properties that arise from their small sizes and high surface-to-volume ratios. Especially, copper nanoparticles are the most desirable candidates for the replacement of precious materials because of their low price. In fact, various synthesis methods have been developed, although these methods usually use hazardous reagents and many chemical substances. Recently, we have succeeded the regenerative synthesis of copper nanoparticles by using photochemical reduction [1]. Herein, we have applied this method to the mixture of copper acetate solution and carbon nanotubes (CNTs) at room temperature. The structure and oxidation state of the products were analyzed by scanning transmission electron microscopy (STEM) and X-ray photoelectron spectroscopy (XPS), respectively.

The synthesis of copper nanoparticles by photoreduction was carried out using a similar method reported previously [1]. Copper acetate powder and CNTs powder were dissolved in ethanol. The mixed solution was photoirradiated using a high-pressure Hg lamp for 18 h at room temperature.

Figure 1 shows a typical STEM image for the as-prepared solution. The nanoparticles in the order of 10 nm diameter are observed on CNTs in the image. This suggests a direct evidence for nanoparticle formation by photoreduction. Two days later for exposed to fresh air, the nanoparticles were kept their shape and size. These indicate that the obtained nanoparticles were deposited and stabilized by CNTs. Furthermore, high concentrated nanoparticles were observed for area of CNTs aggregation. This result expected that, initially, nanoparticles deposited on CNTs evenly. Then these nanoparticles were concentrated by CNTs aggregation.

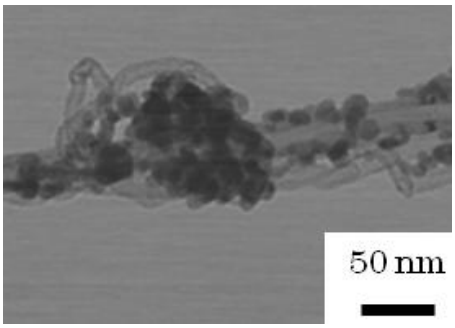

Figure 1. The STEM image of copper nanoparticles on CNTs

Additionally, when amount of CNTs were decreased, the observed diameter for the nanoparticles were increased. This result implies that growth of nanoparticles was inhibited by CNTs. Furthermore, the synthesized nanoparticles were identified as Cu metal by XPS spectrum and XRD patterns.

In summary, we have synthesized copper nanoparticles through the photoreduction of copper acetate and carbon nanotubes at room temperature.

Aerosol synthesis of building blocks for layered catalyst structures for Fischer–Tropsch reaction

Lintao Zeng and Alfred P. Weber

Institute of Particle Technology, TU Clausthal, Leibnizstrasse 19, 38678, Clausthal-Zellerfeld, Germany

Keywords: spray drying, porous layered structure, catalyst support, Fischer–Tropsch synthesis

Fischer–Tropsch synthesis (FTS) has become of interest for production of fuels and chemicals in recent years. Selectivity control is one the biggest challenges for getting an optimal product distribution. However, there is still no catalyst that demonstrates enough selectivity for the direct production of valued chemicals such as olefins from syngas. Therefore, the development of new novel catalysts that has a high selectivity to desired products is an important goal for academic research [1].

The utilization of porous nano-structured materials as FTS catalyst supports has provided new possibilities for optimizing the catalytic properties, for example, selectivity.

We present a novel aerosol approach towards the preparation of well-defined trimodal nano-porous layered structure as catalyst support for Fischer–Tropsch synthesis, which consists of two layers of SiO_2-building blocks and one layer of spherical glass particles (Fig. 1).

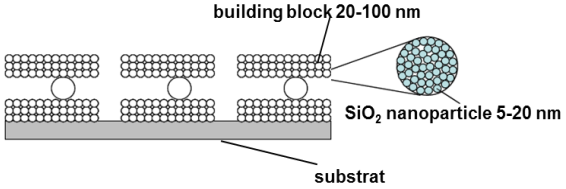

Fig. 1 Schematic representation of nanoporous structured layers of building blocks.

Porous SiO_2 building blocks (20-100nm) containing smaller pores (1-20nm) have been synthesized by spray drying of colloidal SiO_2 suspension (8 or 20nm) followed by tempering in an aerosol furnace at 500-700°C to control mechanical stability and porosity of the building blocks. Fig. 2 (left) shows a REM micrograph of porous SiO_2 building blocks. Then the building blocks were impregnated with cobalt (Fig. 2 right).

Two layers of building blocks were built through surface filtration of the aerosol and reinforced by pressure and thermal treatment. The middle pores (20-50nm) exist between the building blocks. The larger pores (100-200nm) were built by using spherical latex particles as template. The two layers were bound by partially melted glass particles (20-50µm).

The larger pores were designed for rapid transportation of products and reactants and the smaller and middle pores for the diffusions of reactants and products. It was possible to influence the product selectivity by varying pore size and structure of the catalyst support.

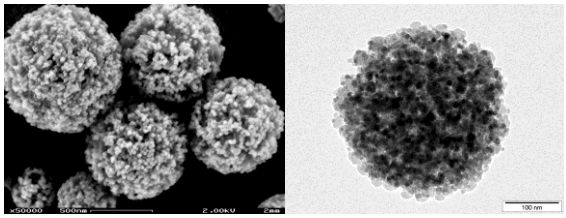

Fig. 2: REM image of porous SiO_2 building blocks (left), TEM image of Co_3O_4/SiO_2 building blocks, after impregnation (right).

The porosity of the building blocks was determined from impaction experiments using a single stage low pressure impactor. This method was particularly helpful when the cobalt catalyst was directly added to silica suspension before spray drying.

In this contribution the aerosol synthesis of the different building blocks will be outlined together with the results of the porosity characterization. In addition, first results for the influence of the impregnation procedure (impregnation of individual building blocks vs. impregnation of layered structure) on the resulting catalytic behavior will be presented.

This work was supported by the Deutsche Forschungs Gesellschaft (DFG) under grant DFG-We 2331/13-1.

Atomic clusters consisting of less than 100 atoms have been a subject of research since the 1970s, and it is agreed that the myriad number of possible properties they have are bound to play an important role in future technology. Nevertheless, they have, until now, scarcely found their way to application, which is, at least in part, a result of the limited production rates and the inflexibility of the state-of-the-art vacuum-based cluster beam technology.

The main purpose of the present paper is to call the attention to the fact that aerosol methods offer an interesting alternative. We believe that they will finally open the door to very interesting applications, e.g., in catalysis. Atomic clusters can arbitrarily be modified chemically, heat treated or charged while suspended in a gas. Size selection can be achieved with differential mobility analyzers (DMAs) suitable for this size range (Peineke et al., 2009). They can softly be deposited or positioned (Zonnevyle et al., 2009) on any desired surface, while this represents a major difficulty in connection with cluster beams.

The spark-discharge aerosol generator (Schwyn et al., 1988, Tabrizi et al., 2008) in connection with a DMA is a very versatile source of atomic clusters for any metallic or semiconducting material. In contrast to vacuum-based cluster beams, this method bears the potential of being scaled up for high mass production rates while being comparatively simple and inexpensive. Spark discharge generators are widely used for a controllable and stable production of high-purity aerosol nanoparticles. The present study shows that their range of application can be extended to atomic clusters in the size range below 1 nm. Peineke et al. (2009) had already shown that a glowing wire combined with a DMA produces equally sized atomic clusters, but the mass production rate of such a system is limited.

Microsecond sparks between two electrodes with an energy per spark between 0.05 mJ and 1 mJ produce Ga and Pt clusters with mobilities in the range of 1 Vs/cm^2, as shown in Fig. 1. In the case of Ga, the gas temperature was cooled to the temperature of boiling nitrogen to avoid melting of the electrodes. The broadness of the peak for 0.07 mJ roughly corresponds to the resolution of the DMA, which indicates that the clusters produced are highly monodisperse. Variation of the spark energy hardly changes the spectrum. In analogy with mass spectra that have been recorded for Al (Khanna et al., 1995), also a metal with 3 valence electrons, we believe that this peak corresponds to Ga_{13}, which exhibits electronically closed shells for the anion, thereby making it much more stable than clusters of different sizes.

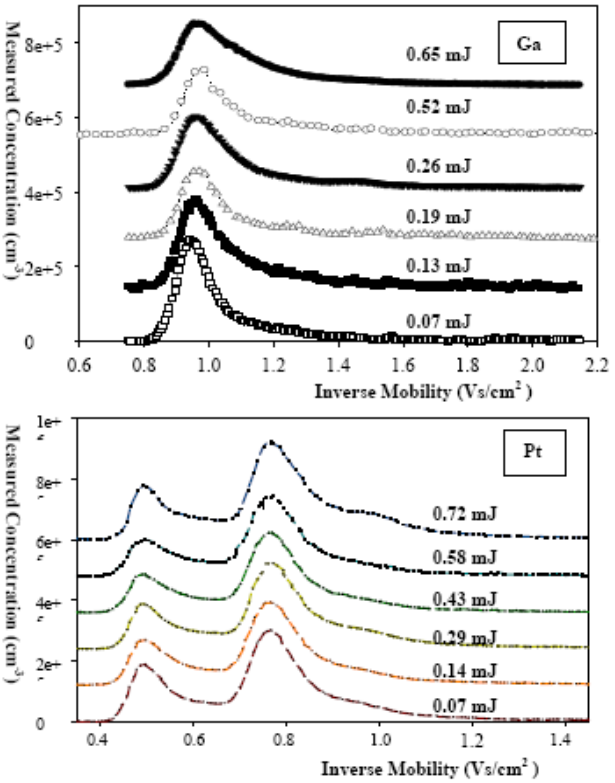

Fig. 1 Inverse mobility spectra of Ga and Pt clusters at different spark energies. In the case of Pt, which has 1 valence electron, 3 stable cluster sizes are seen for the conditions chosen.

The analysis of size-segregated cloud condensation nuclei counter (CCNC) data from SMEAR II and its implications for aerosol-cloud relations.

M. Paramonov[1], T. Petäjä[1], P.P. Aalto[1], M. Dal Maso[1], N. Prisle[1], V.-M. Kerminen[1] and M. Kulmala[1]

Keywords: CCN, cloud formation, critical diameter, hygroscopicity.
Presenting author email: mikhail.paramonov@helsinki.fi

Through a variety of microphysical processes aerosol particles influence the albedo, lifetime and precipitation patterns of clouds in what is known as indirect effects of aerosols on climate (Forster *et al*., 2007). The ability of aerosol particles to act as cloud condensation nuclei (CCN) is strongly linked to CCN number concentration N_{CCN}, aerosol critical diameter D_c and hygroscopicity parameter κ. Size-segregated CCNC measurements have been conducted in the boreal environment of the SMEAR II station (Hari and Kulmala, 2005) in Hyytiälä, Southern Finland since February 2009. The CCNC in question is a diffusion-type CCN counter, providing measurements across 30 size channels, with particle diameters ranging from 20 to 300 nm for five supersaturation levels SS.

Activated fractions A were calculated for each size channel in each CCN spectrum by dividing N_{CCN} by the corresponding N_{CN}. To determine the critical diameter D_c, which in this study is defined as the diameter at which half of the incoming particles are activated at a certain SS level, two methods were used, both based on Eq. 1 from Rose *et al*. (2008). The first fitting method was carried out as per Rose *et al*. (2008). The second fitting method used the observed, non-normalized A values, and allowed the upper plateau of the *s*-shaped function to vary in order to find the best fit. Hereafter, the two methods are referred to as Rose *et al*. (2008) and new methods, respectively. κ was calculated for each pair of D_c and SS using equation A30 from Rose *et al*. (2008) for both sets of critical diameters.

Rose *et al*. (2008) method produced consistently higher D_c values than the new method for all SS levels. Normalizing A values to unity forced the function to level out at A=1, which may not always be the case if aerosol is externally mixed. The Rose *et al*. (2008) method was particularly inappropriate for higher SS levels due to a large scatter of A values at higher sizes. The new method produced better fit to the data, as shown by the root mean square error (RMSE) analysis.

The analysis of monthly variation of D_c showed that a particle of the same diameter is more hygroscopic in the winter than in the summer. No diurnal variation of D_c was found. An overall average κ for aerosol particles at SMEAR II was determined to be 0.18 and 0.29 for Rose *et al*. (2008) and new methods, respectively, indicating the presence of organic species within the particles; κ of 0.18 is the same as was reported by Sihto *et al*. (2010) for the same location. While larger particles (> 100 nm in diameter) in the boreal environment of Southern Finland represent the global continental mean of κ well, smaller particles are highly non-hygroscopic (Fig. 1). κ is largest in February and smallest in July-August, corresponding well with the observed monthly variation of D_c. The annual trend in D_c and κ is mostly pronounced for larger particles, indicating that over the course of the year the chemical composition of smaller particles remains the same, while larger particles exhibit changes in their chemical composition. Considering typical SS levels inside the cloud, the variation in chemical composition of larger particles throughout the year plays a crucial role in cloud formation.

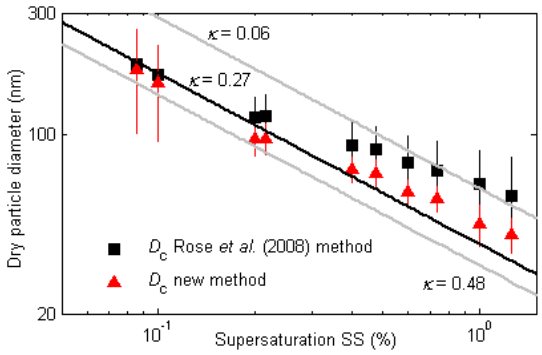

Figure 1. Particle dry size as a function of supersaturation SS. The black and grey lines correspond to the global continental mean of κ of 0.27±0.21, as reported by Pringle *et al*. (2010).

D_c did not correlate with black carbon concentration or with the wind direction, indicating that the chemical composition of CCN-sized aerosol particles in Southern Finland is most likely dominated by regional, non-combustion sources.

Atmospheric elemental carbon (EC) is a product of anthropogenic activities, especially incomplete combustion of fossil fuels by transport, heating, power plants, wood and biomass burning and agriculture activities. EC has negative effects on human health.

Regular EC-OC measurement has been implementing at the Košetice Observatory since February 2009 within the framework of EU-projects EUSAAR (European Supersites for Atmospheric Aerosol Research) and ACTRIS (Aerosols, Clouds, and Trace gases Research Infrastructure Network).

Long-term air quality monitoring and research at Kosetice Observatory, operated by the Czech Hydrometeorological Institute (CHMI), has been carried out since 1988. The observatory is located in free area outside of settlement (49°35´ N, 15°05´E, 534 m above sea level) and represents the Czech Republic in several international long-term monitoring programmes as EMEP (Co-operative Programme for Monitoring and Evaluation of Long-range Transmission of Air Pollutants in Europe), GAW (Global Atmosphere Watch) and International Co-operative Programme on Integrated Monitoring (ICP-IM) under the Convention of Long-Range Transport of Air Pollution (CLRTAP).

Sampling frequency is every 6th day in fraction $PM_{2,5}$ on 2 quartz-fibre filters. Since October 2011 (within ACTRIS) the sampling on filters has been implementing behind the denuder catching the organic vapor. Amount of organic carbon (OC) on back quartz fiber filter represents positive artifact by measurement without denuder and negative artifact by measurements with denuder.

The analytical method is thermal-optical analysis. The samples are analyzed in CHMI Central Laboratories in Prague-Libuš using EC-OC Sunset Lab Dual Analyzer. Charring correction is made by laser transmission monitoring.

Table 1. shows, that the mean annual concentration of total carbon in $PM_{2,5}$ in the period under review was 3,73 µg.m^{-3}. The figure for elemental carbon (0,51 µg.m^{-3}) represents the mean annual ratio of 14% on TC. EC-OC concentrations follow an annual course that reflects their emission levels, i.e. with maximums in winter and minimums in summer. The seasonal variation of EC/TC ratio is not significant and ranges between 12 to 15%.

Table 1. Mean annual and seasonal concentration of EC, OC and TC at Košetice Observatory in 2009-2011.

	EC (µg/m^3)	OC (µg/m^3)	TC (µg/m^3)	EC/TC
spring	0.53	3.27	3.80	0.14
summer	0.27	1.86	2.13	0.13
autumn	0.58	3.22	3.80	0.15
winter	0.76	5.44	6.20	0.12
total	0.51	3.22	3.73	0.14

Mean TC ratio on $PM_{2,5}$ total mass in the period under review was 26%, the highest ratios reached 50%. EC participated on $PM_{2,5}$ total mass by 4% in average.

3D trajectories were used for sector analysis of measured EC-OC data (NILU, 2011). The highest concentrations are recorded in situations when air masses reach the territory of the Czech Republic from the eastern directions or the local air masses prevailing. The difference between sectors is much larger in the cold period of the year.

The comparison with available data from other EUSAAR/ACTRIS sites (Cavalli et al., 2011) shows, that the Košetice EC-OC data are in very good agreement with similarly located central European stations (Melpitz, K-Puszta).

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 262254

Natural and anthropogenic aerosols may have a great impact on climate as they can directly interact with solar radiation and indirectly affect the Earth's radiation balance and precipitation by modifying clouds. In order to quantify the direct and indirect effect, we must understand the complex processes that connect an aerosol particle to a cloud droplet. However, while modern measurement techniques are able to detect particle sizes down to nanometre all the way from ground up to the stratosphere, the data does not serve for all of our needs for understanding the processes. Hence we will demonstrate a modelling approach to investigate the complex processes of aerosols in the atmospheric boundary layer (ABL).

SOSAA (model to **S**imulate the concentration of **O**rganic vapours, **S**ulphuric **A**cid, and **A**erosol) was developed by adding an aerosol dynamics model UHMA (Korhonen, 2004) to an exiting chemistry – transport column model SOSA (Boy, 2011) . It was constructed to study the emissions, transport, chemistry, as well as aerosols in the ABL. Up to our knowledge, it is the first column model existing in the world with detailed chemistry and aerosol dynamics. Thanks to the parallel computing, the model can be used to study the aerosol processes in the ABL for a few days up to a year with high vertical resolution. As a first application of the model, we carried out simulations for the monoterpenes, OH, and H_2SO_4 during the HUMPPA – COPEC campaign in summer 2010 as well as the new particle formation events in March 2010 at a boreal forest site in Hyytiälä, Finland (Figure 1).

We simulated the particle nucleation with different nucleation theories. The results do not suggest us a single theory that works all the time. Instead, it once again emphasizes the complexity of the phenomenon that a combination of different parametrizations may give better fit to the observation. The model SOSAA has also turned out to be a good tool to study the vertical distribution of particles. Scavenging of background particles before a nucleation event has been observed regularly in the morning (Figure 2).

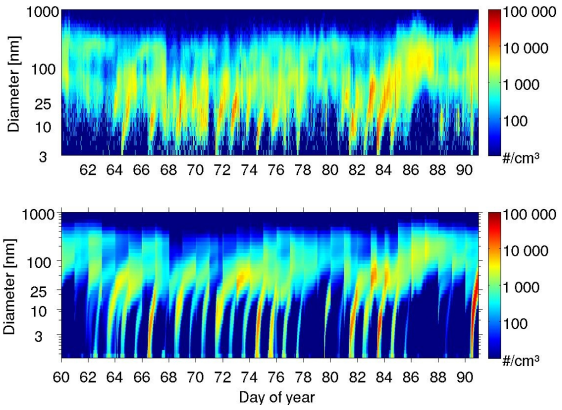

Figure 1. Measured (upper plot) and modelled (lower plot) particle number size distributions for March 2011.

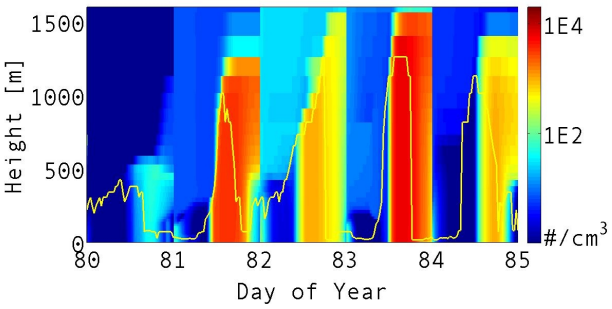

Figure 2. Simulated vertical distributions of particles in size range $3 < D_p < 10$ nm : 21 – 25 March, 2010.

Recently, the numerous epidemiological and toxicological studies have addressed the association between the particulate matter (PM) concentration and the negative health risk to ultrafine particles (UFP, particle diameter $D_p < 0.1\mu m$) compared to particles of greater diameters. Some studies declare that the particle number concentration (PNC) might be a better indicator of health effects of the particulates than the mass-based method; there is a lack in aerosol number investigation studies. The spectral analysis based on Fourier and Wavelet transform (WT) is used to characterize the time series in the frequency domain and to study the periodicities hidden in the data (Sebald *et al*, 2000). The wavelet transform methods have found wide application in various fields of science including meteorology and oceanography (Torrence and Compo, 1998). The dissimilarity between these two kinds of transforms is that the individual wavelet functions are localized in space. The wavelet theory can be viewed as an extension of the Fourier theory and give a flexible alternative to the Fourier method in the non-stationary signal analysis.

The aerosol PNC measurements were performed at the EMEP Preila environmental pollution research station (55°55'N, 21°00'E, 5 m above the sea level) in the coastal/marine environment. This station is located on the Curonian Spit, which separates the Curonian Lagoon and the Baltic Sea, and thus can be characterized as a regionally representative background area.

For the 2008 – 2009 period, the aerosol PNC was continuously measured using a condensation particle counter (CPC) UF-02. The CPC was designed to detect the ultrafine aerosol particles of a few nanometres with the high detection efficiency. The design of the instrument is based on the swirling flow generated inside the saturator (43 ^{o}C) – condenser (10 ^{o}C). The instrument uses a high flow rate (1 $l \cdot min^{-1}$) of the carrier. From the carrier flow, the aerosol flow (0.27 $l \cdot min^{-1}$) is extracted by a capillary. This aerosol flow is divided into two. The first one (0.03 $l \cdot min^{-1}$) is directed to the condenser. The second flow (0.24 $l \cdot min^{-1}$) is circulated through a HEPA filter and a saturator block, in which the flow is saturated with respect to n-butanol and then mixed with the aerosol-laden air at a cooled condenser. This mixing generates a supersaturated region with respect to n-butanol. The butanol vapour condenses on the particles that act as condensation nuclei. This process increases the size of each individual nanoparticle. Such large droplets can be conveniently detected by light scattering.

The monthly mean variation of the PNC showed the high mean concentrations during the summer and early spring seasons and the low concentrations during the winter. The long-range or regional transported smoke emitted by wildfires had a strong impact on the total aerosol number concentrations in Lithuania over early spring period. The lowest monthly PNC values were observed during November 2008 (1500 ± 900 cm^{-3}) and the highest ones during June 2008 (4500 ± 900 cm^{-3}). The results of Fourier and WT analysis (Fig. 1) indicated that the most important variations in the data series are represented with period 4, 6 – 7, 11, 16 to 23 days, which are synoptic scale fluctuations typical for the synoptic weather systems, but also 80 – 120 days cycles were noticeable in period. For the entire period of the experiment the most significant is the diurnal variation of particle number concentration. However, when passing to the cold season the amplitudes of 1- and 2-day oscillations significantly decrease and become less pronounced.

The study also provided a wavelet covariance transformation technique which facilitated the development of adequate new particle formation identification by aerosol number concentration measurement strategy and contributed to a deeper insight into dynamics of aerosol particles. In this work we describe the new results obtained using the wavelet-based methodology to detect and characterize the new particle formation by aerosol number concentration. Mainly, we showed that the wavelet transforms allow us to untangle waves that otherwise would be mixed up in the Fourier decompositions.

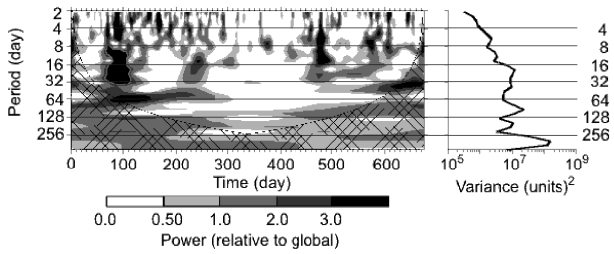

Figure 1. The wavelet power spectrum (left). The power has been scaled by the global wavelet spectrum (on the right). The cross-hatched region is the cone of influence (COI), where zero padding has reduced the variance.

Presenting author email: jean.sciare@lsce.ipsl.fr

Scientific context. The Mediterranean region is characterized by a complex mixture of (mainly transported) aerosols having different origins (anthropogenic, biogenic, biomass burning, dust, sea spray), with strong east-west and north-south trends observed, both by means of concentrations and chemical composition (Querol et al., 2009). The Mediterranean holds among the largest atmospheric concentrations of aerosols at global scale (3 times more than over Europe) inducing locally important direct radiative forcing (Bergamo et al., 2008). Besides, this region is already facing important climatic changes with increasing numbers of forest fires and heat waves inducing significant changes in aerosol concentrations and properties that may, in term, affect regionally air quality and climate. These changes have been confirmed by recent projections (IPCC, 2007) which have designated the Mediterranean as one of the most vulnerable regions at global scale with an increasing occurrence of heat waves and profound changes in water cycle.

Motivation. Compared to the rest of Europe, the Mediterranean region suffers from the lack of a dense ground-based atmospheric network that will provide long term in-situ observations of aerosol properties. The maturity of existing atmospheric stations in the Mediterranean differs; some of them operating upon international standards for many years, whereas others are operational since very recently. They are monitoring various aerosol parameters, few of them being common to all sites. Beyond quality control guidelines and aerosol database supported following international standards (EU-FP7-ACTRIS; EMEP; GAW), there is a clear need to better coordinate experimental strategies in the Mediterranean, in order to ensure a minimum set of common (relevant) aerosol parameters to be monitored in each station. Such efforts are crucial in the context of international programs (such as The Chemistry-Aerosol Mediterranean Experiment, CHARMEX, initiative; http://charmex.lsce.ipsl.fr/), which will have to be fed by large and homogeneous aerosol database. These efforts may also promote intra-Mediterranean collaboration and dissemination, in particular within the non-EU countries bordering the Mediterranean.

Objectives. This presentation aims to provide a (non exhaustive) review of existing atmospheric stations in the Mediterranean (see Fig. 1). Namely, Montseny (Spain), Mallorca (Spain), Corsica (France), Bou Ismail (Algeria), Giordan (Malta), Lampedusa (Italy), NEO (Pylos-Greece), Finokalia (Greece), and Cyprus. It will identify common and relevant in-situ aerosol parameters that are (to be) monitored in most of the stations. Recent experimental efforts in emerging stations will be emphasized here with the objective to bring in-situ aerosol monitoring activities at these stations to an international quality standard level, as it is provided within the EU-FP7-ACTRIS program.

OVOC – precursors for SOA: measurements within ACTRIS-WP4

J. Englert, C. Plass-Dülmer, E. Tensing, K. Michl and A. Werner

Hohenpeissenberg Meteorological Observatory, German Weather Service, 82383 Hohenpeissenberg, Germany
Keywords: SOA, VOC, GC-MS.
Presenting author email: jennifer.englert@dwd.de

Introduction

Work package 4 of the ACTRIS (Aerosols, Clouds and Trace gases Research InfraStructure Network) project focuses on the integration and harmonisation of European nitrogen oxides (NO_{xy}) and volatile organic compounds (VOC) measurements. VOC are subdivided into three groups: non-methane hydrocarbons (NMHC), biogenic hydrocarbons (terpenes) and oxygenated volatile organic compounds (OVOC). The latter include highly functionalised with low saturation vapour pressure and/or high polarity. Hence, they allow gas/particle partitioning and are important precursors for the formation of SOA (Secondary Organic Aerosols) (Camredon et al., 2007).

Generally, OVOC are difficult to measure because they are low concentrated polar compounds and highly sticky to surfaces in the sampling system. Further, they dissolve in water and form artefacts in combination with ozone and other oxidants. Hence a specific GC-MS system for high quality OVOC analysis was developed at the Hohenpeissenberg Meteorological Observatory, an institution of the German Weather Service (DWD). With further measurements of NMHC and terpenes at Hohenpeissenberg (Plass-Dülmer et al., 2002) a wide range of VOC is monitored. These measurements allow the consideration of the contribution of VOC to mass closure experiments (e.g. of the total organic carbon (TOC) budget, work package 21 of ACTRIS) or turn-over rates of trace gases with OH radicals (Figure 1).

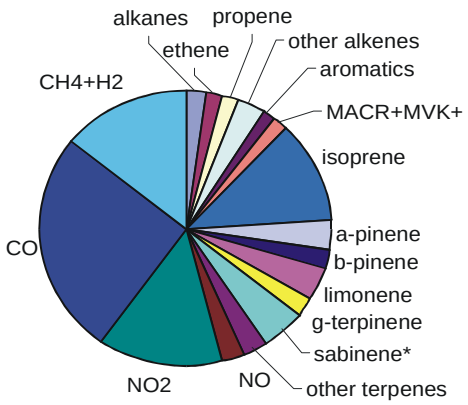

Figure 1. Turn-over of trace gases with OH radicals at Hohenpeissenberg between June to August 2004 (total = $10*10^6$ molecules/(cm³ s), noon time averages).

GC system for OVOC analysis

In the here presented OVOC system, ambient air samples are enriched on a 3-phase adsorbent tube. Water from the sample is frozen out by a cryogenic trap. Ozone is excluded by titration with nitrogen monoxide. After desorption of the analytes from the adsorbent tube, they are refocused cryogenically on a capillary. Subsequently, the sample is injected on a polar GC-capillary column and detected via a split with a flame ionisation detector (FID) and a mass spectrometer (MS).

Measurement campaigns

Campaign activities involving measurements of VOC, OH, RO_x and particles will be performed at Hohenpeissenberg in late spring and early summer 2012.

First results of the OVOC measurements performed during these campaigns will be presented together with a consideration of the TOC budget and a re-evaluation of the turn-over rates of trace gases with OH radicals.

Within the ACTRIS project it is possible to use the observatory's infrastructure for research and training activities in the field of trace gases and aerosol measurements (TransNational Access activity, TNA; http://www.dwd.de/mohp).

This work is supported by the European Union Seventh Framework Programme ACTRIS, FP7/2007-2013, under grant agreement n° 262254.

Filter-based measurements of aerosol optical absorption are widely used to determine Black Carbon ('BC') concentrations in real time. Measurements at multiple wavelengths make the separation of contributions of BC from different combustion sources possible. However, these methods can suffer from non-linearity due to the 'loading' effects of increasing aerosol deposit density on the filter (Gundel *et al.* 1984, Weingartner *et al.* 2003, Arnott *et al.* 2005, Virkkula *et al.* 2007). One model represents this non-linearity by a parameter $\boldsymbol{k}$, which is found to be highly dependent on the nature of the aerosol and is also a function of wavelength $\boldsymbol{\lambda}$. Consequently, a static algorithm to compensate for the effect, either by post-processing of the data or fixed in the instrument firmware, fails to capture the details and potential variability of these aerosol optical properties. When sampling ambient air over an extended period of time at any location, $\boldsymbol{k(\lambda)}$ is found to vary according to season and air-mass origin. The parameter may range from moderate values in winter to zero or opposite-sign values in summer, a behaviour also seen in the post-processing of data (Virkkula *et al*. 2007). Atmospheres dominated by local sources show higher values for fresher aerosols while lower values are seen for well-mixed aerosols exposed to aging and accretion.

We have developed a new Aethalometer® (model AE33), in which two parallel sampling channels are operated at loading rates that differ significantly. Combining the data from the two parallel analyses allow both an extrapolation to "zero density", i.e. the ideal measurement of BC in the absence of any loading effects, and additionally yields a dynamically-calculated value of the non-linearity parameter $\boldsymbol{k}$. These analyses are performed for multiple discrete optical wavelengths spanning the range from 370 nm to 950 nm and with a time resolution as rapid as 1 second.

The results show greatly improved analytical performance for the primary data output of BC versus time across the operational spectrum. The instrument is network-ready and is designed for both research and routine monitoring operations.

We present data examples from this new instrument showing the following:

- Continuity of data across filter tape advances demonstrating elimination of the 'loading effect' as the collection spot saturates.
- Absorption spectra illustrating the identifiable characteristics of diesel and biomass-burning (Sandradewi *et al*. 2008).

The data produced by this new instrument may be interpreted by models of aerosol optical properties in order to yield additional information applicable to studies of source apportionment; radiative forcing; and other impacts.

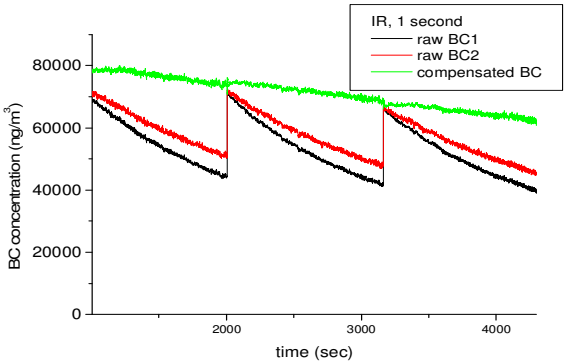

Figure 1. Time series of AE33 raw data with 1-second resolution. BC1 and BC2: raw data from two parallel aerosol spots on the filter. Compensated BC result calculated in real time by the instrument.

New particle formation in the western Mediterranean regional background.

M. Cusack[1], A. Alastuey[1], X. Querol[1], N. Pérez[1], A. Wiedensohler[2]

The study of the formation of new particles and the factors influencing their subsequent growth in the western Mediterranean (WM) regional background (RB) is presented in this work, performed at the Montseny (MSY) ACTRIS site. The variability and comparison of size-segregated aerosols at RB sites in Europe has been well documented by Asmi et al, 2011. This study interpreted results on the harmonized dataset of submicron aerosols obtained during 2008-2009 at a number of ACTRIS and GUAN sites in Europe. However, no data from the WM was presented as the SMPS system at MSY was not yet in operation. Within the framework of the ACTRIS project, the MSY site was equipped with a Scanning Mobility Particle Sizer (SMPS) system (in operation since 2010), supplied by IfT in Leipzig. This paper summarizes data on submicron particle size distribution at MSY and compares the data obtained with other RB sites in Europe, with special focus on new particle formation.

New particle formation (NPF) is currently a topic of great interest and the processes controlling NPF are still not clearly understood. NPF is typically observed under clean atmospheric conditions, as the presence of pre-existing particles act as a condensation sink for gaseous precursors which could potentially nucleate. However some studies have observed NPF occurring under polluted conditions provided the growth rate of newly formed particles is sufficiently rapid to prevent scavenging by pre-existing particles. The condensation of VOCs emitted by vegetation upon newly formed particles is believed to play an important role in particle growth after initial clustering.

Measurements of sub-micron size distributions were performed at MSY from October 2010 to June 2011 by means of an SMPS system. The system provided a complete number size distribution of the number of particles between 9 and 850 nm every five minutes. Levels of gaseous pollutants, PMx, black carbon (BC) and meteorology were also continuously measured on site. Interpretation of time variation of pollutants permitted the identification of frequent nucleation events observed under the study period. These are highlighted in Figure 1, where the red arrows indicate NPF under clean atmospheric conditions (when PM levels are low). The green arrows indicate NPF occurring under polluted conditions (high PM). Note that NPF under polluted conditions occurs exclusively in summer.

Number size distribution of submicron particles has been investigated under different scenarios. As an example, Figure 2 depicts episodes of NPF recorded under low pollution conditions (8/12/2010) and relatively polluted conditions (25/05/2011). On the 8/12/2010, PM_{10} levels recorded a daily mean of 2.4 µg m^{-3}, mean temperature of 11ºC and relative humidity of 66%. NPF commences at 10:00 GMT and continues until 13:00, followed by subsequent growth into the Aitken mode. The growth rate (GR) of nucleation mode particles ($N_{9\text{-}20}$) on this day was 1.7 nm h^{-1}. Conversely, NPF on the 25/05/2011 occurred under relatively polluted conditions, with PM_{10} of 22.6 µg m^{-3} and average temperatures of 19ºC and relative humidity of 40%. The particle GR on this day was significantly higher, at 8 nm h^{-1}. Nucleation on this day is attributed to the condensation of VOCs emitted by surrounding vegetation on the newly formed particles, giving rise to much faster particle GR than that observed on 8/12/2010.

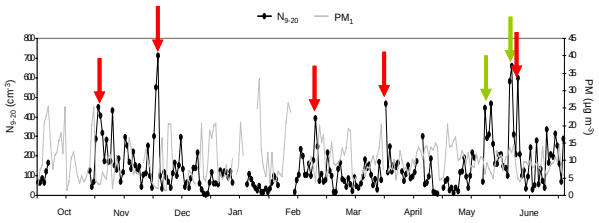

Figure 1. PM_1 and $N_{9\text{-}20}$ from Oct. 2010 – June 2011.

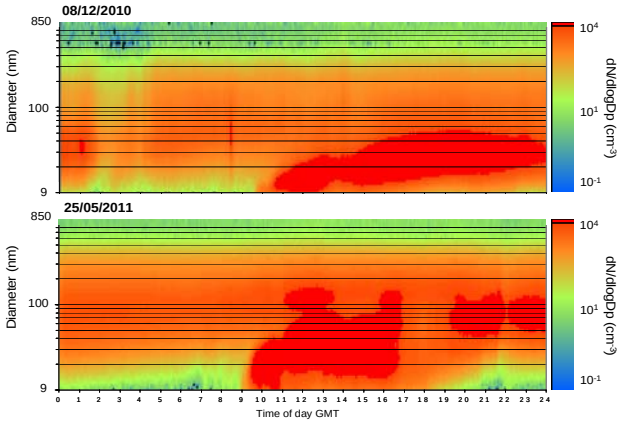

Figure 2. Particle size distribution ($N_{9\text{-}850}$) on 8/12/2010 and 25/05/2011

Presenting author email: Mika.Komppula@fmi.fi

The Earth's energy balance is affected by clouds, which absorb and reflect solar radiation (IPCC, 2007). As clouds also have an important role in the atmospheric hydrological cycle, their evolution, from a microphysical and dynamical point of view, is currently a key research topic.

Ash plumes from the 2010 volcano eruption in Iceland disrupted aviation throughout Europe and were responsible for huge economic losses in the airline industry. In addition, ash and smoke from forest fires are also a health threat for general population. Information on the elevation, thickness, transport and potential for dispersion of these ash and smoke layers is essential for aviation safety and the provision of emergency services. Air quality, atmospheric chemistry, clouds and atmosphere-ecosphere interaction are all influenced by the dispersion of pollutants, moisture, gases and aerosol particles from natural sources through turbulent mixing in the boundary layer.

In order to monitor aerosol layers, clouds and the boundary layer, the Finnish Meteorological Institute has established a network of Doppler lidars (Halo Photonics, Pearson et al., 2009) situated at the following stations, representing different environments

- Helsinki (60.12°N, 25.58°E, 45 m ASL), urban site with marine influence
- Kuopio (62,44°N, 27, 32°E, 190 m ASL), rural
- Sodankylä (67.37°N, 26.63°E, 171 m ASL), sub-arctic

All sites are equipped with standard meteorological, trace gas and aerosol instrumentation, together with Vaisala ceilometers operating at 905 nm wavelength.

Continuous measurements with Doppler lidars, operating at 1.5 μm wavelength and with scanning capability, have been performed at Helsinki and Kuopio since September 2011. Both sites have comprehensive surface in-situ measurements of the chemical, physical and optical properties of aerosols. Kuopio will participate in ACTRIS WP2 and WP3, with a POLLY^{XT} lidar (Althausen et al., 2009) due to restart operations in April 2012. A Doppler cloud radar (Mira-36 by Metek GmbH) and Doppler lidar will be operated continuously at Sodankylä from spring 2012. This site will participate in ACTRIS WP5 (clouds and aerosol quality-controlled observations).

In addition to announcing the new Finnish remote-sensing network, our aim here is to present results from an inter-comparison of three identical Doppler lidar during a short campaign in Helsinki (1 – 15 September 2011)), prior to their deployment in their stated locations. We have compared the backscatter, Doppler velocity and wind profile parameters obtained from the Doppler lidar's internal data processing algorithm. We will show, for example, that the wind profile parameters (i.e. horizontal components as well as speed and direction) obtained from each instrument, measured every 10 minutes, showed very good agreement. The profiles of vertical wind velocity, fluctuating around zero and subject to turbulence, are only comparable when the instruments are situated within a few metres of each other; otherwise the turbulent structures appear uncorrelated. However we will show that the variability is similar in a statistical sense.

We have also, for the first time, examined the capability of the Doppler lidars to operate in harsh winter conditions. During the previous winter, the lidars operated without problems even when the ambient temperature dropped below -20°C for several days. Due to the built-in heating system, the instruments were typically able to melt snow and evaporate any standing water from the surface of the lens and background calibration plate, ensuring reliable operation without additional intervention. However, during heavy snow in temperatures lower than -10°C, the internal heating was insufficient and manual snow removal was required. To rectify this in future winters, an additional blower system will be deployed for each Doppler lidar.

We are planning to extend the network to new stations, which already have comprehensive surface aerosol measurements.

In every major European cities, aerosol pollution is of great scientific, economic, health and social concern. Despite geographical disparities, the particulate phase in urban areas is complex by virtue of its chemical composition and the multitude of emission sources. Long-term and detailed chemical speciation studies are key variables to constrain atmospheric processes and local versus continental imports leading to urban pollution episodes; European standards and legislations however mainly focus on indiscriminate mass concentrations ($PM_{2.5}$ and PM_{10}). While Aerosol Mass Spectrometers (AMS) may provide valuable 'real-time' data for the chemical characterization of submicron particles, their cost and implementation as networking devices make them improper to be used for long-term measurements. Developed by Aerodyne Research Inc. (Billerica, MA), the Aerosol Chemical Speciation Monitor (ACSM) measures quantitative chemical composition for non-refractory sub-micron aerosol particles. Smaller, lower cost and more robust, the ACSM is designed for long-term unattended deployment and routine monitoring applications.

Experimental

In this context, the infrastructure EU-FP7-ACTRIS program has been promoting the use of ACSM for long-term observations at background stations, among which the SIRTA/LSCE site. This station, representative of PM pollution in the region of Paris, has been equipped with an ACSM since June 2011. Co-located multi-wavelength absorption measurements (AE-31, Magee Scientific) allow for Black Carbon source apportionment (Sciare et al. 2011). Reliable PM1 data (TEOM-FDMS 1405F, Thermo) are also available since February 2012.

Results

The ACSM has been providing continuous data since June 2011. This large dataset highlight raising important issues on data processing. Nevertheless, the two datasets (ACSM + BC versus PM1) show very good temporal agreement, with a slope close to 1 (slope=1.08, r^2=0.87), pointing out the very good consistency and long term stability of ACSM measurements.

First results enlighten the major role played by organics and ammonium nitrate on PM loadings in the region of Paris (Fig.1), especially during severe winter pollution episodes.

Statistical tools, such as Potential Source Contribution Function, reveal the strong influence of continental import on secondary species (nitrate and sulphate) highest concentrations (Fig.2). Such methodologies applied to Positive Matrix Factorization outputs will also help to better understand the sources and atmospheric processes of organic aerosols.

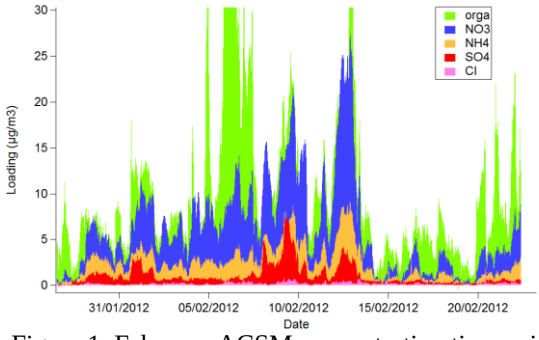

Figure 1. February ACSM concentration timeserie.

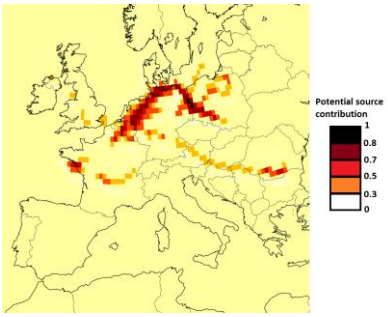

Figure 2. PSCF analysis from Jan. 1st to Feb. 22th 2012; sulphate concentrations; threshold at 75th centile.

Perspectives

For time-limited intensive campaigns, a substantial analytical fleet is engaged in order to investigate specific pollution sources. Since early February 2012, PILS-IC, PILS-TOC and PILS-MS/MS (for the anionic fraction, water-soluble organic carbon and levoglucosan, respectively) have been implemented to constrain wood burning emissions. Fertilizer spreading emissions will be investigated this spring, emphasizing on gaseous precursors of aerosol.

Characterize aerosol properties observed over Lemesos, Cyprus using passive and active remote sensing instruments.

A. Nisantzi[1], RE Mamouri[1], P. Kokkalis[2] and D. G. Hatzimitsis[1]

[1] Department of Civil Engineering and Geomatics, Cyprus University of Technology, Lemesos, Cyprus

Keywords: aerosol, angstrom exponent, lidar
Presenting author email: argyro.nisantzi@cut.ac.cy

Atmospheric aerosols affect the Earth radiative budget by interacting with the solar and the Earth's long-wave radiation (Charlson et al., 1992). Cyprus is located in the eastern part of Mediterranean and the contribution of different aerosol sources comes from air masses originating in Europe and Africa (Sciare et al., 2003). Thus different meteorological patterns transport different aerosol types (Saharan dust, biomass burning) over Lemesos.

Remote sensing techniques have established a great number of records of aerosol measurements since 1970s by giving the opportunity of high spatial and temporal coverage. Daily lidar measurements of the aerosol vertical distribution have been performed over Lemesos (34.675ºN, 33.043ºE) using a backscatter lidar system since May 2010. In this work we selected to present two cases which have been identified as different aerosol types (Saharan dust, biomass burning). Additionally we calculated the back-trajectories in order to identify the origin of air masses ending over the lidar site of Cyprus. For a better characterization of aerosol types sunphotometric measurements retrieved from the ground based AERONET station of Lemesos are used.

For the first case study and according to the Range Corrected Signal (RCS) at 532nm on 30 August 2011 over Lemesos from 08:13 to 09:12UT (figure 1a) an enhanced aerosol layer between 1200 and 2500m height are shown. The same day the Angstrom exponent derived from the CIMEL sun-tracking photometer fluctuate from 1.2 to 1.42 during the day and clearly indicate the existence of small aerosols particles.

In the second case (figure 1b) the RCS at 532nm on 7 September 2010 depicts two distinct dust layers at 600-1500m and 1800-3500m respectively and the Angstrom Exponent has small values (0.2-0.45) similar to the values retrieved in case of Saharan dust episode in previous studies (Mattis et al., 2002).

In both cases the aerosol optical properties will be examined with the respect of the vertical backscatter profile at 532nm and the particle depolarization ratio at the same wavelength. Thus different depolarization ratios could give information of particles with nonspherical geometry. Specifically in this study the depolarization ratio with values greater than 10% characterize desert dust while for biomass burning aerosols depolarization values are lower than 10% and agree with previous studies (Cattrall et al., 2005).

The Aerosol Robotic Network (AERONET, Holben et al., 1998) is a well established ground-based network for aerosol and water vapor content monitoring and characterization. This program, initiated in the 90's by NASA and the University of Lille, is currently greatly expanded, aiming at global coverage and long-term measurements. To enable the development of the network, alternative calibration centers (besides the headquarters in NASA) have been developed in Europe, primarily in France and then in Spain.

Within the European infrastructure project ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network), access to the AERONET-Europe calibration facility is provided. The AERONET-EUROPE Calibration Service is a scientific infrastructure composed by three separate but complementary installations located in France and Spain (Figure 1).

Three institutions collaborate to form AERONET-Europe: the Laboratory of Atmospheric Optics (LOA), University of Lille-CNRS (France); the Group of Atmospheric Optics (GOA), Valladolid University (Spain); and the Izaña Atmospheric Research Center (CIAI), Spanish Meteorological Agency (Spain). Three outdoor platforms for calibration of AERONET-Cimel sun photometers are available: Carpentras from LOA and Autilla from GOA are devoted to inter-calibration of field instruments; a unique facility for calibration of master instruments is provided by CIAI at Izaña. The indoor platforms in Lille and Valladolid include NASA-NIST traceable integrating spheres for radiance calibration, polarized light sources, solar-simulator, maintenance and repair room, spectrometer for filter characterization, thermal chamber for response to temperature characterization and computers linked to AERONET/NASA database for calibration coefficients computation and data reprocessing.

Both new users that want to joint AERONET and institutions already participating in the network can apply to access to this facility and have their Cimel sun photometers calibrated and incorporated to the database. The access to the infrastructure is made under the modality of transnational access. The call for proposals is continuously open throughout the project duration. Visit http://www.actris.net/AERONETEurope/tabid/4321/Default.aspx for further information.

Figure 1: Location of the three calibration facilities of AERONET-Europe.

This work has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement N. 262254. Data interoperability solutions for the Finnish SMEAR station network

M. Dal Maso[1], P. Kolari[1], H. Junninen[1], P.P. Aalto[1], P. Keronen[1], P. Järveläinen[2], S. Sorvari[1] and M. Kulmala[1]

[1]Department of Physics, University of Helsinki, PO Box 48, 00014, Helsinki, Finland
[2]CSC - IT Center for Science Ltd., P.O. Box 405 FI-02101 Espoo, Finland
Keywords: data integration, measurements, infrastructure.
Presenting author email: miikka.dal@helsinki.fi

Today's aerosol and atmospheric scientists have at their disposal a wealth of observations of parameters affecting atmospheric aerosol processes; however, in practical scientific work much delay and frustration arises from lacking data interoperability, such as difficulties to find suitable datasets, unclear documentation, varying conventions for data processing and units, etc.

As the amount of observational data grows, so do the challenges of successful data interoperability. Worldwide, the scale of the storage needed for climate and environmental data is expected to grow to exabytes within next 10 years. Research with such data volumes needs robust, but adaptable and scalable IT infrastructure. It is an old truth that to foster innovation, the components needed – people, knowledge, and resources – must be brought as close to each other as possible.

A significant part of the atmospheric environmental data, including aerosol observations, in Finland is obtained from the SMEAR measurement station network (Hari and Kulmala, 2005). These stations measure weather conditions and interactions between ecosystems and the atmospheres aiming for a comprehensive picture of the matter, energy and momentum budgets and thus increasing the understanding of processes in the climate and Earth system.

Currently, a bottleneck in environmental sciences is often not the aquisition of environmental data itself, but answering interoperability challenges - the *processing, transport, storage* and *combining* of variable datasets that represent different aspects of our environment at different scales and complexities. As it often is the comparison and integration of these variable datasets that gives scientist the most powerful tools for scientific innovation, significant gains should be expected when existing data and computation bottlenecks can be resolved, and scientists can be allowed to focus more of their time to research instead of mechanical data processing.

As instrumentation constantly develops, for example with advances in atmospheric mass spectrometry (eg. measurement of organic compound concentrations and fluxes using time-of-flight mass spectrometry, ToF-MS), the sheer amount of data has grown to volumes that present significant new IT challenges for the integration.

Ongoing research activities lead to established data flows, in which scientists find their own optimized solutions for processing, transport, storage and comparison activities. Individual data flows can refer to individual data sets or time series (for example aerosol size distributions, solar irradiation, or carbon dioxide uptake by trees), or to whole groups of measurements from a single measurement station. The processing and analysis a data set undergoes involves usually several specialized processing steps performed by scientists focusing on this dataset. Currently, many of these steps are known to a small group of scientists. Linking and combining different data sets together requires knowledge of these processing steps, so that the scope and range of validity of the datasets can be verified. For this, the data and related information need to be collected together and described in a formalized manner.

We will discuss the solutions for data interoperability, workflow documentation and orchestration, and data distribution that we develop for the Finnish SMEAR station network. The data environment can be broken down into a data collection environment, data storage solutions, and a data processing and exploration environment. We discuss the challenges and existing (*eg*. Junninen et al., 2009) and future solutions for integrating these three domains, with focus on atmospheric aerosol and cluster data measured in the SMEAR network. We will also discuss solutions of integrating international field campaign data (eg. the European aerosol project PEGASOS) with the continuous measurements at field stations.

This work is supported by the Academy of Finland. The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 262254, and the FP7 project ENVRI (FP7/2011-2014).

Keywords: sulfate formation, cloud processing, aerosol radiative forcing.

Presenting author email: eliza.harris@mpic.de

Processing of aerosol by clouds has been shown to modify the cloud condensation nucleus spectrum, leading to important climatological effects (Hegg *et al.*, 2004). In-cloud SO_2 oxidation and uptake of sulfate play a large role in this processing, causing both hygroscopicity changes and mass increases. However, the in-cloud oxidation of SO_2 is not well understood. Measurements of stable sulfur isotopes can be used to investigate the chemistry of SO_2 in the environment, providing insight into sources, sinks and oxidation pathways. Due to the distinctive isotopic signature of the reaction, sulfur isotope measurements are particularly useful to quantify the importance of transition metal-catalysed oxidation of SO_2, which may be significantly underestimated in current models (Hegg *et al.*, 2004).

Sulfur isotopic compositions in SO_2 and H_2SO_4 gas and particulate sulfate were measured upwind, in-cloud and downwind of an orographic cloud during three cloud events as part of the HCCT 2010 campaign. Changes in the sulfur isotope composition of SO_2 between the upwind and downwind stations were used to determine the dominant SO_2 removal process occurring in the cloud, as shown in Table 1.

Event	LWC g m^{-3}	α_{cloud} ‰	Oxidant	α_{ox} ‰
FCE7.1	0.14	20.4±5.3	H_2O_2	15.1±1.3
FCE11.2	0.37	-12.7±2.3	TM-cat	-9.5±3.1
FCE11.3	0.32	-7.9±1.7	TM-cat	-9.5±3.1

Table 1: Comparison between isotopic fractionation factors measured during in-cloud SO_2 oxidation and fractionation factors for known reactions (Harris *et al.*, 2011a,b).

Changes in the isotopic composition of particulate sulfate were then used to show that the dominant SO_2 oxidation reaction, the transition metal catalysis pathway, was primarily occurring on coarse mineral dust particles (summarised in Figure 1). Sulfate produced from in-cloud SO_2 oxidation will therefore be removed relatively quickly from the atmosphere and will have a minor climatic effect. The reactive uptake coefficient for the transition metal catalysis reaction, γ_{obs}, was calculated to be between 0.02 and 0.11. This is close to the accommodation coefficient for SO_2 uptake, and shows the pathway is significantly underestimated in most global climate models. Improving our understanding of the extent and climatic effects of this reaction is particularly important considering the majority of future SO_2 emissions are predicted to be in the dust source regions of India and China (Solomon *et al.*, 2007).

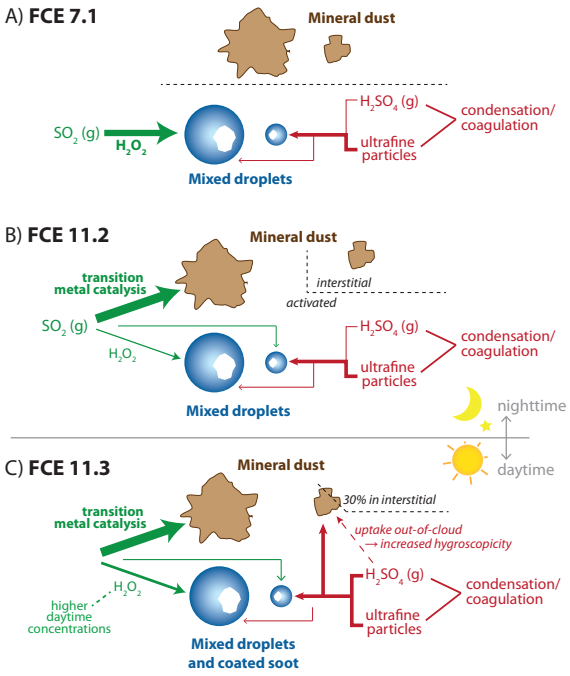

Figure 1: Major processes adding sulfate to particulate during passage through a cloud in HCCT 2010.

Keywords: size segregated aerosol, chemical interaction, cloud water
Presenting author email: konrad@tropos.de

During HCCT at the two valley sites in Goldlauter (upwind site) and Gehlberg (downwind site) aerosol collection by low-pressure impactors (Hauke, LPI 80/0.05) and high-volume filter samplers (Digitel, DHA-80) took place. At the mountain site Schmücke cloud water was collected by four bulk samplers, a three stage and a five stage sampler (Moore et al., 2004; Raja et al., 2008). Aerosol and cloud water samples were stored and transported frozen up to analysis.

During the six week campaign in September and October 2010 nine cloud events have been selected where a connected flow between the three sites was observed. Additionally three non-cloud events have been added for comparison to cloud events.

Water soluble ions, OC and EC were analysed from filter and impactor samples. Cloud water samples were analysed for the content of WSOC, H_2O_2, water soluble ions, and further species reported in other contributions.

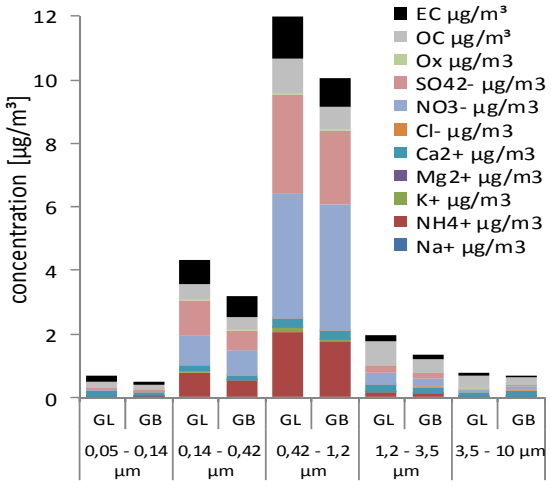

Figure 1. Mass concentration of OC, EC and ionic constituents of size segregated aerosol samples collected during cloud event 13.1 at both valley sites (GL: Goldlauter; GB: Gehlberg).

Ionic constituents are predominant components of the two fractions d_p = 0.14 to 0.42 and 0.42 to 1.2 µm. These fractions contain mainly the long range transported secondary material. The three other fraction were dominated by a high percentage of organic carbon (OC) and in the ultrafine mode of the stage 1 (0.05-0.14 µm) elemental carbon (EC) was found up to 30 % decreasing with PM size. OC from biogenic sources was reported up to 55 % in the coarse mode samples with higher concentrations typically at the upwind site. EC was found in all samples of the cloud events at the upwind site in all fractions in higher concentration than after the cloud passage at the downwind site. Not only the cloud but also the deposition on the humid forest surface influence the decrease in concentrations of nearly all components towards the downwind sampling station in Gehlberg in the mass rich fractions 2 to 4. For ultrafine and coarse mode particles some exceptions were reported.

The comparison between cloud water bulk samplers and the droplet size selective three- and five-stage sampler delivered comparable results. In nearly all samples the measured concentration of species is highest in the smallest droplet class (d<4 µm). The cloud water pH values were measured between 5.5 and 3.3.

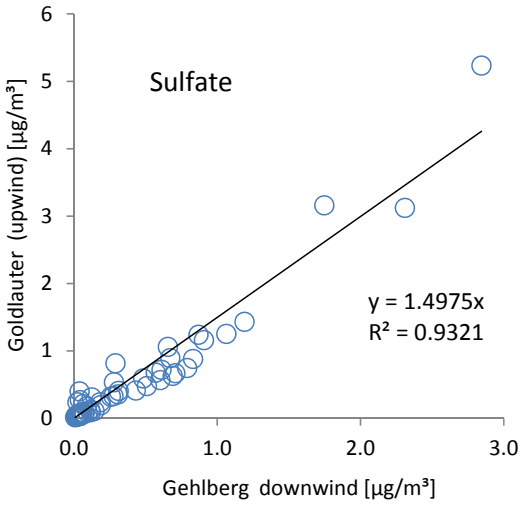

Figure 2. Comparison of sulphate content in impactor samples (all stages) during all cloud events between upwind site Goldlauter and downwind site Gehlberg.

For all major ionic species a decrease in particle concentration was observed between the valley sites in all size classes. Similar results according to Fig. 2 were found for other ions. The correlation coefficient was found to be lower for ammonium (R^2 = 0.879) and nitrate (R^2 = 0.724). Deposition and dilution of PM are the main causes.

Keywords: PM_{10}, Instrumentation, Tropospheric aerosols, Chemical composition
Presenting author email: fahlbusch@tropos.de

During the HCCT 2010 campaign (Hill Cap Cloud Thuringia) in September and October 2010 the online system MARGA (Monitor for Aerosols and Gases in ambient Air, Applikon Analytical, NL, *ten Brink et al., 2007*) was deployed at the upwind station in Goldlauter. The instrument was connected to a PM_{10} inlet to measure the mass concentrations of the water-soluble ions Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+} and their corresponding trace gases HCl, HNO_2, SO_2, HNO_3 and NH_3 at a time resolution of one hour.

The hourly PM_{10} MARGA measurements were analyzed with consideration of the meteorological conditions. The mean concentrations of the measured aerosols are shown in table 1.

Table 1. Summary of the measured concentrations between 11 Sep and 24 Oct 2010. The mean, the standard deviation (stdev) and the number of data points (N) are presented.

	Mean [µg/m³]	Stdev [µg/m³]	N
HCl	0.13	0.14	164
HNO_2	0.64	0.39	999
SO_2	0.67	1.34	1002
HNO_3	0.23	0.62	989
NH_3	0.81	0.84	1000
Cl^-	0.19	0.21	402
NO_3^-	1.94	2.08	1003
SO_4^{2-}	1.38	0.80	1003
Na^+	0.12	0.16	922
NH_4^+	1.12	3.27	1001
K^+	0.10	0.04	888
Mg^{2+}	0.14	0.15	981
Ca^{2+}	0.59	0.36	992

To evaluate the dataset obtained by the MARGA the measurements were compared with a SO_2 gas monitor (Thermo Environmental Instruments Inc., USA) and with a High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne, USA, *DeCarlo et al., 2006*).

The SO_2 concentration of the MARGA and the gas monitor are in good agreement (R^2: 0.82). But discrepancies can be seen during periods with low SO_2 concentrations.

A good correlation was observed between the MARGA and AMS measurements for nitrate, ammonium and sulphate with correlation coefficients (R^2) between 0.8 and 0.9 despite the different size cutting of the two instruments. This indicates that these three compounds were mainly present in the submicron fraction of particles during the HCCT campaign. Only during the first week of the campaign a significant higher NO_3^--concentration was measured by the MARGA compared to the AMS. This difference points out the presence of high nitrate concentrations in the particle coarse mode which was not observed during the rest of the campaign. Figure 1 shows the correlation between the MARGA and the AMS for NH_4^+ and SO_4^{2-}.

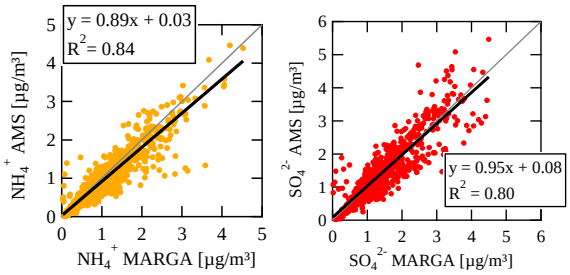

Figure 1. Comparison between MARGA and AMS measurements of ammonium (yellow) and sulphate (red).

HOx measurements at the upwind site during HCCT

D. Amedro, C. Schoemaecker, C. Fittschen and Jean-François Pauwels

Laboratory "Physicochimie des Processus de Combustion et de l'Atmosphère," PC2A, University of Lille 1, Villeneuve d'Ascq, 59655 cedex, France
Keywords: radicals, gas removal, cloud, field measurements.
Presenting author email: coralie.schoemaecker@univ-lille1.fr

The oxidative capacity of the troposphere is mainly driven by OH radicals. They are at the origin of most of the oxidation processes that takes place in the gas phase. HO_2 radicals are closely related to OH (OH and HO_2 are called together HOx radicals) as they are a product of hydrocarbon reactions with OH radicals. In most of the studies, the characterization of the sources and sinks of OH and HO_2 focused mainly on the gas phase. Nevertheless, uptake coefficient of HO_2 on aerosols was the subject of several laboratory studies (Taketani, 2008) and was taken into account as an HO_2 sink in atmospheric chemical models (Sommariva, 2006). The impact of HOx uptakes on aerosols in the cloud formations needs to be understood.

The HCCT (Hill Cap Cloud Thuringia) field campaign was organised by the IfT (Leipzig) during the autumn 2010 (from September 14th until October 24th). The newly built UL-FAGE (University of Lille, Fluorescence Assay by Gas Expansion) was deployed during the entire campaign to measure OH and HO_2 at the upwind site in Goldlauter.

Ambient air is probed into a low pressure cell, where OH is measured by Laser Induced Fluorescence (LIF). HO_2 is measured in a second cell following its conversion to OH using NO (see Figure 1). The detection limit was 6×10^5 molecules.cm^{-3} for OH and 1×10^6 molecules.cm^{-3} for HO_2 for a one minute integration time.

Special attention was driven on the so-called Cloud Events (orographic cloud formation on top of the hill with connectivity between the sites) and Non Cloud Events (absence of cloud, connectivity between the sites). HOx radicals were measured at two different sites in order to characterise the oxidative budget of the gas phase upwind and on top of the hill where the University of Leeds FAGE instrument was installed. In this configuration, during a Cloud Event, the HOx radicals were measured in the cloud (Leeds) and before the cloud formation at the upwind site (Lille).

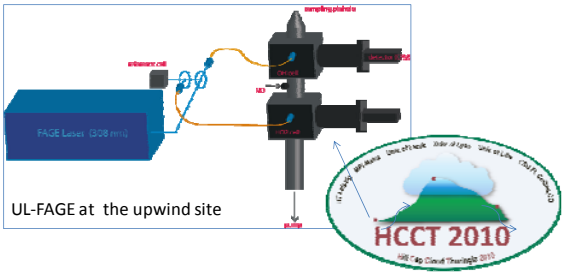

Figure 1. Deployment of the UL-FAGE during HCCT

Most of the cloud events occurred at night or under cloudy conditions, as a consequence the different photolytic sources of OH were diminished strongly. OH concentration was always under our detection limit and HO_2 concentration was measured at a very low level approximately $2.5.10^7$ molecules.cm^{-3} (~1 ppt).

During the entire campaign, maximum measured concentrations were 9×10^6 molecules.cm^{-3} for OH and 7×10^8 molecules.cm^{-3} for HO_2 (Figure 2).

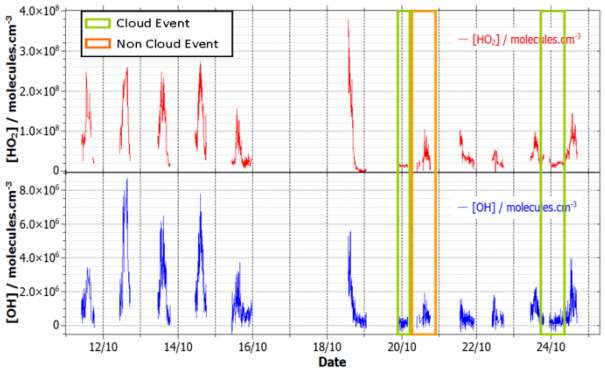

Figure 2. OH and HO_2 profiles during HCCT. Cloud Event and Non Cloud Event are highlighted.

HOx profiles were similar between the two sites, nevertheless significant differences between the HO_2 concentrations were observed, with systematic higher concentrations at the upwind site (UL-FAGE). HO_2 concentrations can be affected locally due to different chemical processes on the two different sites. However instrument interferences cannot be discarded: a recent work (Fuchs, 2011) has shown the interferences of several peroxy radicals on HO_2 signals. Further investigations need to be done in order to characterise the possible interferences for the principal Volatile Organic Compounds (VOCs) measured at both sites.

An atmospheric chemical model will be realised. Comparing the model with the measurements will be of importance in order to check how the cloud formation is affected by the local chemistry and also the long range transport of well characterized aerosols.

Characterisation of biological and biomass burning monosaccharides during Hill Cap Cloud Thuringia 2010 (HCCT 2010) campaign

Y. Iinuma and H. Herrmann

Leibniz-Institut für Troposphärenforschung, Leipzig, 04318, Germany

Keywords: Chemical composition, Aerosol cloud interaction, Biomass burning
Presenting author email: yoshi@tropos.de

Over the past few decades, substantial efforts have been made to study chemical properties of cloud and fog waters. Most of studies have reported similar chemical composition to that of ambient aerosol with sulphate, chloride, nitrate, ammonium and sodium as the dominant inorganic ions in cloud and fog waters. More recently, a wide variety of organic compounds have been identified in cloud and fog waters ranging from small carbonyl compounds such as glyoxal and methylglyoxal to macromolecules such as humic like substances (HULIS). Although the formation processes of these organic compounds in cloud and fog waters is not fully understood, an aerosol cloud interaction likely plays an important role in the occurrence of these compounds in cloud and fog waters. Furthermore, multiphase chemical mechanisms likely contribute to the formation of these compounds in the cloud and fog waters. In the present study, we present first results of size resolved biological and biomass burning originating monosaccharides concentrations in cloud water and aerosol between September and October 2010 as part of Hill Cap Cloud Thuringia 2010 (HCCT-2010) campaign. The focus of the campaign was to study aerosol cloud interaction through orographic cloud that formed at Mt. Schmücke, Germany. The samples collected during the campaign contained monosaccharides at non-negligible levels. A comparison of 5 stage Berner impactor aerosol samples taken at upwind and downwind sites indicates that more effective scavenging of PM10 bound biological monosaccharides (i.e. arabitol and glucose) than PM1 bound biomass burning originating levoglucosan (Figure 1).

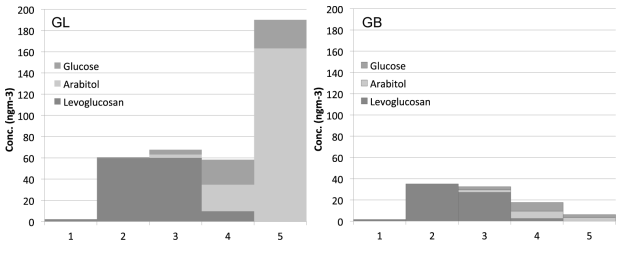

Figure 1. The composition of size resolved aerosol samples collected at the downwind site (Goldlauter, GL) and upwind site (Gehlberg, GB) on 14 September 2010 with a Berner type impactor with 50% cut-offs at 0.05, 0.14, 0.42, 1.2, 3.5 and 10 mm aerodynamic diameter (Dpa).

Similarly to the aerosol samples, the concentrations of arabitol and glucose were found at elevated levels in larger droplet fraction of the cloud water samples (Figure 2). Figure 3 shows the time series of size fractionated monosaccharide concentrations in the cloud water samples during 14 September 2010. The concentrations of all three monosaccharides increased steeply towards the night, especially arabitol and glucose in 20 μm droplet. This is consistent with earlier reports about inorganic ions that the chemical size distribution of aerosol is partly kept during the activation and growth processes (e.g. Collett *et al.*, 1993), with larger particles being more readily activated to cloud droplets.

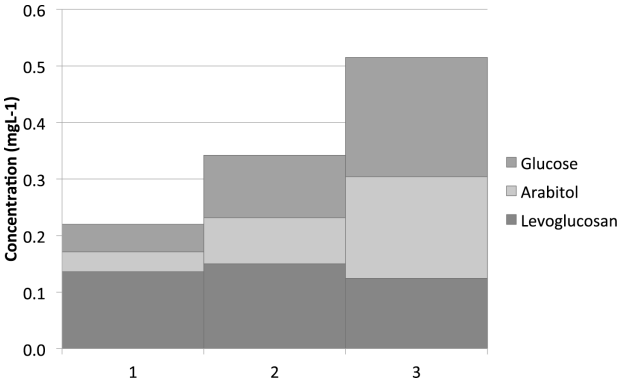

Figure 2. The composition of size resolved cloud water samples collected on 14 September 2010 at the Schmücke site with 50% cut-offs at 4, 16, and 20 mm aerodynamic diameter (Dpa).

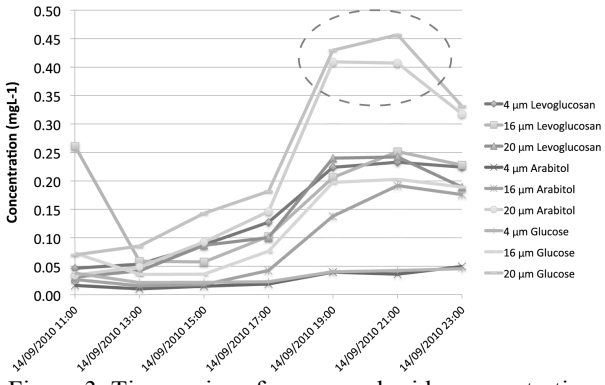

Figure 3. Time series of monosaccharide concentrations for the size fractionated cloud water samples collected on 14 September 2010 at the Schmücke site.

Trace elements in aerosols and cloud water are useful tools to study important processes that govern aerosol behavior. Soluble trace metals especially transition metal ions are known to influence the redox processes in atmospheric aqueous phase systems. Amongst others, they are known to strongly influence the HO_x cycle as well as the sulfur budget (Deguillaume, 2005).

To better understand the role these metals played during the Hill Cap Cloud Thuringia (HCCT) 2010 campaign in Thüringer Wald (Germany), trace metals and transition metal ions (TMI) analysis in aerosols and bulk and size resolved cloud water have been performed. The measured transition metals ions were Fe (III), Fe (II), Cu (II), Mn (II), Ni (II) and Zn (II), using a Dionex ICS 900 ion chromatography. The trace metals Al, Si, Ca, Ti, V, Co, Cd, Mn, Fe, Mo, Sr, Pb, Zn, Cu were analyzed using total reflection x-ray fluorescence spectroscopy (TXRF).

Figure 1 shows the hourly TMI concentration in cloud water observed during the first cloud events on the 14th of September 2010. The figure shows typical TMI concentrations observed throughout the campaign. The concentrations obtained during the whole campaign for the TMI's (iron 0.1 to 1.8 µM) where within expected range for cloud water (Deguillaume, 2005; K. Plessow, 2001).

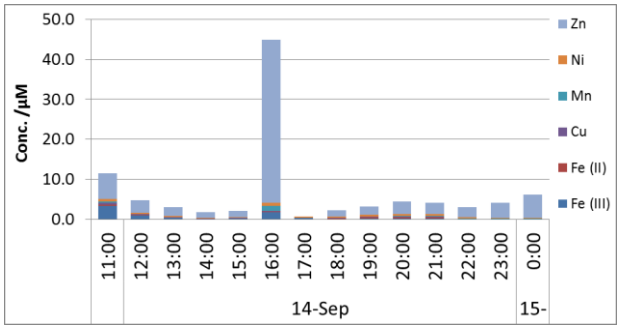

Figure 1. Hourly TMI concentration profile in cloud water during the first day of HCCT2010

Zinc was found to be the most abundant element in the cloud water with periods of high zinc concentration correlated with westerly air masses that traveled through regions of high industrial activities. The soluble iron was about 4 % of the total iron in the cloud water implying a significant amount of the iron was mobilized from the crust. Nevertheless, most of the observed soluble iron was present in the Fe (III) redox state compared to Fe (II) state except for some periods wherein the cloud was exposed to a high UV radiation during which higher Fe (II) concentrations compared to Fe (III) were observed.

Our results show indication of photochemical processes occurring during day time cloud events that influence iron processing. However, no strong correlation could be found between the HO_x cycling and the iron redox state processing.

Via estimation of crustal enrichment factors, the anthropogenic contribution to the cloud water concentration was obtained. Iron showed good correlation with other crustal elements such as Ti, Si and Al while no correlation with iron and higher enrichment factors were observed for elements like V, Co, Cd, Sr, Pb, Zn, Cu, indicating their likely anthropogenic origin.

The difference in the origin of the metals was further observed from the TMI measurements of the size resolved cloud water samples. Different size distributions were observed for Zn, Ni, and Cu which were mostly found in the second and third stages in comparison to iron species which were mostly found in the second and first stages. These differences in size distribution and enrichment factor comparison show that the observed metals during the campaign were of mixed origin.

Keywords: AMS, Aerosol cloud interaction, particle characterization, PM1.
Presenting author email: poulain@tropos.de

The impact of orographic clouds to the local aerosol chemical composition was measured during the Hill Cap Cloud Thuringia 2010 (HCCT-2010) field campaign, which took place in September/October 2010 at the Schmücke mountain ridge in the Thuringia forest (Germany). The main objectives of the HCCT-2010 project were to assess the effects of clouds on particle composition, gas phase oxidant budget, changes of hygroscopic properties and activation of aerosol particles. Three sampling sites were equipped: one on the top of the Schmücke Mountain, where clouds were sampled, and two valley stations located upwind and downwind of the summit. In total, four Aerodyne ToF-AMSs were deployed during the campaign. One at each valley station and two at the summit station: one downstream of a Cloud Virtual Impactor (CVI) for droplet residual analysis and one to measure interstitial particles. Based on air mass trajectories, gas tracer experiments and meteorological parameters, it is possible to identify periods during which the air mass of the three stations were connected. The overflow periods were divided in two subsections corresponding to the presence of cloud at the summit station (Full Cloud Events, FCE) and to the absence (Non Cloud Events, NCE) of cloud at the summit station. For these two categories of connected flow, the AMS results were compared in order to follow the cloud induced modification of the aerosol chemical compositions as well as modification of the chemical size distribution.

AMS results were successfully compared according to instrumental uncertainties and possible particle loss and dilution effects between the stations during the NCE periods and to the bulk chemical composition measured at the three stations show similar mass fraction. The comparison of the two valley stations is presented in Figure 1. Because the results measured at the three stations during NCE events were comparable, the same approach could be directly used to investigate aerosol cloud interaction and influence of clouds to local particles. Figure 1 also shows the first results of the comparison between the upwind and downwind station during several FCE periods. The scatter plots suggest a possible change on the bulk chemical composition of the particles corresponding to a small decrease of the particulate nitrate fraction as well as a tiny increase of sulfate. Details on the aerosol changes during the different cloud events including a comparison of the organic components as well as chemical size resolved will be presented.

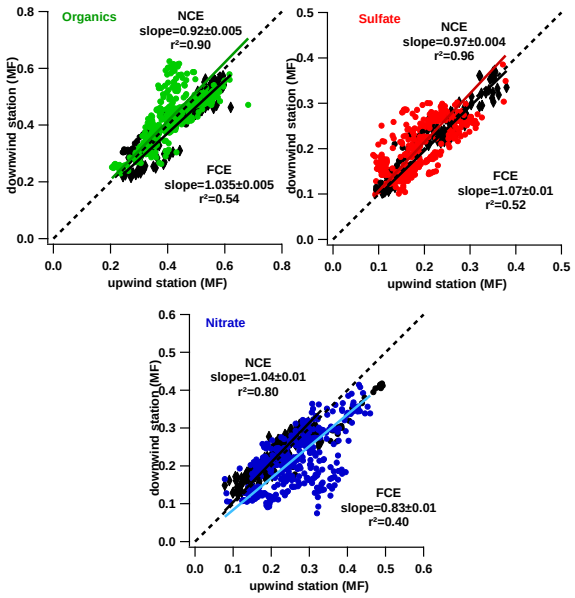

Figure 1: Scatter plots of the organics, sulphate and nitrate mass fraction measured at the upwind and downwind stations during NCE (black) and FCE (color). Regression slopes were calculated using orthogonal linear fitting.

Particle hygroscopicity during atmospheric new particle formation events: Implications for the chemical species contributing to particle growth

Z.J. Wu, W. Birmili, L. Poulain, M. Merkel, B. Fahlbusch, D. van Pinxteren, H. Herrmann, A. Wiedensohler
Leibniz Institute for Tropospheric Research (IfT) Leipzig
Keywords: New particle formation, hygroscopicity, HCCT
Presenting author email: wuzhijun@tropos.de

New particle formation (NPF) is an important source of atmospheric particles and likely contributes to the balance of optically active particles and cloud condensation nuclei. However, the mechanisms of atmospheric nucleation and particle subsequent growth still remain unclear. In this abstract, we will present the observations on NPF events at a mid-level mountain site in Germany during the field experiment HCCT-2010 (Hill Cap Cloud Thuringia 2010) to analyze the growth process of newly formed particles based on the hygroscopicity measurements.

During the HCCT campaign, a total of two NPF events with different features could be characterized in much detail. The particle number size distribution and meteorological parameters are shown in Fig. 1. The particle hygroscopic growth of nucleation mode was investigated to deduce the chemical species contributing to particle growth during NPF events. The results are given in Fig.2. A significant difference in particle hygroscopicity was observed between the two NPF events, indicating that the chemical species driving particle growing were not exactly the same. During both events, the hygroscopic growth of newly formed particles decreased with particle growing. This means that the condensing vapors changed during the particle growth process from more to less hygroscopic vapors.

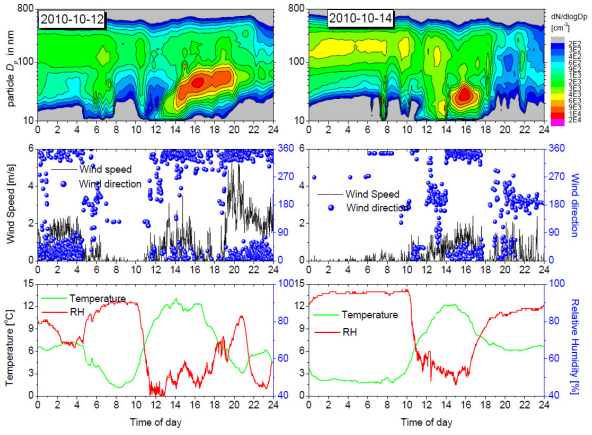

Fig. 1: The evolution of particle number size distribution and weather conditions during NPF events on 12 and 14 October, 2010.

An analysis of High Resolution-Time of Flight-Aerosol Mass Spectrum (AMS) data confirmed that sulfate may have played a more pronounced role in the first NPF case featuring a clear growth process. The contribution of sulfuric acid condensation to the soluble fraction was estimated. Result shows that a larger soluble fraction are failed to be explained by H_2SO_4 condensation, indicating that some other soluble compound contributing to the particle growth. Recently, Smith and coworkers (2010) have shown that alkylammoniumcarboxylate salts account for 20–50% of the mass of freshly nucleated particles in locations that include Atlanta, Mexico City, Boulder, and Hyytiälä, while sulfates account for only about 10%. That new finding may explain the miss source of the soluble fraction.

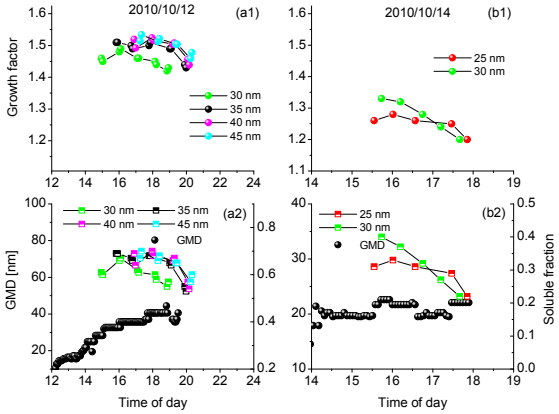

Fig. 2: The temporal evolution of geometric number mean particle diameter (GMD), growth factor, and the soluble equivalent fraction during the two NPF events. Time is indicated in CET.

Clouds play a crucial role for physical and chemical processes in the atmosphere. During HCCT, a lagrangian-type field experiment, an orographic cloud is used as a natural flow-through reactor to study in-cloud aerosol processing. Three measurement sites were installed at Schmücke Mountain in Thuringia, Germany: An upwind site, which served for the characterisation of incoming air masses, an in-cloud site on the Schmücke summit, and a downwind site, where under appropriate meteorological conditions air masses after their passage through a hill cap cloud could be studied. Particles were collected at all three stations on gold coated Nuclepore filters mounted in a stacked filter unit. At the in-cloud site droplet residues and interstitial particles were collected separately.

Elemental composition, morphology and mixing states of aerosol particles were determined using SEM-EDX and NanoSIMS for one nighttime and one daytime cloud event using the methodology described in Sinha *et al* (2008) and Sinha *et al* (in prep.).

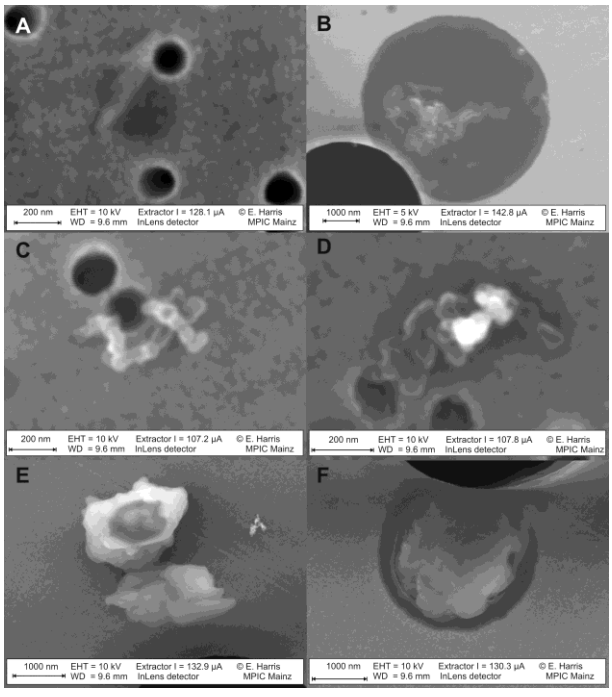

Fig.1: Particle types encountered during HCCT 2010. A) fine mixed SOA/SIA particles, B) coarse mixed SOA/SIA particles, C) soot, D) soot with SOA coating, E) mineral dust, F) mineral dust with SOA coating

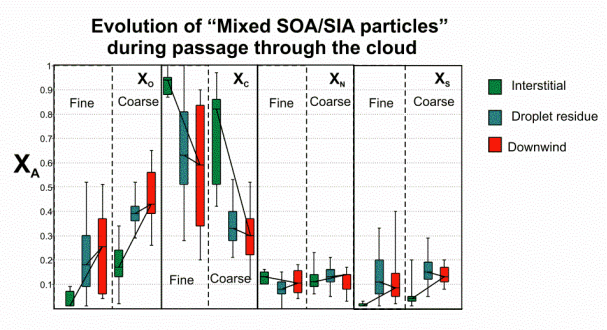

Fig. 2: Evolution of the composition of SOA/SIA particles from the in-cloud to the downwind station

The particle number distribution is dominated by secondary aerosol particles with a high fraction of organic aerosol (SOA). However, secondary aerosol particles are typically mixed in nature, i.e. they contain a secondary inorganic component (SIA). The inorganic fraction in secondary droplets is higher during the daytime event resulting in a smaller activation diameter of the mixed SOA/SIA particles during daytime (80±8 nm) compared to the nighttime event (116±12).

The inorganic fraction is larger in coarse compared to the fine mixed SOA/SIA particles and increases during the passage through the cloud while the organic fraction decreases. The SIA is added to the particles which activated (droplet residues).

Soot particles without coatings were not CCN active at night. During day all soot particles were coated with SIA. The CCN properties of coated soot depended on the amount of soluble material present in the coating and were independent of the size of the primary soot core. Once activated soot particles accumulated additional SIA during the passage of the cloud and coarse soot particles showed signs of repeated processing prior to reaching the site.

Activation, phase partitioning, and cloud processing of ambient aerosol particles in low continental clouds were investigated during the Hill Cap Cloud Thuringia field experiment (HCCT-2010) in central Germany during September and October 2010. The measurement area is located in the low mountain range "Thüringer Wald" and included the mountain ridge cloud site Schmücke (938 m asl) and an upwind and a downwind site, respectively.

Inside clouds that prevailed at the mountain ridge site, an interstitial inlet and two counterflow virtual impactors (CVI) were operated side by side in order to separate and collect interstitial particles (IP) and cloud drops (Mertes et al., 2005). Inside the CVI systems the collected cloud drops are evaporated releasing dry cloud drop residues (CDR), which are closely related to the original cloud condensation nuclei forming the clouds. Downstream the inlets, microphysical and chemical properties of IP and CDR were simultaneously determined by two sets of instruments connected to each inlet type.

Here we present results from measurements of IP and CDR number concentration (CPC), size distribution (SMPS and OPC), mass concentration of non-refractory substances (C- and HR-ToF-AMS, filter analysis), and black carbon (PSAP, MAAP). Moreover, cloud microphysical parameters like liquid water content, effective drop radius and drop concentration were detected by a PVM and a FSSP, respectively.

The phase partitioning of particle number concentration N_P and mass concentrations of chemical species is derived by the respective CDR concentration divided by the total concentration, CDR+IP. The obtained results are shown in Figure 1 for eight different cloud events, which are identified as periods of connected flow between upwind, summit, and downwind site. It was found that 10 to 30 % of the abundant particles were activated to cloud droplets. Concerning black carbon (BC) an equal distribution between both phases is observed (phase partitioning between 40 and 60 %), but two times more than 80 % of the BC mass was found in the CDR, which is surprisingly high for hydrophobic substances. Nitrate and ammonium have always the highest activated fractions, whereas for organic matter (OM) and sulphate this fraction varies substantially between 60 and 95 %. These findings are evaluated in more detail with respect to absolute concentrations, mixing states, cloud microphysics, air mass history and upwind/downwind measurements.

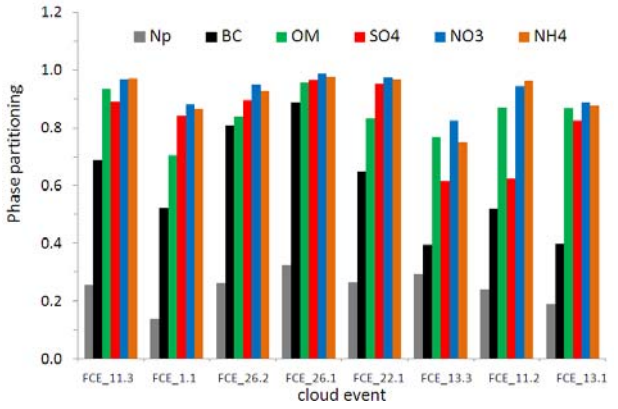

Figure 1. Partitioning between droplet and interstitial phase of particle number N_P and mass concentration of several chemical compounds indicated in the legend.

Typical number size distributions of CDR and IP measured with two SMPS are shown in Figure 2. From these results, the activation diameters of the cloud events are inferred ranging roughly between 100 and 200 nm.

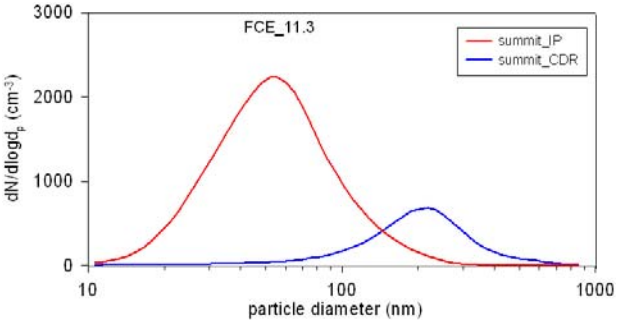

Figure 2. Mean IP and CDR number size distribution during cloud event FCE_11.3.

For the cloud events with connected flow between the three sites, the in-cloud particle number size distributions as well as the activation diameters will be compared to the total particle number size distributions (SMPS) and particle activation measurements (CCN counters) in the upwind and downwind site, which means in the inflow and outflow of the clouds.

Keywords: meteorology, aerosol cloud interaction
tilgner@tropos.de

To study aerosol-cloud interactions in more detail, Lagrangian-type field experiments, where an orographic cloud is used as a natural flow-through reactor, were performed. In Sept./Oct. 2010, the Lagrangian-type cloud passage experiment HCCT-2010 (Hill Cap Cloud Thuringia 2010) was conducted at Mt. Schmücke in Thuringia, Germany (see Figure 1) due to the utmost probability of the occurrence of warm orographic clouds and the south-westerly incoming flow perpendicular to the mountain range. These two conditions are essential for the experimental design (Herrmann et al., 2005). The philosophy is based on the connected flow between the two valley stations via Mt. Schmücke including an orographic hill cap cloud. Hence, the quality of such cloud passage experiments strongly depend on the meteorology and particularly on the flow connectivity between the measurement sites (see Tilgner et al., 2005; Heinold et al., 2005).

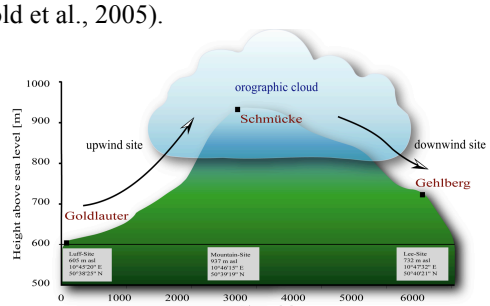

Figure 1. Schematic representation of the campaign area of the cloud passage experiment HCCT-2010.

At first, the meteorological characterisation was focused on the evaluation of large-scale conditions with particular emphasis on the incident flow conditions and on the separation of orographic and non-orographic clouds. In the case of the flow characterisation, weather charts and calculated backward trajectories are used to determine the horizontal wind pattern and the rawinsonde data for the vertical wind structure. Synoptic charts were analysed for detection of frontal processes, synoptic scale advection and air mass classification. Additionally, backward trajectories were used to identify the origin and characteristics of air masses reaching the experimental area, the sources for aerosols and constancy of the advection.

For the examination of the cloud conditions including the orographic character, satellite pictures of different spectral channels, rawinsonde observations of a nearby weather station as well as the measured liquid water content and cloud base height were evaluated. Furthermore, the meteorological and microphysical datasets of the three sites assisted the cloud analysis, the temporal detection of frontal-induced air mass change and the constancy of the local wind. Especially for the anticyclonic southwest weather-type (SWZAF), stable incoming flow conditions combined with orographic cloudiness were identified. In total, about 30% HCCT-2010 cloud event periods were characterised by orographic cloudiness and about 60% by clouds occurring associated to synoptic front systems.

In the following, the characterisation was devoted to further detailed local flow analyses. An analysis of the locally measured quasi-inert trace gas ozone and the measured aerosol particle distributions was intended to assure that measurements were performed in identical air masses and under connected flow conditions. By means of a comprehensive COD (Coefficient of Divergence) and cross-correlation analysis of the measured time series data of ozone and a selected particle number concentration interval, the links and the possible time delay between different measurement sites were investigated. The latter analysis was also done to characterise the typical flow times between the sites. Particularly, for days with constant south-westerly flow conditions, high wind speeds and less stable stratification strong link between the sites were found. Additionally to the above-mentioned investigations, relevant non-dimensional flow parameters such as the Froude number (Fr) were used to characterise the flow regime in mountainous terrain (Pierrehumbert and Wyman, 1985). By means of scale analysis of the calculated Fr, the limiting or supporting flow parameters such as synoptical flow and the thermal stratification conditions were investigated. Moreover, data from locally performed tracer experiments using the inert gas SF6 were used for studies on transport processes in the experimental site.

Finally, a qualitative classification results in 6 out of 10 cloud events, which relatively well conform the philosophy of the cloud passage experiment, and which provided the basis for subsequent investigations of the obtained HCCT-2010 dataset.

This work was supported by the German Research Foundation (DFG, He 3086/15-1).

Hill Cap Cloud Thuringia 2010 (HCCT-2010) was a complex field campaign on aerosol cloud interaction, performed at Mount Schmücke in central Germany in September and October 2010. Cloud water was sampled on a tower, 20 m above ground, using different cloud water collectors: The Caltech Active Strand Cloud Water Collector (CASCC2, [*Demoz et al.*, 1996]) sampled bulk cloud water with a 50 percent droplet size cut (D_{50}) of 3.5 µm and a one hour time resolution. A 3-stage version of the CASCC [*Raja et al.*, 2008] was applied to sample size-resolved cloud water with D_{50} of 22, 16, and 4 µm diameter for stages 1, 2, and 3, respectively. Additionally, a 5 stage collector [*Moore et al.*, 2002] was used with D_{50} of 30, 25, 15, 10, and 4 µm for stages 1 to 5. Due to the lower amounts of cloud water available in the different droplet size classes, the multistage collectors usually sampled 2-hourly (3-stage) and 4-hourly (5-stage) cloud water samples.

In addition to the liquid cloud water samples, droplet residuals and interstitial particles were collected on filters downstream of a counterflow virtual impactor (CVI) and an interstitial inlet (INT) [*Mertes et al.*, 2005]. The samples were analysed for short-chain mono- and dicarboxylic acids (C1-C5) using capillary electrophoresis with indirect UV detection. Additionally, a suite of longer-chain (C5-C10) functionalised carboxylic acids, i.e. acids with an additional functional group (hydroxy-, oxo-, or nitro-group) were determined by a relatively new technique based on hollow-fibre liquid phase microextraction and capillary electrophoresis – mass spectrometry.

The concentration ranges of short-chain carboxylic acids are given in Figure 1. Formic and acetic acid usually showed the highest concentrations, followed by oxalic acid. The concentrations of longer-chain functionalised acids are generally 1-2 orders of magnitude lower. Many of the compounds are reported for the first time in cloud water samples.

The dataset will be discussed with regards to cloud microphysical and meteorological parameters. For the short-chain acids, results from size-resolved cloud water sampling will be presented as well. Additionally, the phase partitioning of the most abundant short-chain diacids, obtained from the CVI and INT filters, will be discussed.

In September/October 2010 the ground-based cloud experiment “Hill Cap Cloud Thuringia 2010” took place at Mount Schmücke in the Thuringian Forest, Germany. The chemical composition of clouds was studied by means of different sampling and analytical techniques. Four Caltech Active Strand Cloud Water Collectors (CASCC2, [*Demoz et al.*, 1996]) were applied to sample large volumes (up to 640 ml) of bulk cloud water with a 50 percent droplet size cut (D_{50}) of 3.5 µm and a one hour time resolution. Additionally, two multistage versions of the CASCC were used. A 3-stage collector [*Raja et al.*, 2008] with D_{50} of 22, 16, and 4 µm diameter for stages 1, 2, and 3, respectively, and a 5 stage collector [*Moore et al.*, 2002] with D_{50} of 30, 25, 15, 10, and 4 µm for stages 1 to 5. Due to the lower amounts of cloud water available in the different droplet size classes, the multistage collectors usually sampled 2-hourly (3-stage) and 4-hourly (5-stage) cloud water samples. All cloud water collectors were installed on top of a 20 m high tower.

To complement the liquid cloud water samples, droplet residuals and interstitial particles were sampled downstream of a counterflow virtual impactor (CVI) and an interstitial inlet [*Mertes et al.*, 2005] using filters and an aerosol mass spectrometer (AMS).

Water soluble organic carbon (WSOC) was measured as non-purgable organic carbon (NPOC) with a commercial TOC analyser (Shimadzu TOC-V) after filtration of the samples through 0.45 µm syringe filters. The samples were stored frozen in pre-cleaned plastic bottles until analysis.

As can be seen in Figure 1, the bulk water concentrations of WSOC were between 1.2 and 34 mgC l^{-1} with an average concentration of 6.2 mgC l^{-1}. From the size-resolved sampling with the 3-stage CASCC (Figure 2) it can be observed, that the smalles droplets (stage 3) typically have higher concentrations than the larger ones (stages 1 and 2).

The cloud water concentration data will be discussed with regards to cloud microphysical parameters (liquid water content, droplet size spectrum), meteorology, and air mass origin. Additionally, a comparison of WSOC concentrations from cloud water and CVI filters will be given, as well as the fraction of organics measured by the AMS behind the CVI that can be explained by WSOC.

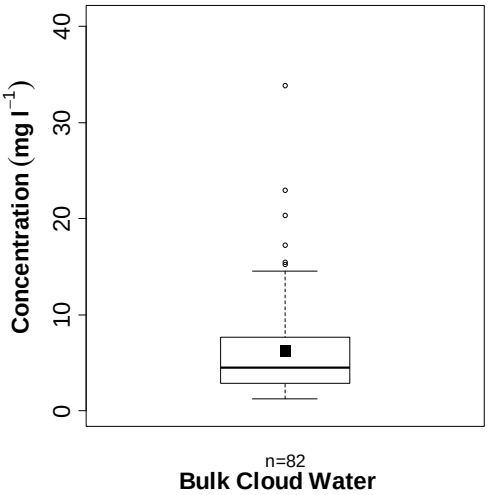

Figure 1: Bulk concentrations of WSOC in mg l^{-1}.

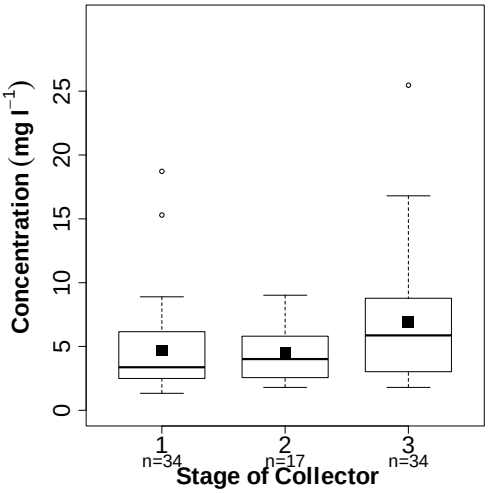

Figure 2: Size resolved concentrations of WSOC from 3-stage collector.

On-road particulate matter was collected during an in-vehicle sampling campaign in March-April of 2011 on two major Los Angeles freeways, 710 and 110. The 710 freeway is a major route for trucks traveling to and from the Ports of Long Beach and Los Angeles. The 110 freeway is a high-traffic route parallel to 710 but with a very low truck fraction. Two sets of samples were collected for each roadway, each set representing approximately 50 hours of on-road sampling. Concurrent sampling at a fixed site at the USC's downtown L.A. campus provided estimates of urban background levels.

Chemical analysis was performed for elemental carbon (EC), organic carbon (OC), polycyclic aromatic hydrocarbons (PAHs), hopanes and steranes. On-road concentrations (mass per m^3) and freeway-based emission rates (ERs) (mass per km of roadway per hour) are presented here. These ERs are presented such that freeways could be analyzed as a line source of emissions, with implications for population exposure models for nearby communities.

Concentrations are compared to previous studies of fixed sites near 710, while ERs are compared to previous freeway and tunnel studies. Concentrations and ERs were generally lower on 110 than 710, findings consistent with the former's significantly lower truck fraction. Compared to previously reported values, current 710 concentrations were largely comparable for PAHs and hopanes but significantly lower for steranes. Current trace metal concentrations on both freeways were significantly higher, especially for Fe, Cu, and Ba.

Current ERs for light molecular weight PAHs are much higher on 710 than 110, while ERs for heavy MW PAHs are more comparable. Compared to previously reported values, current 110 PAH ERs are significantly lower; current 710 PAH ERs are comparable; current 110 hopane and sterane ERs are generally comparable (with trisnorhopane significantly lower and homohompanes significantly higher); current 710 hopane and sterane ERs are comparable (but significantly lower for trisnorhopane, norhopane, bishomohopanes, and sitostane); both freeway metal and trace element ERs were lower for Mg, P, and K, but higher for Fe and Cu.

Table 1. Trace element emission rates from current and previous studies.

	110 (Current)	710 (Current)	710 (previous)
Mg	685.6	601.2	1042.0
P	162.3	123.6	589.0
S	1040.2	0.0	12821.5
K	624.0	146.8	860.8
Ca	2044.7	2346.3	2537.1
V	0.0	7.4	90.6
Mn	110.4	119.3	45.3
Fe	14787.2	16448.0	7611.4
Ni	5.6	7.4	45.3
Cu	1002.2	630.9	362.4
Zn	324.9	268.5	317.1
Mo	39.8	37.5	45.3
Ba	1444.7	1812.3	1268.6
Pb	9.8	0.4	90.6

Presenting author email: brotto@fisica.unige.it

In the framework of local and international projects, the Department of Physics of the University of Genoa is involved in the evaluation of the impact of on the urban air quality. Among the others, the Programme MED APICE project (http://www.apice-project.eu/) aims at the evaluation of the impact of harbor activities on urban air quality and the definition of strategies to reduce air pollution in port cities. In this frame, the year 2011 was devoted to monitoring campaigns, in particular addressing the Particulate Matter (PM) levels, composition and sources, in the five cities joining the project (Barcelona, Genoa, Marseille, Thessaloniki and Venice).

The monitoring activities were addressed to the source apportionment in each study area and to the set-up of numerical tools able to reproduce the experimental results. In Genoa, this turned out in a PM2.5 sampling campaign with daily samples collected in three sites for a 6-month period (May-October 2011). Subsequent compositional analyses (anions, cations, metals, EC/OC) produced a large database for a receptor model analysis through Positive Matrix Factorization (Paatero, 1994) and the comparison with numerical dispersion models. PM2.5 samples were collected on daily basis and in the same period in three sites in the urban area of Genoa (namely: Bolzaneto, C.so Firenze and Multedo) selected considering the direction of prevailing wind. Also, a meteorological and air quality modelling system was implemented, based on the mesoscale NWP model WRF (Skamarock 2008) and the Eulerian CTM CAMx (ENVIRON 2010) Through subsequent nestings, meteorological and pollutant concentration fields are obtained up to resolutions of order of 1 km.

A large amount of data has been collected and is now under analysis while simulations are running in order to get results over the whole monitoring period. Some discussion can be already done about what has been preliminary observed.

Despite of a distance of several kilometers and of the quite complex topography of the area, the time trends of PM2.5 daily concentration values measured in the three sites are very well correlated and have the same mean value over the six month period of sampling (see Figure 1). Interesting results has been obtained by analysing the correlation between the concentration values of V and Ni, typical tracers of heavy oil combustion and therefore of ship emissions, which have shown the same average ratio in the three monitoring sites, consistent with values previously observed in the urban area of Genoa (Mazzei *et al.*, 2008 and references therein).

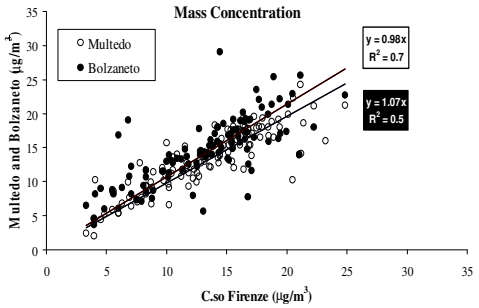

Figure 1. Correlation study among the PM2.5 data sets for the three sites in Genoa

The effect of transport phenomenon has been clearly evidenced by the comparison of concentration values observed in the two near-harbour sites (Multedo and C.so Firenze) with respect to Bolzaneto, a few km inlands. Furthermore, a strong correlation has been observed with wind directions while no correlation turns out between the time series of the concentration of one of the two elements measured in two different sites this suggesting that the dispersion of ships emission from the harbour is driven by meteorological conditions.

The full results of the source apportionment performed with PMF and with the Eulerian models will be given.

This work was supported by the Programme MED under the APICE grant.

Presenting author email: r.m.harrison@bham.ac.uk

Road traffic emissions, both exhaust and non-exhaust contribute significantly to particulate matter concentrations in urban areas. In the current milieu, much attention is being paid towards an improved understanding of these emissions and their contribution to overall PM concentrations.

Receptor modelling, particularly the chemical mass balance model is one of the often-used tools for estimation of source contributions to concentrations of particulate matter in ambient air. Further, the chemical mass balance model relies to a large extent on the accuracy of the source profiles used as an input. However, in the absence of locally-relevant source profiles, the source contribution estimates can be prone to erroneous results. Further, in recent years, significant differences have been observed between laboratory-tested and real-world mixed source traffic emissions (Ancelet et al., 2011; Yan et al., 2009).

To achieve the twin goals of assessing existing source profiles with respect to the ambient traffic emissions data and preparation of a mixed-source traffic profile for London, samples were collected at two different urban sites (background and roadside) in London, United Kingdom and it was assumed that if all other sources contribute to the same extent at both sites, the increment in marker concentrations would be due to traffic emissions. This approach has been used in previously published studies (Gietl et al., 2010; Pey et al., 2010). The traffic increment thus obtained was assessed in relation to existing profiles using ratio-ratio plots (Figure 1).

It was observed that there were significant differences between the (mainly U.S.) source profiles and the ambient data which can be attributed to differences in local conditions and vehicular technology. A European mixed-source traffic profile (El Haddad et al., 2009) was found to correspond best with one of the diesel profiles also finding a good fit with ambient data.

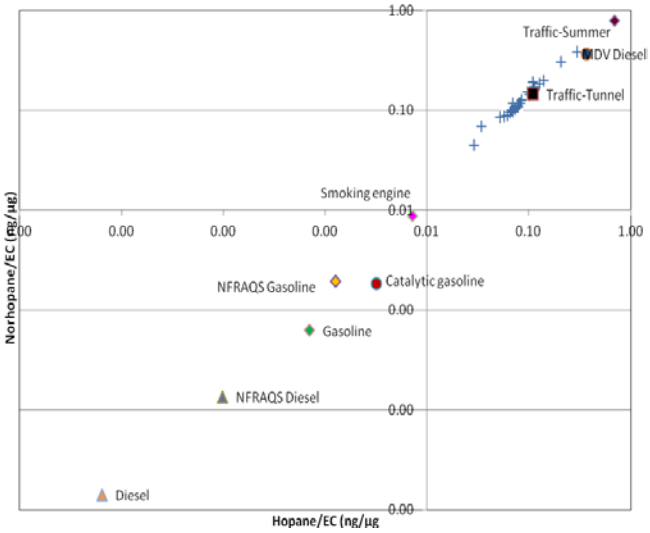

Figure 1. Ratio-ratio plot for ambient traffic increment data with published source profiles

Results indicate that mixed-traffic profiles might fare better for source apportionment using chemical mass balance. This might be due to their relative similarity to the real-world driving and emission conditions. The next step will be to use this mixed-traffic source profile to run the chemical mass balance model.

Compliance with the tougher regulations of ambient particulate matter (PM) in the European Union will require detailed and quantitative information about the sources of PM. Such information can be provided by source apportionment studies based on determination of the chemical composition of PM and application of receptor models (RM). These RM can be applied to on-line measurements or off-line PM sampling. Off-line PM sampling is developing largely because of the ease of implementation, especially by air quality networks throughout Europe. From the off-line chemical characterization of PM, different RM have been proposed in the literature (see review of Viana *et al.*, 2008), including the Molecular Marker - Chemical Mass Balance (MM-CMB) and multivariate statistical models, e.g. Positive Matrix Factorization (PMF).

MM-CMB is commonly based on the organic speciation of PM while PMF is typically applied to major components, metals and traces elements. Given differences between the two models (mass balance or statistical analysis) and the chemical speciation used, identified sources and estimated contributions may be different and intercomparisons of these two models are necessary. Just a few of these intercomparisons have been published so far (Ke *et al.*, 2008 ; Shrivastava *et al.*, 2007). In this work, the two models were applied on the same set of PM10 samples collected in various types of environments and seasons, representing various sources and chemical composition of PM: urban background, urban kerbside, rural and alpine valley sites in France and in Switzerland.

Results obtained in the urban background site of Zurich (Switzerland) and in the rural site of Payerne (Switzerland) for the estimation of PM10 show a reasonable agreement between the two models (Fig. 1) particularly in winter and confirm the estimated contributions. Differences are observed in summer for vehicular emissions due probably to an underestimation of this source by CMB (organic tracers of this source are lower than limits of detection in this season). Estimations of secondary inorganic (sulphates and nitrates) and organic aerosols (SOA) are almost equivalent despite the method of estimation: in MM-CMB they are indirectly estimated while in PMF they represent some individual factors (containing inorganics and SOA in same factors).

The presentation will also cover comparisons of the estimation of OC and EC in various types of environments. From these comparisons, MM-CMB seems to be more adapted to primary organic sources and source apportionment of OC. PMF allows estimation of a greater number of inorganic sources but by reconstructing the total mass of PM it can overestimate the fraction of each source. All this will be discussed in the presentation focusing on the complementarity of the two models.

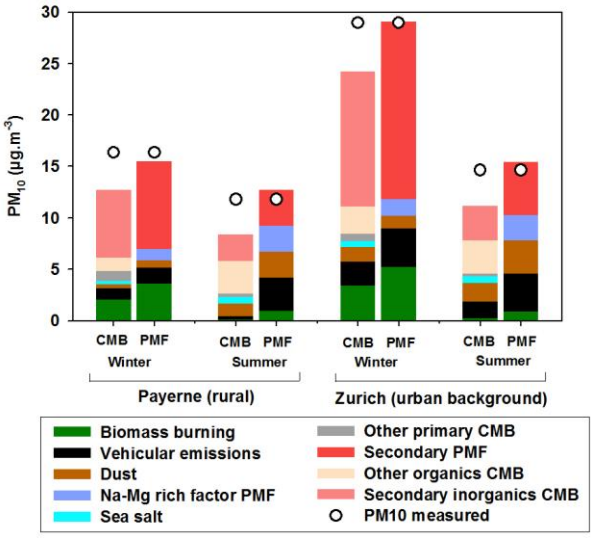

Figure 1. Contributions to PM10 estimated by PMF and MM-CMB in Zurich and Payerne.

Low emission zones (LEZ) are areas in which vehicular access is restricted to vehicles that emit low levels of air pollutants only. In 2008 a low emission zone (LEZ) was established in the inner city of Munich, Germany, in order to pursue the reduction of pollution. Samples of $PM_{2.5}$ were collected at the monitoring site in Lothstrasse before and after the implementation of the LEZ every third day from October 2006 to February 2007 and from October 2009 to February 2010. The Lothstrasse is located within the LEZ, allowing for a thorough monitoring of the LEZ implementation effect upon the reduction of hazardous, particle associated organic substances and the different sources of PM pollution.

The samples were analyzed for particulate organic compounds (POC) by in-situ derivatization thermal desorption gas chromatography time of flight mass spectrometry (IDTD-GC-ToF-MS) (Orasche *et al.*, 2011).

The results of the measurements of the two sampling periods were compared. The implementation of LEZ has no significant reduction effect on the concentrations of the organic compounds. Moreover, a higher concentration of some organic compounds in the 2009-2010 sampling period was detected.

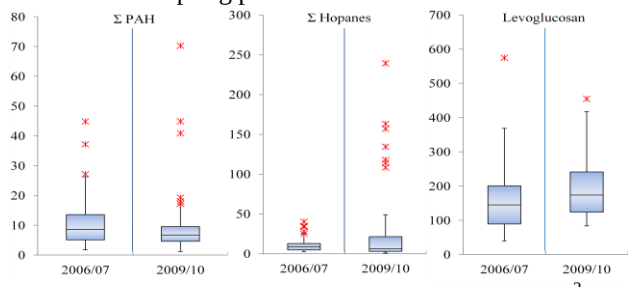

Figure 1. Box plots for the concentrations (ng m^{-3}) of some organic compounds before and after the LEZ

The main sources of POC were identified using positive matrix factorization (PMF) (Paatero and Tapper, 1994). More than 60 organic species were used for PMF analysis, including PAH, oxidized PAH, n-alkanes, iso & anteiso alkanes, hopanes, resin acids, fatty acids, anhydrous sugars and phenolic compounds. The PMF analysis with four factors afforded the most reasonable interpretation of the source profiles, which were related to primary PM emissions.

The factors are dominated by the pattern of a single source or groups of sources with similar time dependency of emissions.

In the first factor, the influence of the vehicular emission source is predominant. 55-85% of hopanes with mineral-oil-based pattern (homohopane index of 0.49) and n-alkanes (CPI of 0.78) are associated in this factor.

The second factor is characterized by compound patterns which represent a mix from tobacco smoke (iso & anteiso alkanes and n-alkanes with CPI of 2.13), cooking emissions (fatty acids) and traffic (homohopane index of 0.59).

In the third factor, about 10-85% of PAH and 15-45% of oxidized PAH are associated beside the hopane pattern (homohopane index of 0.22) what is similar to emissions from brown coal combustion.

The last factor is characterized by pattern which represents a wood combustion source. 60% of Levoglucosan, 59% of Dehydroabietic acid, 60% of Retene and 40-80% of the oxidized PAH are associated with this factor.

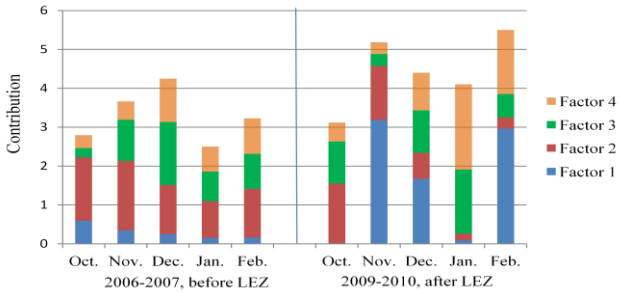

Figure 2. The monthly mean proportions of source factors

Differences in contributions are seen between the two sampling periods for all factors. For example, a high contribution of the first factor is noticed in the second sampling period and that most probably due to some construction activities near the sampling site.

The health effects of organic compounds in aerosols are currently investigated in the framework of the Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health, HICE (www.hice-vi.eu).

angeliki.karanasiou@idaea.csic.es

The objective of this study was to identify the major pollution sources in Athens urban area by means of receptor models. Two different multivariable methods were used (Unmix and PMF) and compared for their effectiveness to apportion aerosol emission sources.

Two aerosol-sampling campaigns were performed in Athens urban area, covering the cold and warm period. PM_{10} and PM_2 were collected simultaneously at three typical urban sites. Black carbon concentrations (BC) were concurrently measured by means of an aethalometer (AE-9, Maggee Sci). After gravimetric analysis the loaded filters were analysed for major and trace elements Fe, Al, Ca, Na, Mg, K, Ni, Mn, Cr, Cu, Cd, Pb and V by atomic absorption spectrometry and for water soluble ions by ion chromatography.

PMF and Unmix models were used to identify the sources of fine PM_2 and coarse PM_{2-10} particles. Here we present the results for the fine aerosol fraction. PMF identified five sources: motor vehicles emissions, road dust, biomass burning, marine aerosol and fuel oil combustion (Karanasiou et al., 2009). In order to determine if certain species could act as unique tracers the Pearson correlation coefficients between source contributions and variable concentrations were calculated. In fine particles Na, BC and Fe were exclusively correlated to marine aerosol, motor vehicles and oil combustion respectively. These species were at the same time the predominant variable in the mass profile of these sources. Surprisingly, Ni is exclusively correlated to motor vehicles emissions although this element had a minor contribution in the mass profile of this source. It was concluded that for Athens urban area Ni could be a unique tracer of traffic.

The initial runs of the Unmix model identified only 3 sources: road dust, marine aerosol and a third source that appeared as a mixture of sources such as vehicles emissions, oil combustion and biomass burning. However, Unmix model has the option of selecting one variable as tracer (only emitted by one source). The pearson correlation coefficients between source contributions and variable concentrations (determined by PMF) allowed the consideration of various species to be introduced as tracers in Umnix model. When Ni was used as a tracer (Figure 1) four sources were resolved by Unmix with similar profiles to those resolved by PMF.

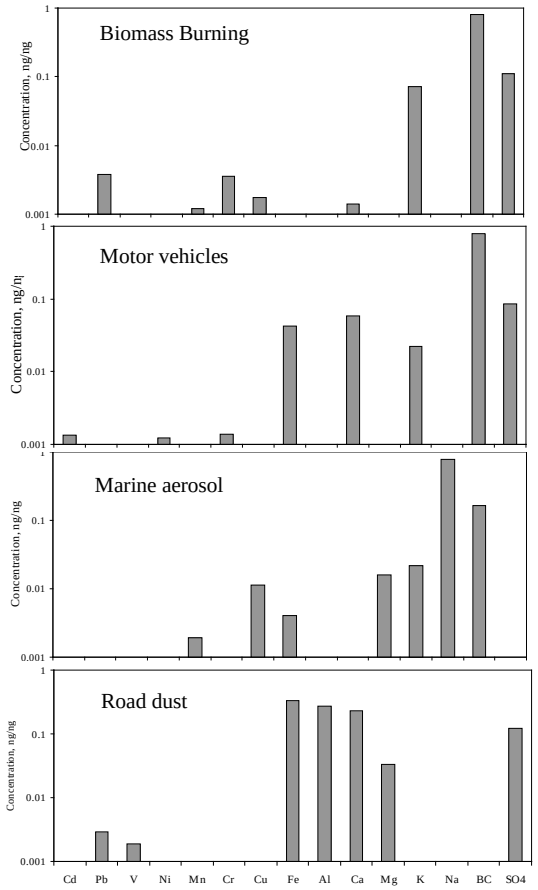

Figure 1. Source profiles for fine particles resolved from Unmix using Ni as a tracer.

PMF was proved to be powerful in resolving the sources of fine aerosol while Unmix could not separate the diverse combustion sources.

email: ehgere.abidi@etu.univ-provence.fr

Within the framework of the MEGAPOLI project, an intensive field campaign has been conducted in the Paris metropolitan area during winter, from 15 January to 15 February 2010. With 12 millions of inhabitants, Paris is one of the most populated areas in Europe and is relatively isolated from other urban areas. During this campaign, comprehensive chemical characterization of PM2.5 has been carried out including major ions, trace metals, OC/EC, and organic markers. Source apportionment has been performed using Chemical Mass Balance model (CMB). At the same time, High-resolution time-of-flight aerosol mass spectrometers (HR-ToF-AMS) was employed and PMF analysis was applied. The measurements were performed at two sites situated in the Paris region : one urban supersite (LHVP) and one suburban supersite (SIRTA) located 20 km southwest of the city center.

The contributions of seven primary fine particles sources were quantified in ambient air samples with the CMB approach, including some major primary anthropogenic sources. The obtained results show that among the 35% of the PM2.5 concentration apportioned to the primary sources, the biomass burning and vehicular emission contribute equally to the PM2.5 concentration (16 and 17%, respectively). Industrial emissions impacted also the atmosphere of Paris during a long range transport episode from Eastern Europe. Their contribution, characterized by the aggregate emissions from three industrial processes (heavy fuel oil combustion, coke production and steel manufacturing) remains very limited (2% on average) during the field campaign. A meat charbroiling source has also been apportioned, but these results need improvement.

Comparisons of the CMB approach with AMS-PMF (Crippa et al., 2012) have also been performed, with some first results presented in Figure 1 for the organic fraction. A very good agreement is observed for the traffic source (VEOM for CMB and HOA for AMS/PMF). Absolute contribution calculated by CMB are, however, slightly higher by a factor of 1.5. This difference could be explained by the different aerosol collection cut-off sizes (PM2.5 for CMB and PM1 for AMS/PMF) and/or oxidation and/or volatilization of the organic aerosol during its transport from the emission point to the receptor site. For biomass burning aerosol, we compare BBOM calculated by CMB and the sum of BBOA and OOA2-BBOA derived from AMS-PMF. The OOA2-BBOA profile is dominated by both the masses typical of the biomass burning and the semi volatile OOA (OOA2) spectra. The interpretation of this factor is not fully clear since it could be considered both as a BBOA SOA and/or processed BBOA POA, or alternatively as an atmospheric mixture of BBOA POA with OOA from another source (Crippa et al, 2012). Our results support the first two assumptions since differences between CMB and AMS/PMF increase for this source during the period dominated by long range transport episodes (Figure 1). The discrepancy observed between CMB and AMS-PMF approach may also be explained by the OC/levoglucosan used to apportion the CMB BBOA, as this ratio may be variable according to the source area.

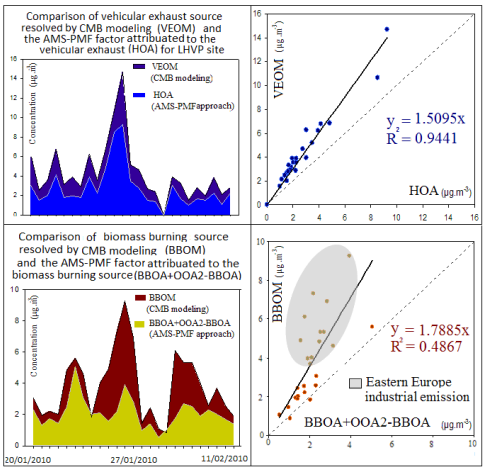

Figure1. Comparison of CMB modeling and AMS-PMF results in contributions from vehicular exhaust and biomass burning sources to PM concentrations at LHVP (PM2.5 for CMB modeling and PM1 for AMS-PMF approach).

A strong correlation in terms of mass loadings and temporal variability of the sources at the two sites is also observed. This result suggests that the particulate pollution from Paris is dominated by regional transport and the influences of local emissions from Paris itself do not significantly influence its surroundings.

This research was funded by the European Union's Seventh Framework program FP/2007-2011 within the project MEGAPOLI, grant agreement n°212520. E.A. gratefully acknowledges the ADEME and PACA region for their support.

Source Apportionment of Particles in London Paddington Station

U. Chong[1], J.J. Swanson[1], and A.M. Boies[1]

Exposure to airborne particles from combustion sources and industrial processes are a major health risk in the urban environment. The health impacts of particle emissions are exacerbated when emissions occur within densely populated areas with enclosed boundaries that do not allow for diffusive or convective dispersion. Enclosed train stations with diesel-powered locomotives, in particular, represent a health risk because of the close proximity of the emissions to the passengers. In order to reduce the impacts from diesel locomotives, particle emissions by mass for new EU diesel locomotive engines greater than 130 kW have been regulated by EU Directive 2004/26/EC since 2006. In January 2012, this PM mass emissions standard was lowered by 87.5% (0.200 g/kWh to 0.025 g/kWh) (EU, 2004). Locomotive PM emissions are also influenced by EU Directive 2003/17/EC, which has limited the fuel sulphur content of gas oil to 0.1% by mass since 2008 (Silver, 2007).

To evaluate the impact of diesel engine exhaust within a train station relative to other emission sources, particle measurements (PM mass, size, concentration, and composition) were taken at London Paddington Station, the 8th largest station in Great Britain serving 30 million passengers per year (ORR, 2010). Of the 14 lines in this station all but two host rail traffic powered by diesel engines. The purpose of this study is to determine the sources of particle emissions in Paddington Station and evaluate the potential impact of the new emission regulations. While a few air quality monitoring studies have been conducted inside and adjacent to the station, none provide an in depth apportionment of the sources of PM beyond a mass-based metric. We determine the relative contribution of PM from various emissions sources by measuring particles in different locations and analysing their chemical and size characteristics.

An initial survey was conducted with mobile measurement instruments from TSI, Inc. A P-TRAK 8525 Ultrafine Particle Counter was used to measure number concentration of PM below 0.1µm. An Optical Particle Sizer (OPS) was used to measure the concentration of particles between 0.3-10 µm. Figure 1 shows the averaged results of the P-TRAK measurements (<0.1 µm) sorted by activity.

Elevated levels of PM were observed during departing and arriving train activity, with departing engine acceleration causing higher levels of PM than braking from arriving trains. Beyond the locomotives, it was determined that other activities, such as food vendors, can contribute to elevated levels of PM.

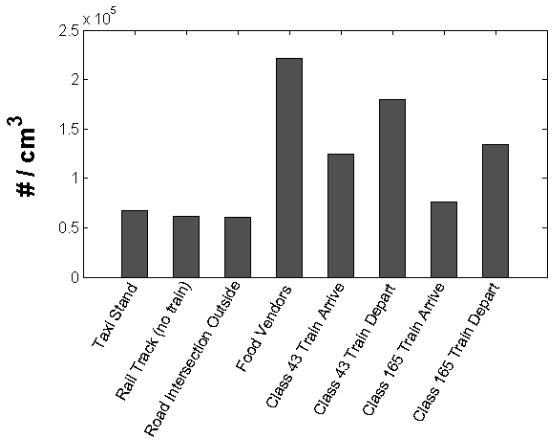

Figure 1: Results of initial survey of particle concentrations at different Paddington locations.

A subsequent measurement campaign was conducted in order to rigorously apportion the sources of PM. Six measurement locations were selected and are described in Table 1.

Table 1: Measurement locations

Location	Purpose
Hot food vendors	Cooking exhaust
Eastbourne Terrace	Taxi exhaust
Platform 1 Bridge	Class 43 Train exhaust
Platform 13 Stairs	Class 165 Train exhaust
The Lawn Shopping	Indoor; away from trains
Praed St. Intersection	Outside ambient location

PM mass concentration measurements were taken continuously at all locations using a TSI AM510 SIDEPAK monitor. A SMPS and an ELPI were rotated on a daily basis between the six locations. SMPS measurements were taken with and without a catalytic stripper to determine the EC/OC ratios of measurements, which allowed for source apportionment of PM emissions. Filtered PM samples from the ELPI were used to determine the chemical composition of particles. Ultimately, the results of this study will better inform policy decisions on improving air quality in Paddington by efficiently targeting the appropriate sources.

Northern Italy is one of the most industrialized and populated regions in Western Europe and is characterized by high levels of fine particulate matter (PM2.5). Harmful health effects have been associated with exposure to PM2.5 and to associated toxic compounds.In Europe, the recent Air Quality Directive (2008/30/CE) establishes an annually averaged PM2.5 concentration of 25 μg m^{-3}, which will be the legal limit value from 2015 onwards. With the aim of designing effective PM2.5 reduction strategies, information on the strength of impacting sources is required.

In order to study PM2.5 mass concentrations and chemical compositions in Northern Italy, we conducted measurement campaigns at an urban site in Milan (MI) and a rural site in Oasi Le Bine (OB), over a three-year period (2006-2009) (Perrone et al., 2012).

Chemical mass balance modelling (CMB) was applied to PM chemical composition data in order to quantify the major PM2.5 sources during different seasons. 13 fitting species (EC, levoglucosan , C29 and C31 *n*-alkanes, five PAHs and four elements), comprised of compounds known to be good molecular markers, were used in CMB modelling with the aim of assessing contributions from five primary sources: traffic (TR), biomass burning (BB), natural gas combustion (NGC), plant debris (PD) and road dust (RD). A critical issue for CMB modelling is the availability of source profiles that represent the aggregate emissions from a given source at the considered receptor site. In the present study we used profiles representative of the region in question, where such were available (TR, BB and PD), and various composite profiles derived by literature data. The sensitivity of the CMB model to the selection of different profiles (TR and BB) was assessed .

From CMB calculations the contributions of primary sources to OC was estimated for seasonally averaged PM2.5 samples, and the PM mass from each source was reconstructed by applying a specific OM-to-OC conversion factor to each source and adding other primary components (e.g. EC; primary sulphate, nitrate and ammonium; major elements and their oxides) (El Haddad et al., 2011).

In MI, TR was found to be the strongest primary source (17-24%) for PM2.5 in all seasons, together with secondary inorganic and organic aerosol (21-54%) (Fig.1).In fall (F) and winter (W), BB was a major contributing primary source to PM2.5 concentrations at the MI urban site as well at the OB rural site, with a source contribution estimation (SCE) ranging from 8 to

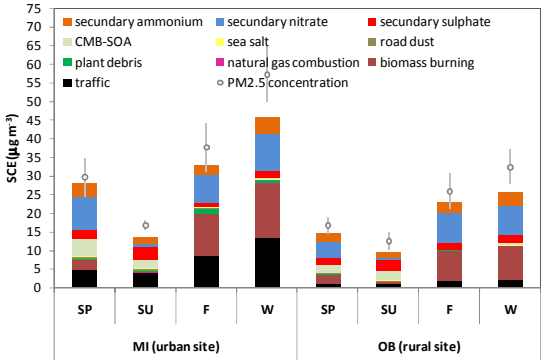

Figure 1. Source contribution estimation (SCE) to averaged seasonal PM2.5 concentrations in MI and OB.

15 μg m^{-3} at the MI urban site as well at the OB rural site. While TR is mainly a local source, and it has a stronger impact nearer the source, BB is a widespread source with a substantial regional contribution.

BB was also a contributing source to the high PAHs concentrations measured in the PM2.5 samples in the cold season. In figure 2 the ratio-ratio plot compares PAHs/EC ratios in the ambient air with those of sources. Winter data mainly cluster between a 50/50 and a 25/75 mix of BB and TR sources, thus suggesting a relative contribution of 25-50% for BB source to PAHs (BghiP and IcdP) ambient concentrations at the MI site.

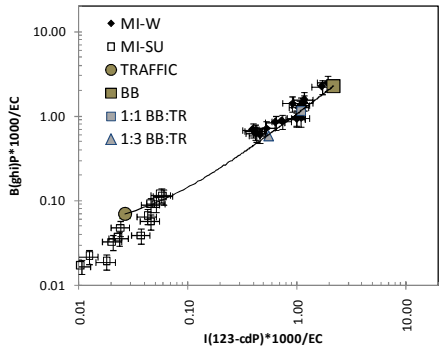

Figure 2. Ratio-ratio plot using PAHs and EC. Ambient data for MI site (W=winter; SU=summer) and source profiles for TR and BB.

Impacts of industrial and harbor activities on fine particles over Marseille

D. Salameh[1], A. Detournay[1], H. Wortham[1], J.L. Jaffrezo[2], J. Cozic[2], A. Armengaud[3], D. Piga[3], J. Dron[4], P. Chamaret[4], M. Parra[5], M. Deveze[5] and N. Marchand[1]

Email: dalia.salameh@etu.univ-provence.fr

With traffic of about 97 million tons (Mt) (62.5% of crude oil and oil products) in 2007, the autonomous port of Marseille is the most important port of the Mediterranean Sea. A huge petrochemical area among other industrial plants (steel mill, coke plant…) is also located close to Marseille, the second most populated city in France with more than 1 million inhabitants. This area is also well known for its huge photochemical pollution.

Within the framework of the EU-MED APICE project (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions ; www.apice-project.eu) a long monitoring campaign began in Marseille in July 2011, and will end in July 2012. Samples of fine particulate matter (PM2.5) are collected with a temporal resolution of 24 or 48 hours on two main sites. The first one is in an urban background environment ("Cinq avenues" site). This measurement site belonging to the air quality network AirPACA, is also equipped with instruments for continuous measurement of NOx, SO_2, O_3 and both PM2.5 and PM10. The second site is located in the eastern docks of Marseille harbor in the vicinity of ships emissions. These strategic locations allow, first, to characterize the physicochemical composition of the particulate matter emitted by the harbor activities, and secondly, to characterize and to quantify the contribution of these specific emission sources in the atmosphere of Marseille. A comprehensive chemical characterization of the collected samples is carried out including major fractions (OC/EC, ionic species), 33 elements and trace metals and about 100 organics markers (PAHs, levoglucosan, linear alkanes, hopanes…).

An intensive measurement campaign has also been conducted in the industrial area near Marseille in June 2011 (Fos-sur-Mer). High time resolved measurements have been performed for both submicron aerosol and VOCs (HR-ToF-AMS, PTR-ToF-MS, SMPS, MAAP, OPC) in addition to offline samples collection. Results from this intensive campaign are presented in figure 1. While PM10 and SO_2 concentrations were significantly lower than those usually observed in this environment at the same period of the year, we observed intense particle events reaching 140 000 cm^{-3}, most of the time associated with SO_2. This particles events are associated to ultrafine particles (D<50 nm). As well intense and sharp peaks of submicron organic aerosol up to 200µg/m3 are observed all along the campaign. These OA events are associated with particles in the 300-400 nm size range.

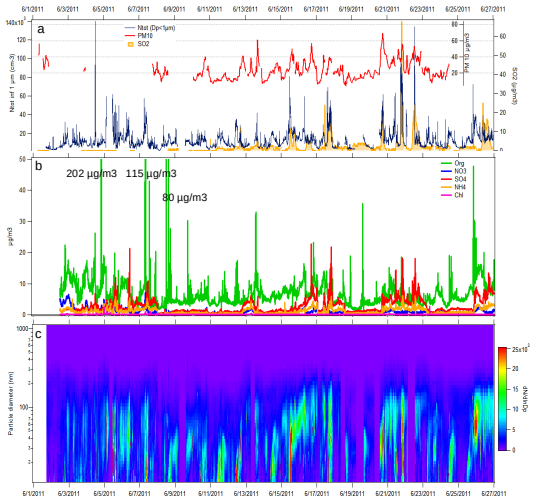

Figure 1. Results from a one month intensive campaign held in the industrial area of Fos-Berre (Juin 2011).

From these results two major lessons can be drawn. First, particle mass concentration (PM10 and PM2.5) do not constitute a totally relevant parameter to study the impact of industrial emissions and, second, these industrial particles events are associated to an important fraction of organic materials. Metals usually used to trace industrial emissions offer only a partial view of the complexity of industrial particles emissions.
In addition to the results obtained within this intensive campaign, preliminary results of source apportionment realized during the long monitoring campaigns carried out in Marseille will be presented.

Absorption Ångström exponent, and its correlation with other aerosol variables such as number size distribution, gas phase- and trace elements of the atmosphere. A field study.

T. Ajtai, Á. Filep, N. Utry, M. Pintér, Z. Bozóki, G. Szabó
Department of Optics and Quantum Electronics, University of Szeged, Hungary

Keywords: source apportionment, photoacoustic, optical absorption, Ångström exponent.
ajtai@titan.physx.u-szeged.hu

One of the major contributions in uncertainties on climate forcing is associated to aerosol. Optical absorption coefficient of aerosol (OAC) is one of the most uncertain parameters associated to both direct and indirect effect on climate and is one of the most difficult quantities to measure Due to its strong influence on the climate and its adverse health effects, in-situ characterisation of light absorbing carbonaceous matter (LAC) is in the middle of scientific interest today. LAC is a mixture of graphite-like particles and light-absorbing organic matter having various origins. The term absorption Ångström exponent (AAE) is introduced to describe the wavelength dependence of OAC. Great many papers demonstrated that AAE of LAC is characteristic for its constituents, therefore its measurement can be a valuable tool for in-situ source apportionment (Andreae and Gelencsér, 2005). Although the only method that can measure OAC of LAC, in-situ, is photoacoustic spectroscopy, it is not widespread in its application yet. During last decades several promising photoacoustic instruments for OAC measurement with high reliability have been published, but most of them operate only at one wavelength. Recently multi-wavelength photoacoustic instruments become available and initial laboratory and field measurements demonstrate experimentally that AAE might be an indicator of the chemical composition of atmospheric bulk.

We present a study of OAC of ambient aerosol measured by our four wavelength photoacoustic instrument (4λ-PAS) in the UV, VIS, near IR spectral region (1064 nm, 532 nm, 355 nm and 266 nm) The instrument applies wavelength independent, non-site specific calibration with accuracy below 5%, therefore it provides unique and novel possibility for investigation of absorption spectra with high selectivity. Segregated AAEs were calculated at different wavelength pairs of the 4λ-PAS. Systematic daily fluctuation of AAE was identified with different dynamics. Correlation with other aerosol variables such as size distribution and elemental composition, as well as concentration of trace gases were revealed and quantified. Reliable correlation was found between $AAE_{532nm\text{-}266nm}/AAE_{1064\text{-}532nm}$ and N_{GMD20}/N_{GMD100} ratios. Similarity of volume size distributions measured at the two representative periods confirms that variations in AAE were not caused by variation in particle size, but by chemical composition. High correlation between $AAE_{532nm\text{-}266nm}/AAE_{1064\text{-}532nm}$ and CO/NO_x ratio further confirms that daily changes in absorption spectra are related to the changes in relative strength of emission sources most likely between traffic and residential heating. Finally, we have demonstrated and quantified the correlation between $AAE_{532nm\text{-}266nm}/AAE_{1064\text{-}532nm}$ and the ratio of source specific trace elements.

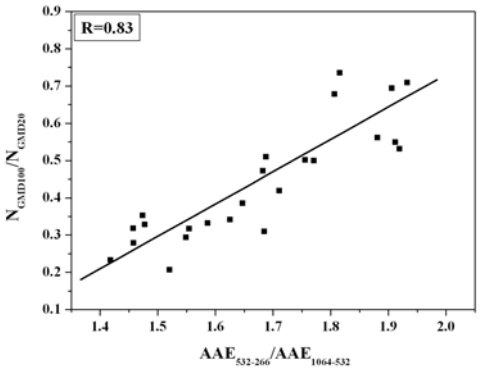

Figure 1: Correlation of the modal number concentration ratio and the ratio of AAE calculated from 532-266 nm and from 1064-532 nm.

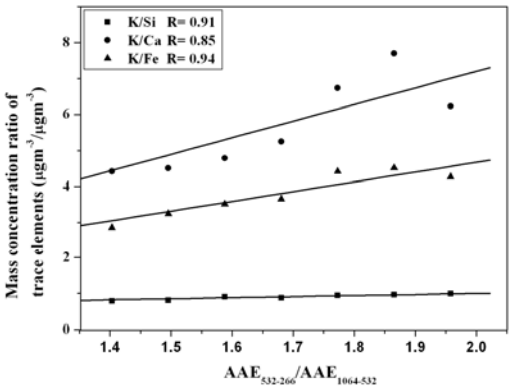

Figure 2: Correlation of ratio of K with Si (labelled with squares), Ca (circles), Fe (triangles) and AAE calculated from 532-266 nm and from 1064-532 nm.

Source apportionment of indoor and outdoor $PM_{2.5}$ in an apartment situated in central Athens, Greece

D.E. Saraga[1], M. Seleventi[2], C.G. Helmis[2], Ch. Vasilakos[1] and Th. Maggos[1]

[1]Environmental Research Laboratory/INT-RP, National Centre for Scientific Research "Demokritos", Aghia Paraskevi Attikis, P.O.B. 60228, 15310 Athens, Greece

Presenting author email: dsaraga@ipta.demokritos.gr

The role of the outdoor environment in indoor particles concentration presents special interest in cases where the house is situated in an aggravated urban atmosphere. The aim of the present study is to identify the main sources and estimate their contribution to the indoor and outdoor $PM_{2.5}$ levels measured in an apartment situated on a high-traffic street (Ch. Trikoupi), in central Athens. For the purpose of the study, Positive Matrix Factorization (PMF) model was applied on a set of indoor and outdoor $PM_{2.5}$ samples collected during a 2-week campaign (winter 2011).

Using two similar low volume controlled flow rate ($2.3m^3/h$) samplers (DERENDA), $PM_{2.5}$ samples were collected both indoors and outdoors of a $120m^2$ apartment situated on the 5^{th} store of a block of flats. The samples were analysed for 10 ionic species (F^-, Cl^-, K^+, Na^+, Mg^{2+}, Ca^{2+}, NO_3^-, PO_4^{3-}, SO_4^{2-}, NH_4^+) and organic/elemental carbon (OC/EC and organic carbon fractions). The chemical analysis for the ionic species was conducted with the use of ion chromatography and organic/elemental carbon analysis with the use of NIOSH Method 5040, IMPROVE methods. Occupants' activities were daily recorded on questionnaires.

Experimental results showed that particles concentration ranged between 9.0 and 65.4 $\mu g/m^3$ indoors and between 11.7 and 43.5 $\mu g/m^3$ outdoors. The maximum indoor concentration was noticed during the day that smoking took place. Furthermore, OC/EC ratio exceeded the value of 2 in all indoor samples and in the 77% of the outdoor samples, implying the presence of secondary organic aerosol (SOA). A strong correlation was observed between indoor and outdoor EC (R^2 =0.94), implying common (outdoor) origin. Finally, among the ions measured, Cl- and SO_4^{2-} presented the most significant variation. I/O ratio for NO_3^- and NH_4^+ was much lower than unity because of the presence of strong outdoor sources (intense vehicles circulation).

For the source apportionment analysis EPA PMF model (version 3.0) was used. Data pre-treatment included concentration data below the methods detection limit replacement with one-half of the detection limit and missing concentration data substitution with the median value. Correspondingly, uncertainty for data below the detection limit was set equal to 5/6 of the detection limit while uncertainty for missing data were set equal to 4 times the median concentration (Polissar et al., 2001). The model was run for 3 to 10 factors, in a random seed and the optimal number of factors ranged between three and five, depending on the species used in each run. Finally, bootstrap and Fpeak runs were conducted in order to examine the stability and the rotational ambiguity of the solutions, respectively.

Preliminary results indicate four main groups of sources contributing to both indoor and outdoor $PM_{2.5}$ levels: a combustions-related source (including smoking for indoor air), a traffic-related source (vehicles and road dust), a crustal source (soil dust) and a source connected with secondary aerosols. Representative quantitative results are presented in figures 1a,b. A preliminary conclusion underlines the different sources contributions in indoor and outdoor air. Smoking (combustion sources) and dust is the main sources indoors while traffic and soil dust contribute the most to outdoor particles.

Keywords: Arctic, PMF, COPREM, Atmospheric particles
Presenting author email: jakn@dmu.dk

Sources of particulate matter (PM) were evaluated at Station Nord (81°36'N, 16°40'W) in North East Greenland based on two-years of measurements of black carbon, elements and inorganic ions from March 2008 to February 2010. Particulate species were sampled on filters with weekly resolution, while the time resolution of gasses and black carbon were 30 and 15 min, respectively. Sources of PM were apportioned using Positive Matrix Factorization (PMF) and the Constrained Physical Receptor model (COPREM). COPREM is a hybrid receptor model, which unifies qualities from both Chemical Mass Balance (CMB) and PMF (Wåhlin, 2003).

Table 1. Analytical methods and analysed species

Elements (Proton Induced X-ray Emission) Al, Si, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Ga, As, Se, Br, Rb, Sr, Zr, Pb
Inorganic ions (Ion Chromatography) SO_4^{2-}, Na^+, NH_4^+, NO_3^-, Br^-
Carbon (Particle Soot Absorption Photometer) Black carbon
Inorganic gasses (gas monitors) O_3, NO_2, NO, SO_2

In general, COPREM and PMF solutions agreed well as was expected since only the natural sources were constrained in COPREM. Five factors (sources) were chosen to describe the dataset, including a *Marine* and a *Soil* (crustal) factor of natural origin. Anthropogenic sources were heavily influenced by metal industry. *Metal (Zn)* was the largest source of Zn with a time profile different from the other anthropogenic sources. Significant peaks were observed during the summer in addition to typical high concentrations in the winter/spring. Most Cr was associated with this source, while most non-crustal elements and combustion related species were of low abundance, e.g. NO_3^-, SO_X=SO_2+SO_4^{2-} and black carbon (BC). *Metal (Cu/Ni)* was the predominant source of Cu. Furthermore, significant amounts of NH_4^+, NO_3^-, SO_4^{2-} and BC were apportioned to this source, which evidently was highly influenced by anthropogenic emissions, predominantly husbandry and combustion processes. The time profile of *Metal (Pb/As)* resembled *Metal (Cu/Ni)*, but the chemical composition was different. Most As, Pb and Br were apportioned to this source, in addition to combustion-related SO_X and BC. The comparable time profiles of *Metal (Pb/As)* and *Metal (Cu/Ni)* showed a typical *Arctic haze pattern* with low summer and high winter/spring concentrations. This suggest that both factors had a common origin, most likely an Eastern source to which Cu, Ni and As have previously been associated (Heidam *et al.*, 2004; Maenhaut *et al.*, 1989). Also, combustion has previously been associated with Pb and As in the high Arctic (Heidam et al., 2004).

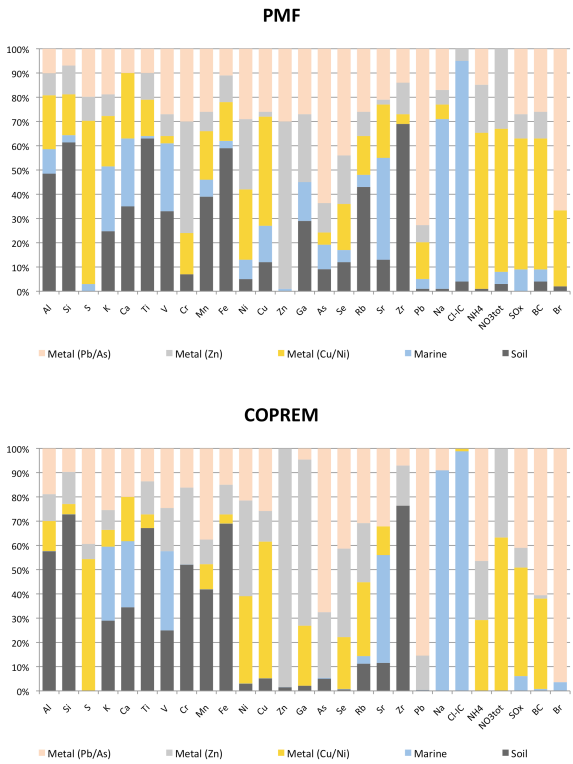

Figure 1. Comparison of PMF and COPREM

Se was present in all anthropogenic factors (21-41%), which suggests, that coal is important as energy carrier for the corresponding anthropogenic activities. With respect to climate issues, as much as 80-98 % of BC was apportioned to *Metal (As/Pb)* and *Metal (Cu/Ni)*.

This work was supported by the Arctic Monitoring and Assessment Programme (AMAP) and Short-Lived Climate Forcers (SLCF) granted by the Danish EPA.

Structural properties of mineral dust from vehicle resuspension

E. Coz[1], C. Barrios[1], C. Martín[1], A. Domínguez[1], and B. Artíñano[1]

[1]Department of Environment. CIEMAT, Madrid, 28040, Spain
Keywords: road dust, resuspension, morphology, CCSEM
Presenting author email: esther.coz@ciemat.es

Recent studies suggest that resuspension of road dust might represent a major source of particle matter (PM) in urban Spanish environments (Amato et al., 2011) A combined effect of PM accumulation in roads due to the absence of rainfall during long periods with extremely high vehicle densities in large cities are pointed out as the main cause (Amato et al., 2009). Quantifying this type of emissions and differentiating their properties from remote desert transports is a key to solve the natural/anthropogenic dust fluxes debate relating climate change. With this regard, direct comparisons of the different morphological properties of particles with similar mineralogy from the different sources might be determinant on the novel radiative transfer and cloud condensation nuclei models that include particle shape (Otto et al., 2011; Kurmar et al., 2011).

The aim of the study was to quantify the structural properties of the particles emitted by the disk brakes of road vehicles in absence of traffic (to isolate the emission). Previous urban campaigns in Madrid and Barcelona pointed out the presence of Fe-oxides from disk brake abrasion with a unique nanostructure forming aggregates of 20-30 nm monomers that highly differs from natural occurring ones (Coz et al., 2011). This might be associated to the high temperatures during abrasion. This fact is of special importance for health since the peak of maximum deposition in the alveolar region of human respiratory system is between 10-30 nm (Oberdörster et al., 2005).

Particle load density in the substrate (load density after here), size, shape and elemental chemical composition of 0.2-15 μm sized individual particles from vehicle resuspension in a test circuit were analyzed by Computer-Controlled Scanning Electron Microscopy coupled to Energy Dispersive X-ray Spectroscopy (CCSEM/EDS) (Coz et al., 2009). The samples were collected in a closed circuit inside the research centre (CIEMAT) of 5 minutes duration in the absence of traffic. Three passive samplers were strategically located and three types of samples were taken during the experiment: up and down sides of the fender ("up-fender" and "down-fender" sample notation) and next to the wheel tire ("wheel" sample) of an Audi A2 as testing vehicle. Direct samples from the break disk ("break" sample) and road deposited dust ("road dust" sample) were collected for comparison. Particles were classified in six main clusters based on their elemental ratios: Si-rich, Ca-rich, Ca/Si-rich, Fe-rich, other Metal-rich, and Miscellaneous particles.

As expected, the down-fender sample recovered most of the road resuspension with the highest efficiency (load density of $8.1 \cdot 10^4$ Np·cm-2, Np – particle number). Particles from down-fender and road dust samples are statistically equal in all the studied properties. Less than 5% (by number) of the particles can be associated to break abrasion. The dominating clusters is Ca-rich, mostly occurring as carbonates, followed by the Si-rich and Ca/Si-rich clusters, mostly comprised of quartz, phyllosilicates and feldspars. The up-fender sample presents 50/50 contribution from break/tyre abrasion and soil resuspension, and half load density than the down-fender sample. In the case of the wheel sample, the estimated ratio break abrasion to soil resuspension is of 80/20. Primary organic particles from the tyre were rare in sizes smaller than 10 μm. 5% of the particles in the sample were identified as a characteristic Si-rich subgroup from the tire. Fe-oxides comprise nearly 80% of the total particle number. Fe-oxides in the wheel sample presented higher contents of Mg, and Ca-Cr-Mn-Cu were fingerprints in the particles. P-S-Cl and Ti-Mn-Ba are typically associated to the Fe-oxides in the brake sample.

Fe-oxides are generally at smaller sizes than the rest of the mineral particles. They are mostly concentrated in sizes smaller than 2 μm. The PM2.5 from both wheel and tyre abrasion seem to be formed of the hypothesized aggregation of nanometer sized oxides. Quantification of these unique structural properties as well the associated AR (aspect ratio) values of the different clusters and sources will be discussed during the presentation.

CCSEM analyses were performed at RJLee Group, Inc. This study has been supported by the Spanish National Research Plan (CGL2011-27020) and AEROCLIMA project (Fundación Ramón Areces).

Thermo-chemical properties of fleet ship emitted aerosols: relation to composition and structure

H. Bladt[1], J. Schmid[1], E. Kireeva[2], O. B. Popovicheva[2], J. Moldanová[3], N. P. Ivleva[1] and R. Niessner[1]

Transport-emitted aerosols are known to significantly impact air quality, the atmospheric radiative and chemical balance, cloud formation and human health. Especially emission by shipping is of major concern as it contributes to 0.4 -1.4 % to the total black carbon burden and an increment in the total particle number concentration of up to 25 % overseas (Lauer et al., 2007). In contrary to urban traffic, marine traffic is not subject to stringent emission control. In order to evaluate particulate emission from shipping, design appropriate exhaust particle filters and set limitations in consequence, a detailed characterization of the aerosol particle oxidation reactivity in relation to its chemical and structural properties is required.

For this purpose, the exhaust of 9 different seagoing transport ships was investigated in the frameworks of the QUANTIFY EU project in the Odessa port, Black Sea in 2008/2009 (Popovicheva et al., 2010) and the TRANSPHORM project on the Baltic Sea in 2010. The samples were analyzed by ICP-MS, Raman Microspectroscopy (RM), Infrared spectroscopy (IR) and Temperature-Programmed Oxidation (TPO). The water-soluble fraction was investigated by Ion Chromatography and Atomic Absorption Spectroscopy.

The quantification of specific elements and ions and the analysis of the particle surface chemistry revealed great variability in composition and structure between different ship emission samples. Concerning heavy metals, Fe is the most dominant element and accounts for up to 5.0 % (m/m) of the total particulate emission of a ferry (2 200 000 t) shipping across the Black Sea and fueled with light fuel oil in summer and gas oil in winter. In contrary, only traces of V, Ni and Pb were quantified (<1.3 % (m/m)). Ions of the alkaline metals, i.e. Na^+ and K^+, in the water extract were found to amount for less than 0.5 % (m/m). However, the earth alkaline metal ion Ca^{2+} was found in concentrations of up to 6.5 % (m/m). IR spectra of some ship particles demonstrate the presence of $CaSO_4$. Anions in the water extract are most dominantly SO_4^{2-} (up to 15 % (m/m)). Cl^-, NO_3^- and PO_4^{3-} are below 0.4 % (m/m).

Raman analysis of ~140 individual particles of each ship PM deposit revealed the presence of diverse inorganic salts and oxides. Specifically α-Fe_2O_3 and $CaSO_4$ were found in up to 20 and 12 % of all particles, respectively (Fig. 1). These species can be derived from engine corrosion or contaminations and additives in fuel or lubricating oil. Fe and Ca are known catalysts for soot oxidation (Bladt et al., 2012, Castoldi et al., 2009).

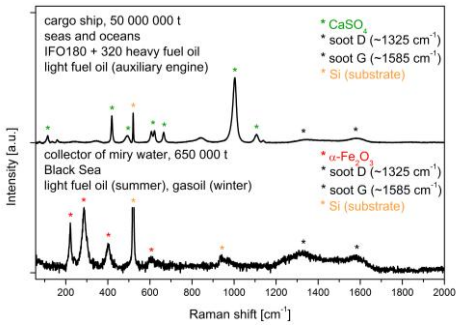

Fig. 1. Raman spectra of particles of different ship exhaust samples.

TPO shows the oxidation reactivity of emitted carbonaceous aerosols which depends on its microstructure as well as on the catalytic effect of present inorganic contaminations. The TPO profiles of the analyzed ship emitted particles show high diversity. The temperature of maximum CO and CO_2 emission T_{max} is a criterion for soot oxidation reactivity. It strongly depends on impurities and varies in a broad range from 343°C for very reactive particles to 630°C for rather unreactive particles. Furthermore, the emission profiles show from one up to three emission maxima (see Fig. 2).

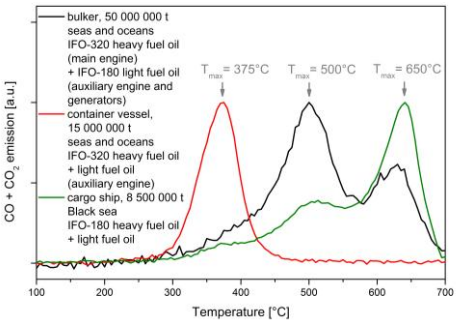

Fig. 2. TPO profiles of different ship exhaust samples.

This study reveals the relation of composition and structure of multicomponent fleet ship particulate emission to its thermo-chemical properties.

Detailed chemical characterization of ultrafine particles from vehicle exhaust

F. Donaz[1], L. Polo[1], C. Piot[1,2], J. Cozic[1], B. Golly[2], N. Marchand[3], J.L. Besombes[2] and J.L. Jaffrezo[1]

Keywords: Ultrafine particles chemistry, organic speciation, urban kerbside, France.
Contact email: jaffrezo@lgge.obs.ujf-grenoble.fr

The knowledge of the PM10 and PM2.5 chemical composition is now quite large, while just a few studies exist about that of ultrafine particles (UF-PM ; PM < 150 nm). However, because of its size, this PM fraction could be involved in regional and global climate changes, and also affect the human health. Further, their chemical composition can be largely different from that of larger particle and could significantly change their impacts for these two topics.

Few studies present the global composition of UF-PM. It is known that a major proportion is generally made of organic matter and others important components are EC, sulphate and ammonium (Kudo et al., 2011). Very few authors have studied the speciation of organic matter, but Di Filippo et al. (2010) showed higher percentage of PAHs, methyl-PAHs and nitro-PAHs in UF-PM than in PM_{10} and $PM_{2.5}$.

In this study, the chemical composition of UF-PM was investigated during 15 days in September 2011 in the course of the MOCOPO (http://mocopo.ifsttar.fr/) and PM-Drive programs, conducted along a highway in an urban environment (Grenoble-Echirolles, France). UF-PM were collected daily with a high volume cascade impactor BGI© (2008 BGI Incorporated, Waltham, USA). In order to compare with the chemical composition of larger PM, PM10 were also simultaneously collected at this site and at a nearby urban background site (Grenoble-Les Frênes, France) with high-volume samplers (Digitel DA80) in both cases. All of these samples were analysed for major ions, EC-OC, trace metals, and organic speciation with GC-MS analysis.

Significant differences in the global chemical composition of PM10 between samples from kerbside and urban background can be observed (Fig. 1). Vehicular emissions increase the contribution of elemental carbon whereas the major ions and organic matter (OM) concentrations decrease. The results obtained for the UF-PM fraction indicate that this feature is accentuated for this PM fraction, with a higher proportion of elemental carbon and a smaller proportion of ions and OM than in PM10. Further, with an average concentration of 2 µg.m^{-3}, the UF-PM fraction comprises one third of the total EC.

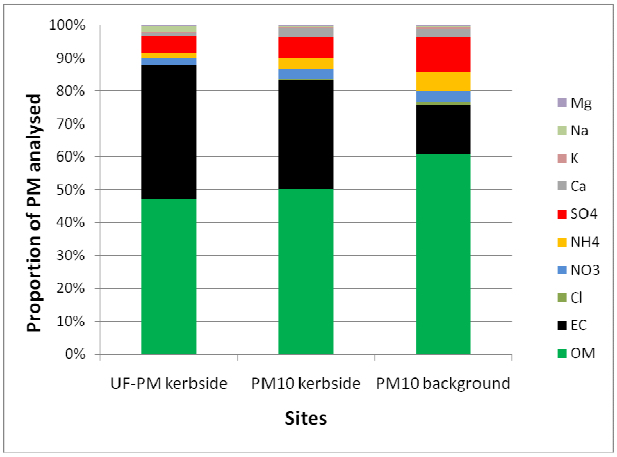

Figure 1. Comparison of the global chemical composition of UF-PM and PM_{10} at an urban kerbside site and PM_{10} at an urban background site. Results are the average of 12 daily samples.

The detailed chemical composition of PM measured at these three sites will be discussed in the presentation, focusing, on the trace metals and organic markers. UF-PM chemical composition from kerbside environment will also be compared with those obtain in urban sites highly impacted by biomass burning and during episodes influenced by photochemistry.

This work was supported by the Université Grenoble-1 Pole SMINGUE with a grant for the equipment. JL Jaffrezo would also like to acknowledge the general support of CNRS-INSU and that of ADEME for the PM Drive program.

Keywords: scavenging, wet removal, field measurements, atmospheric pollution, tritiated water(HTO)
Presenting author email: balashov.yu@gmail.com

The results of the field experiments of HTO washout with rainfall in the vicinity of the HT and HTO emission source are presented. The objective of the current study was to obtain the direct experimental data on the impact of raindrops characteristics (rate and spectrum of the drops) on HTO washout from the atmosphere.

The site of the scavenging experiments was around a 30 m emission source. The experimental site was a relatively flat one (the maximal height variations within the site were - ±5 m) covered with single buildings and individual trees whose height was from 10 to 30 m. The sampling arcs were chosen at 150 m from the base of the source to minimize dry deposition on the precipitation collectors (Fig.1).

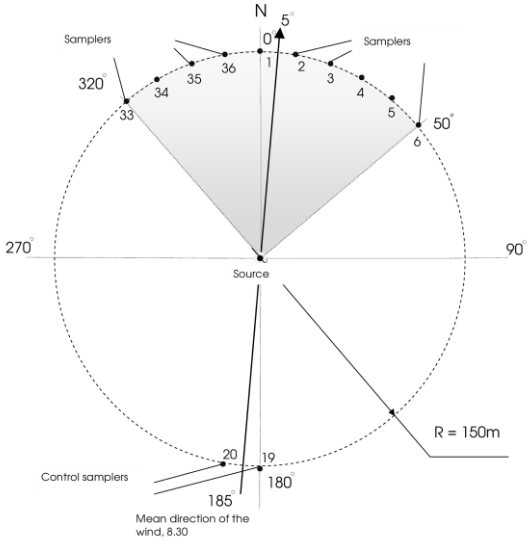

Figure 1. Experimental setup.

To study dependence of scavenging of tritium on raindrops characteristics, a laser optical device was constructed and used to measure the distribution of the drop radius and velocities during the period of experiment (Fig.2) (Hauser et al, 1984).

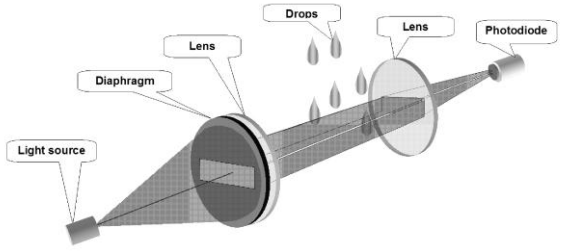

Figure. 2. The optical layout of the device to measure rain drops' parameters.

The following parameters were measured in every experiment: temperature and air humidity; HT and HTO activity in a stack gases; rain event parameters, including rain intensity, raindrop's size and falling down velocity (Fig.3); HTO activity in rainwater samples, activity of volatile tritiated organics in water samples.

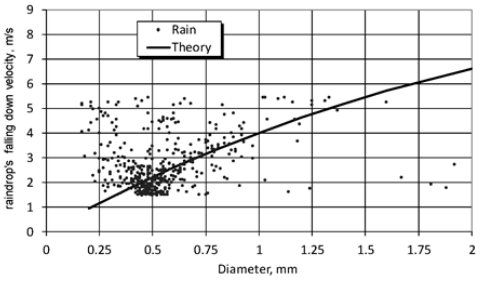

Figure. 3. Drops' sedimentation velocity vs. their diameter *V(D).*

Processing of the results of field experiments allowed evaluating the HTO wash-out factor with rain precipitation (Table 1).. The results are applied in (Piskunov, 2011) for the development and validation of various models of washout.

Table 1. Experimental values of the wash-out factor.

Long-range transport of radionuclides released from Fukushima accident into the Iberian Peninsula

M.A. Hernández-Ceballos, R.L.Lozano*, E.G. San Miguel and J.P. Bolívar

[1]Department of Applied Physic, University of Huelva, Huelva, 21171, Spain
Keywords: Fukushima, Iberian Peninsula, air masses, radionuclides.
*Presenting author email: rafa.lozano@dfa.uhu.es

Massive amount of artificial radionuclides were released from the nuclear reactors located at Fukushima, northeast of Japan between 12th and 16th March 2011 following the earthquake and tsunami occurred on 11th March. The total atmospheric releases of ^{134}Cs and ^{137}Cs during this period were estimated to be around 15.6 and 13 PBq, respectively. The analysis of the 8 days air mass forward movements at 1000 m during 12th -16th March showed an eastward displacement of the plume from Fukushima (Figure 1), bifurcated in two branches outside of Japan during 12th-16th March: northern and southern branches, being in agreement with the simulation of the potential dispersion of the radioactive cloud after the nuclear accident of Fukushima.

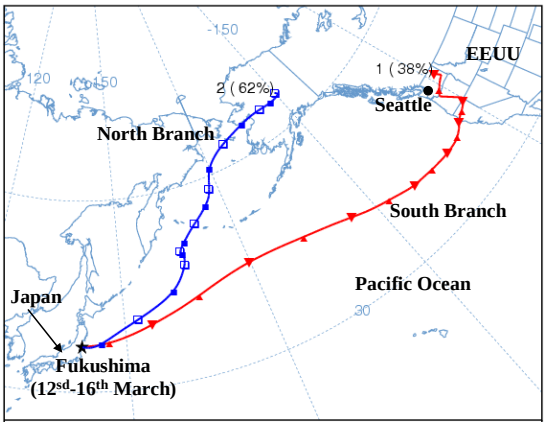

Figure 1. The two main air mass branches (centroids) from Fukushima Daiichi nuclear power plant from 12th to 16th March. Each centroid has a temporal coverage of 192 hours (8 days) and initial height of 1000 m.

The south branch air mass was displaced toward the western North America, located more than 7000 km, and arrived the western part of the North America on March 16 (Díaz-León et al 2011). Taking this fact into account, the analysis of backward trajectories over south-western Iberian Peninsula justified the connection of this south branch with the higher activity concentrations of several man-made radionuclides (such as 131I, 132I, 132Te, 134Cs and 137Cs) registered in Huelva city on 27th-28th March (Lozano et al 2011).

Trying to minimize the uncertainty calculation associated to each trajectory, the backward air mass analysis was carried out in two steps. In a first step, 8 days hourly backward trajectories at 1000 m were calculated at Huelva city from 27th-28th March, and secondly, taking the city of Washington DC as reference point of the east coast of North America, from 19th- 20th March. After that, the daily average path (centroid) was calculated for each day, representing the 8 day backward dynamic pattern over both sites, and, thus, joining both studies it was possible to analyze the dynamic of air mass over Huelva city with a temporal coverage of 16 days.

The results obtained (Figure 2) confirmed the relationship between the Fukushima release and the higher concentrations measured in Huelva 27th-28th March, defining an air mass movement throughout the Pacific Ocean–North America–Atlantic Ocean until finally reaching the South-western Iberian Peninsula. In addition, these results indicated the limited influence of the north branch in south Europe, which was responsible of the activity concentrations observed in central-north Europe (Masson et al 2011).

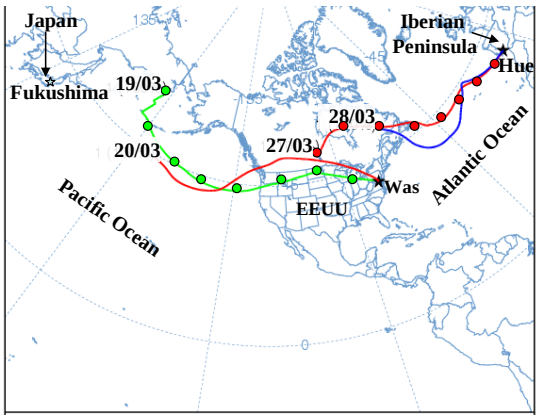

Figure 2. Horizontal displacement of the 8 days backward trajectories over Washington DC (Was) during 19th-20th March and Huelva (Hue) during 27th-28th March 2011 at a final height of 1000 m.

Atmospheric radioactivity in the High Arctic following the Fukushima nuclear accident

J. Paatero[1], J. Vira[1], J. Hatakka[1], K. Holmén[2], A.-P. Hyvärinen[1] and Y. Viisanen[1]

[1]Finnish Meteorological Institute, P.O.Box 503, FI-00101 Helsinki, Finland

Presenting author email: antti-pekka.hyvarinen@fmi.fi

A huge earthquake with a magnitude of 9.0 occurred east of the Honshu Island, Japan (38.32°N, 142.379°E) on 11 March 2011 05:46 UTC. The earthquake and especially the resulting tsunami destroyed the nuclear power plant of Fukushima Dai-ichi. This caused releases of radioactivity to both the atmosphere and the ocean (International Atomic Energy Agency, 2011).

In this work we analysed the aerosol samples collected at Mt. Zeppelin Global Atmosphere Watch (GAW) station (78°58´ N, 11°53´ E), Svalbard to determine the Fukushima-related radionuclides in them. The exposed filters and the field blanks are measured for total beta activity with an automatic alpha/beta analyzer (Mattsson et al., 1996). The gamma emitter content of the filters is assayed with semiconductor gamma spectrometry.

Dispersion of the radioactive release was simulated with the SILAM model (Sofiev et al., 2006). The source term was based on the values reported by the Japan Nuclear Safety Commission, with a total ^{131}I release of 150 PBq. This was assumed to consist of equal fractions in gas and particulate phase.

Particle-bound iodine-131 was first detected at Mt. Zeppelin from a sample collected between 25 March 2011 10:11 UTC and 28 March 2011 13:04 UTC (Fig. 1; Paatero et al., 2012). The highest total beta activity concentration value, 1140 μBq/m³, can in rare cases be of natural origin, i.e. caused by lead-210 (Paatero et al., 2010).

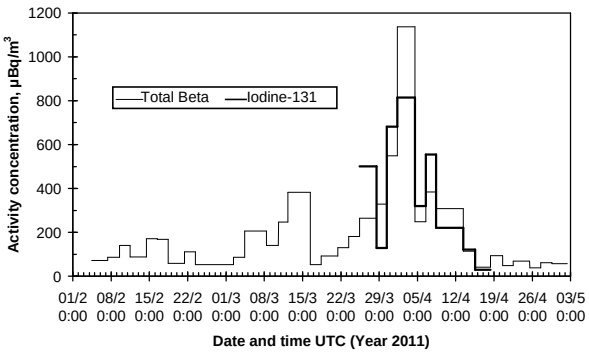

Figure 1. Activity concentrations of total beta and particle-bound ^{131}I (μBq/m3) at Mt. Zeppelin, Svalbard.

The modeled ^{131}I activity concentration at Mt. Zeppelin calculated with the SILAM model supports the time frame (Fig. 2). The calculated concentration levels are clearly lower than the measured ones. This may be related to the uncertainties in the source term. But the model predicts well the temporal behaviour of the ^{131}I activity concentration features. The maximum ^{131}I activity concentration observed at Svalbard was 810 ± 20 μBq/m3. For comparison, a leaking underground nuclear test at Novaya Zemlya, Soviet Union, caused an ^{131}I activity concentration of 5300 μBq/m^3 in northern Finland in August 1987 (Bjurman et al., 1990). It has to be emphasized that we have measured only the fraction of ^{131}I bound to aerosol particles.

The amounts of airborne fission products observed in the High Arctic are insignificant from the radiological point of view. The contribution of the Fukushima-related fission products to the airborne total beta activity is limited too. Similar variations can be found due to the fluctuations in the natural radionuclide content of the air.

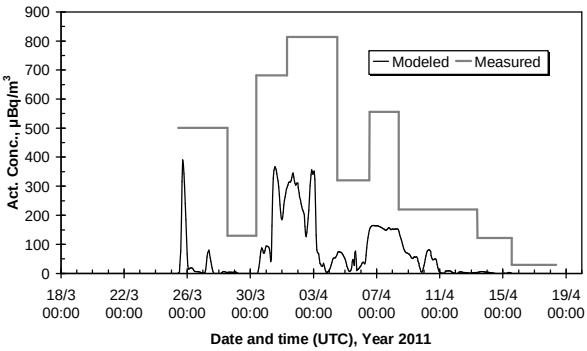

Figure 2. Observed and modeled particle-bound ^{131}I activity concentration (μBq/m^3) at Mt. Zeppelin, Svalbard. The model calculations were performed with the SILAM model.

An earthquake of magnitude 9.0 occurred on March 11, 2011 on the Pacific Ocean side of northern Honshu, Japan, followed by a tsunami that struck the east coast of the Tohoku region. A serious nuclear accident at the Fukushima Daiichi Nuclear Power Plant was caused and fission nuclides released since March 12, 2011. The contaminated air masses were transported up to Europe despite dispersion and washout along the trip (Masson et al., 2011).

Analyses of ^{131}I, ^{137}Cs and ^{134}Cs in airborne aerosols were carried out in daily samples in Milano, Italy (45°N) after the Fukushima accident during the period of March-April, 2011. The two maxima found in radionuclide concentrations (April 3, 2011 and April 7, 2011) were related to complicated long-range air mass transport from Japan across the Pacific to Central Europe. HYSPLIT backward trajectories and meteorological data were applied for interpretation of activity variations of measured radionuclides observed at the site of investigation.

The maximum ^{131}I activity concentration observed in Milano (467 μBq m^{-3}) was almost similar with the highest value (497 μBq m^{-3}) observed in Thessaloniki, Greece, 40°N, (Manolopoulou et al, 2011) and the highest observed value (490μBq m^{-3}) in Athens Greece, 37°, (Kritidis et al., 2012) but lower than that observed (810 μBq m^{-3}) in Svalbard, 78°, (Paatero et al., 2012) and in Lithuania, 54°, (3700 μBq m^{-3}, Lujaniene, 2012). The maximum ^{137}Cs activity concentration at Milano was 63 μBq m^{-3}, while in Thessaloniki, Greece was 145 μBq m^{-3} and in Svalbard was 675 μBq m^{-3}.

The ^{134}Cs/^{137}Cs activity ratio was about 1, related to the burn-up history of the damaged nuclear fuel of the damaged nuclear reactor. The presence of more than one peak of ^{131}I and $^{137,\ 134}$Cs indicates that the radionuclides were continuously transferred from Fukushima, Japan to Europe till the end of April, 2011. The large ^{131}I/^{137}Cs ratio, observed during the first days after the accident, as high as 18, followed by lower values during the next days, as low as 3, reflects not only the initial release ratio but also the different volatility, attachment and removal of the two isotopes during transportation due to their different physicochemical properties.

The NOAA HYSPLIT model (Draxler and Rolph, 2011) was used to assess the transport pattern and to explain the deviation in radionuclide activity concentrations found in Milano, Italy. Thirteen days (312) back-trajectories were calculated for 500, 3000 and 5000m arrival height and for 12 UTC time. The trajectories are labeled every 24 h by a filled symbol. The vertical projection of the trajectories with time is shown in the panel below the map. An example of transported air mass at 07 of April 2011 at Milano is presented in Fig. 1. The results showed a direct transfer from Fukushima across the Pacific Ocean, a transport through the North Pole and a pathway through the Greenland and Iceland at height of 500m to Milano. The air masses at higher altitudes were rapidly transported, while the air masses at 500m exhibited rather slow transport.

This work gives the extent of contamination in Northern Italy due to Fukushima fallout and interprets any measured activity at the site of investigation as these resulted from a complicated air mass transport, arrival time and height, meteorology and downward transport.

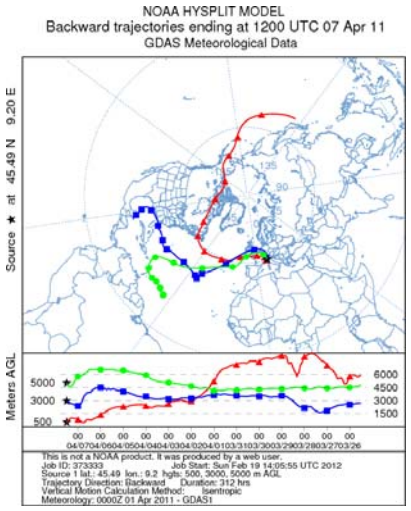

Figure 1. Thirteen-day back trajectories, arrival to Milano 7 April 2011, at heights 500, 3000 5000 m.

Keywords: activation, cloud, aerosol modelling, regional scale, volcanic ash.
Presenting author email: heike.vogel@kit.edu

After resting for 187 years the volcano Eyjafjallajökull, Island, woke up again at March 20th, 2010. Starting at April 14th massive emissions of volcanic ash occurred and finally lead to a shutdown of civil aviation over entire Europe. The emissions went on with variable strength until May 23rd, 2010. The volcanic eruption offers a unique field experiment for investigating atmospheric processes as transport, radiation and cloud formation on a large variety of scales applying both observations and numerical models.

We used the comprehensive online coupled model system COSMO-ART (Vogel *et al.*, 2009) to simulate the dispersion of the ash plume. COSMO-ART is the extension of the operational weather forecast model COSMO (Baldauf *et al.*, 2011) of the Deutscher Wetterdienst (German Weather Service). Six individual size distributions of the ash particles were simulated starting from 1 µm up to 30 µm. Deposition, sedimentation, and below cloud scavenging were taken into account. For the source heights we used data that were published by the volcanic ash advisory centre London (VAAC). During specific periods not only ash particles were emitted but also SO_2. Simulations taken into account these gas phase emissions additionally to all the other anthropogenic and natural emissions of gases and particles show the impact on the various aerosol concentrations. E.g. at the beginning of May 2008 due to strong northerly winds nucleation over the Iberian Peninsula is simulated leading to rather high number concentrations in that area (Fig.1).

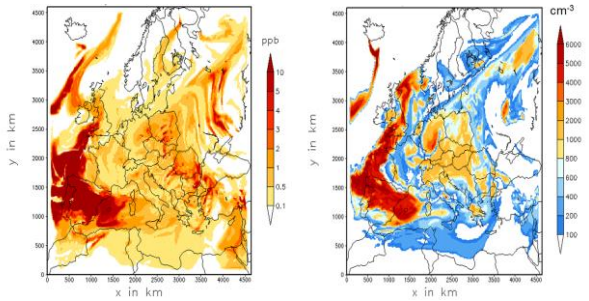

Figure 1. Simulated SO2 concentration (left) and number concentration of the Aitken mode particles (right) at 3 km height on 06/05/2010 at 23 CET.

For the investigation of the impact of the various aerosol particles on the cloud microphysics and therefore on cloud properties COSMO-ART was coupled with the two-moment cloud microphysics scheme of Seifert and Beheng (2006) by using comprehensive parameterisations for aerosol activation (Barahona *et al.*, 2010) and ice nucleation (Barahona and Nenes, 2009). The activation of the ash particles is based on FHH adsorption activation theory (Kumar *et al.*, 2009) and measurements of the activation behaviour of ash samples of the Eyjafjallajökull. Simulations were performed taking into account the anthropogenic and natural emissions of gases and particles to investigate the impact of the ash particles on cloud formation. Figure 2 shows a joint histogram of the difference of occurrence of grid points with a specific ice crystal number concentration at April 18th 2008. The ash particles cause an increase in ice crystal number concentration in the temperature range between 250 and 265 K. The implication on the microphysical cloud properties will be presented.

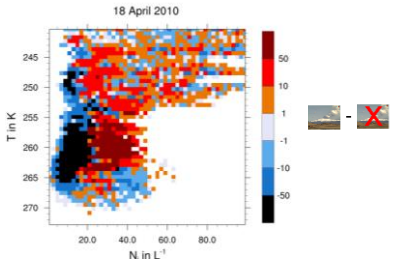

Figure 2. Joint histogram of the difference of occurrence of ice crystal number concentration.

Aerosol particle measurement is widely applied for example in clean rooms of production facilities and in studying particulate emissions from traffic and industry. In these applications, measurements of particle number concentration is of particular interest because it is limited by standards and/or legislation. In these fields, the commonly applied instruments are optical and condensation particle counters (OPC/CPC). Calibration of OPCs/CPCs is, however, challenging for at least two reasons. Firstly, no internationally coherent number concentration standard (NCS) exists for this purpose. Secondly, no single standard can cover the whole measuring particle size range of these instruments, which extends to several orders of magnitude.

In our recent study, a comparison between three number concentration standards was conducted by calibrating the same CPC unit (Model 3772, TSI Inc.) with each standard (Yli-Ojanperä et al., 2012). The standards were: the primary NCS of the National Institute of Advanced Industrial Science and Technology (AIST, Japan), the Single Charged Aerosol Reference (SCAR, Finland) and the Inkjet Aerosol Generator (IAG) of AIST (Sakurai and Ehara, 2011; Yli-Ojanperä et al., 2010; Iida et al., 2010). All of the measurements were carried out at AIST in the same laboratory.

The first two standards are measurement instrument-type standards, in which the reference number concentration is measured with a Faraday cup aerosol electrometer simultaneously with the CPC concentration measurement. These standards use different approach for producing singly charged calibration aerosol. The third standard, the IAG, is a generator-type standard, in which the particle number concentration and the particle size at the inlet of the CPC can be derived directly from the operation parameters of the generator. The particle size ranges in the CPC calibration performed in this study were between 10 and 300 nm for the primary NCS of AIST, between 12 nm and 1 µm for the SCAR and between 200 nm and 10 µm for the IAG.

Regarding the comparison, the SCAR and two other standards had sufficient overlaps in the size axis. Comparisons were made in terms of the CPC detection efficiency which was the ratio of the concentration reported by the CPC to the concentration by a standard. The results obtained with the three standards were found to agree at all overlapping particle sizes within the uncertainty limits, which was for each standard ~ 0.01 – 0.02 in the expanded uncertainty with k = 2. From the metrological perspective, the agreement of the results is an important step towards internationally coherent number concentration standards.

As a result of this study, a traceable calibration from 10 nm to 10 µm, which covered the whole operating particle size range of the CPC, was carried out for the first time (Yli-Ojanperä et al., 2012). The calibration results are presented in Fig. 1. The results indicate that the detection efficiency was constant at the plateau efficiency of ~ 0.95 approximately from 30 nm to 3 µm.

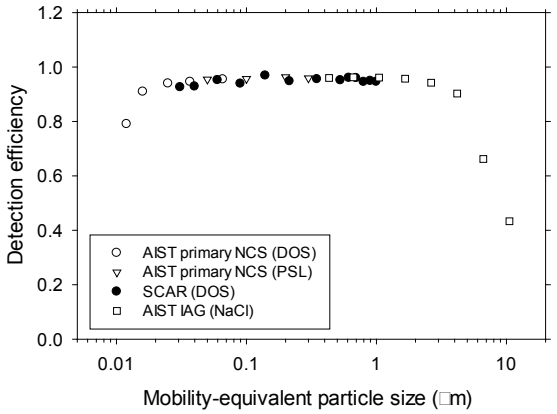

Figure 1. Calibration results obtained with the three standards for the same CPC unit (TSI Model 3772).

Large-scale modelling of polycyclic aromatic hydrocarbons and polychlorinated dibenzodioxins in open fire aerosols: On the contribution of biomass burning to POPs in air in Africa

G. Lammel [1,2], A. Heil [3] and I. Stemmler [1]

[1]Max Planck Institute for Chemistry, Mainz, Germany
[2]Masaryk University, Research Centre for Toxic Compounds in the Environment, Brno, Czech Republic
[3]Helmholtz Research Centre Jülich, Institute for Energy & Climate Research, Jülich, Germany
Keywords: persistent organic pollutants, aerosol model, biomass burning, gas-particle partitioning
E-mail contact: g.lammel@mpic.de

Biomass burning is a source for persistent organic pollutants (POPs), i.e. polychlorinated dibenzodioxins and -furanes (PCDD/Fs) and polycyclic aromatic hydrocarbons (PAHs) and may trigger secondary emissions of other POPs stored in soil.

Transport, transformation (OH and O_3 reactions in the gas-phase) and surface exchange are simulated using the global multicompartment chemistry-transport model MPI-MCTM (Semeena et al., 2006; Lammel et al., 2009) which includes the dynamic aerosol sub-model HAM. The atmospheric sub-model was nudged to ECMWF re-analysis data. Emissions were based on recommended (PCDDs; UNEP, 2005) and selected (PAHs) emission factors and daily real-time fire data (fire radiative power measured from MODIS; Heil et al., 2010). Gas-particle partitioning is determined by absorption in OM (PCDDs) or absorption and adsorption to BC (PAHs; Lohmann and Lammel, 2004). Reactions on particles were neglected in lack of data.

Continental half-year (Jan-June 2008) mean near-ground atmospheric concentrations are 0.0076, 0.52 and 3.32 fg m^{-3} of 2,3,7,8-TCDD, 1,2,3,4,6,7,8-HpCDD and OCDD, respectively, and 0.82, 0.48, 0.25 and 0.022 ng m^{-3} of phenanthrene, fluoranthene, pyrene and benzo(a)pyrene, respectively. Maxima are in the range 10-100 fg m^{-3} for HpCDD and OCDD, one order of magnitude lower for TCDD. High concentrations of PCDD and PAH are predicted in the free troposphere, stretching far into the Gulf of Guinea (Fig. 1). Based on comparison with observations (passive air sampling at 14 sites; Klánová et al., 2009) it is concluded that large open fires in Africa in 2008 have determined the observed PAH levels in the respective region, contributed up to ≈30% of observed PCDD levels, and accounted for typically 1-10% of the continental background of these POPs.

Exceedances of observed PAH levels indicate overestimated emission factors. The incomplete knowledge of chemical kinetics of gaseous and particle-associated PAHs is severely limiting source attribution and understanding of transport and fate (Lammel et al., 2009; Dvorská et al., 2011). Validation of passive sampling techniques by side-by-side sampling with active samplers needs to be extended to high temperatures, particularly for semivolatile species.

Gas-particle partitioning and air-sea exchange of polycyclic aromatic hydrocarbons and polychlorinated biphenyls in the central and eastern Mediterranean

Marie D. Mulder[1], Jana Klánová[1], Petr Kukučka[1], Jan Kuta[1], Gerhard Lammel[1,2], Roman Prokeš[1]

[1]Masaryk University, Research Centre for Toxic Compounds in the Environment, Brno, Czech Republic
[2]Max Planck Institute for Chemistry, Mainz, Germany
E-mail contact: mulder@recetox.muni.cz

The marine atmospheric environment is a receptor for polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) which are advected from combustion sources on land (power plants, biomass burning, road transport). Marine PAH sources may be significant near transport routes (ship exhaust). A number of PAHs and PCBs are semivolatile (saturation vapour pressures at 298 K in the range 10^{-6}-10^{-2} Pa) and, hence partition between the phases of the atmospheric aerosol, influenced by temperature, particulate phase chemical composition and particle size. Semivolatile substances may be subject to re-volatilisation from the sea surface. Net-deposition seems to prevail for PAHs wherever determined (e.g. Tsapakis et al., 2006).

Samples were collected along a cruise of RV Urania in the central and eastern Mediterranean, 27 August – 11 September 2010. The gaseous and particulate phases were addressed separately by sorption to polyurethane foam placed downstream a total high-volume filter or cascade impactor, respectively (e.g. Lammel et al., 2010). Analysis was by GC-MS (Holoubek et al., 2007).

The total concentration of 27 3-6 ring PAHs (24 were positively determined) was by average 1.8 ng m^{-3} and varied between 0.3 to 6.3 ng m^{-3} (Figure 1), with ≈10% in the particulate phase, i.e. particles <0.25 µm of aerodynamic diameter. The concentration of the sum of 7 indicator PCBs (PCB28, PCB52, PCB101, PCB118, PCB153, PCB138 and PCB180) was 3.5 (2.0-7.7) pg m^{-3} (Figure 1), with 0.5% in the particulate phase. For abundance aerosol loading and air mass trajectory were apparently less influential than mixing (diel variation of the marine boundary layer). Models to explain gas-particle partitioning models, such as K_{oa} (Finizio et al., 1997) and combined absorption and adsorption (Lohmann and Lammel, 2004) were tested. For chrysene (particle-associated mass fraction $\theta = 0.35$) the latter model predictions are in agreement with observations (given large input data uncertainties, i.e. unknown organic and black carbon concentrations), while the K_{oa} model underestimates for half of the samples, the latter one a small overestimation. For the PCBs in most of the samples, the K_{oa} model underestimates θ, even more so considering a possible sampling artifact (underestimated particulate mass fraction; Mandalakis and Stephanou, 2002).

The fugacity analysis suggests net volitalisation of retene from the sea surface for most of the samples, while for fluoranthene and pyrene a few samples suggest volatilisation, but most fugacity ratios were within the range of uncertainty.

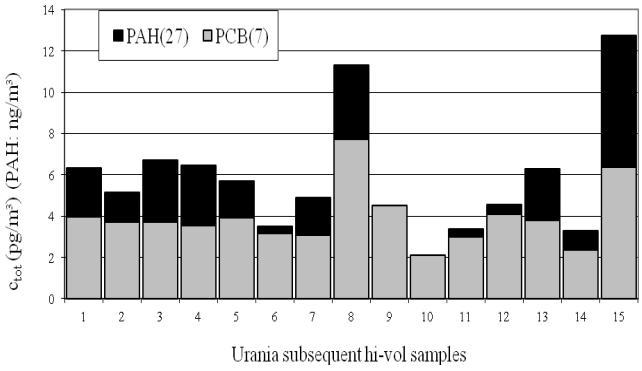

Figure 1. RV Urania high-volume samples total concentration (gas +particle) of 7 PCBs (pg/m^3) and 27 PAHs (ng/m^3), 27 August – 11 September 2010.

Biothreat and distant detection of bioaerosol

P.Grzybowski and T.Ciach

Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warsaw 00-645, Poland

Keywords: Bioaerosol, Biaerosol detectionfirst.
Presenting author email: grzybows@ichip.pw.edu.pl

Introduction

Bioterrorism is a potential thread nowadays. It is considered by terroristic groups and it is rather a matter of time when it happens. The spreading of knowledge and experience in biotechnology and accessibility of pathogen cultures increase the risk of terror acts with the use of pathogenic factors. The “natural” SARS epidemic in 2003 demonstrated how weak could be social services struggling with the quickly increasing number of infected individuals. The possibility of the rise of a global pandemic was also being taken into consideration then. It is necessary to work out testing techniques save for the personnel operating in a contaminated area.

Mobile sampling and detecting platform

In the case of bioattack suspicion or biological contamination of the area it is necessary to:

- confirm the contamination
- identify the genus of the pathogen applied
- determine the contaminated zone

A new concept of a wireless controlled mobile platform capable to fill the above outlined expectations is the subject of our study. The platform itself is based onto the IBIS robot (Fig.1). It is electrically driven vehicle operating in the range of 1000 m form the controlling unit. The robot itself plays the role of the carrier of the

Fig.1. Wireless robot IBIS from Industrial Institute for Automation and Measurements (PIAP), Warsaw.

analytical equipment, collects the samples of the air together with the samples of water and the soil, prepares the samples and provide them to the analytical units. It also drives the environment samples to the controlling station where they are additionally analyzed.

The measurements techniques applied

The main function of the mobile platform is the detection of the biothread. To fill this task the vehicle is equipped with the UV light detector operating based on effect of fluorescence of the biomaterial and helps the operator to lead the vehicle toward the most contaminated area where the bioaerosol concentration is increased. Being at the place the IBIS robot takes the samples of the environment and pack them tightly and safely for further analysis. At the same time IBIS prepares the sample of the bioaerosol and sample of the soil, transfers them into a liquid form as a water suspensions and deliver to the next apparatus where follows the analysis based on the surface plasmon resonance phenomenon (SPR). In this step a quick detection of selected types of pathogens is performed. In the case when the SPR test gives a positive result a radio signal is emitted to the control station.

During the whole mission the permanent control of the chemical and radiological threads is conducted thanks to the third detecting device mounted on the vehicle.

Samples of the environment return to the controlling station together with the robot and are additionally analysed with classical polymerase chain reaction (PCR) methods.

Results

A new concept of practical distant detection of biological contamination or bioterror attacks was achieved. The movable setup is able to undertake the mission in various day time and at various weather conditions. The procedures applied are safe for the person and effective in detection and identification steps.

Isoprene, a five-carbon diene, is a major contributor to non-methane hydrocarbon emissions in the atmosphere, where it is rapidly oxidised by the hydroxyl (OH) radical. Photooxidation of isoprene leads to volatile gas-phase products but also to secondary organic aerosol (SOA) products such as the 2-methyltetrols (2-MTs). These SOA tracers are known to be second-generation oxidation products but their formation mechanism is uncertain and an outstanding puzzle in atmospheric aerosol chemistry (Claeys et al., 2004, 2010; Surratt et al., 2006; Kleindienst et al., 2009; Paulot et al., 2009). Evidence is available for the formation of isomeric C_5-alkene diols, i.e., 1,2-dihydroxy-2-methyl-3-butene (DMB-1) and 1,2-dihydroxy-3-methyl-3-butene (DMB-2) in both laboratory-generated isoprene SOA and ambient denuder samples (Ruppert and Becker, 2000; Kleindienst et al., 2009). Here, we demonstrate that C_5-alkene diols play a role as intermediates in the formation of the 2-methyltetrols.

DMB-1 was prepared from 2-methyl-2-vinyl-oxirane as reported by Ruppert and Becker (2000), whereas DMB-2 was synthesised from 3,4-epoxy-tetrahydrofuran as described by Hodgson et al. (2001). Isoprene and the C_5-alkene diols were oxidised by OH generated through the photolysis of hydrogen peroxide (H_2O_2) in a Teflon bag. Known amounts of isoprene, DMB-1 or DMB-2 and H_2O_2 were introduced into the chamber before ultraviolet lights were switched on. For experiments with isoprene volatile gas-phase products (i.e., methacrolein, methylvinylketone and methylfuran) and unreacted isoprene were quantified off-line with thermal desorption – gas chromatography/mass spectrometry (TD-GC/MS). Isoprene SOA products were collected on Teflon filters and measured using GC/MS with prior trimethylsilylation (TMS-ation).

Figure 1 shows GC/MS data for isoprene SOA products, analysed directly and after leaving the TMS-ated reaction mixture for two days at room temperature. Upon direct analysis, it can be seen that in addition to the 2-MTs there are two abundant products (labelled with *) with retention times between those of the 2-MTs and 2-methylglyceric acid. These products are assigned to thermal degradation products of C_5-trihydroxyhydro-peroxides, which are unstable and are almost completely converted to the 2-MTs after two days at room temperature. The same products are also formed by photooxidation of DMB-1, whereas isomeric unstable products are formed from DMB-2. Close examination of the GC/MS data obtained for isoprene SOA reveals that the latter DMB-2-related unstable products are also present but at lower relative abundances than the DMB-1-related unstable products.

In conclusion, our results demonstrate that the isomeric C_5-alkene diols DMB-1 and DMB-2 can serve as gas-phase precursors for the 2-methyltetrols through unstable products, tentatively identified as intermediary C_5-trihydroxyhydroperoxides.

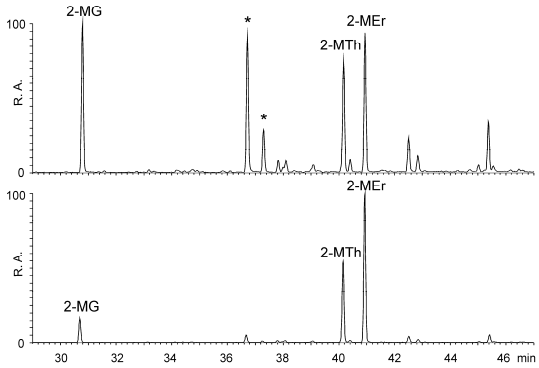

Figure 1. GC/MS data (*m/z* 219 extracted ion chromatograms) for isoprene SOA: TMS-ated extract analysed directly (top panel) and after two days at room temperature (bottom panel). The products labelled with * correspond to thermal degradation products of unstable intermediates that result in the 2-methyltetrols. Abbreviations: 2-MG, 2-methylglyceric acid; 2-MTh, 2-methylthreitol; 2-MEr, 2-methylerythritol; R.A., relative abundance.

Purpose

To develop a non-invasive method to monitor small airways

Background

Aerosol particles are generated in the human airways and leave the respiratory tract by exhaled breath. We have recently developed a non-invasive method to count and sample endogenously formed particles in exhaled air (PEx) by use of a cascade impactor. The method can provide important information on ongoing changes in the composition of respiratory tract lining fluid (RTLF) and be valuable for monitoring of ongoing pathological processes in the respiratory system.

Method

A special breathing maneuver is applied during the sampling procedure involving airway closure and re-opening. After inhalation of particle-free air, the subject exhales into the device. Particle concentration in exhaled air is measured with an optical particle counter (Grimm) and the surplus of exhaled air is drawn through a cascade impactor. Concentrations of particles (0.3-2.0 μm) are recorded by means of an optical particle counter. In a separate experiment a scanning mobility particle sizer was used to also measure particles in 0.01-0.43 μm range. The biochemical analyses of the samples are made by MALDI TOF MS (lipids), LC-MS (proteins) and ELISA.

Results

The number and size distribution of endogenous exhaled particles varies between tidal breathing and breathing with airway closure. The majority of exhaled particles are distributed as a broad maximum between 0.2-0.5 μm following re-opening of the airways while number of particles <0.05 μm does not increase with a breathing maneuver that promotes airway closure. The mechanisms of formation of these smaller endogenous particles in exhaled air are still unclear. Number of exhaled particles varies between individuals, but in average 100 L of exhaled air generates 150 ng particles, of which around 25% are proteins and the rest phospholipids. We have characterized the protein composition of PEx and identified 124 proteins. The protein amylase could not be detected, indicating the absence of saliva contamination with this sampling technique.

Conclusions

Our non-invasive method for sampling of exhaled endogenous particles from the respiratory tract represents a new approach for monitoring biochemical processes in the small airways.

Field-Performance of a new time-resolved sampler for the collection of dry aerosol particles

A. Eiguren-Fernandez[1], G.S. Lewis[1], S.R. Spielman[1] and S.V. Hering[1]
[1]Aerosol Dynamics Inc., 935 Grayson St., Berkeley, CA
Keywords: time-resolved PM sampler, anions, PAHs.
Presenting author email: arantza@aerosol.us

A versatile and compact sampling system has been developed to collect sequential time-resolved, dry aerosol particles down to 5 nm in diameter. Using the same technology as in the water-based condensation particle counters this system collects and deposits dry samples of ambient fine and ultrafine particles in small spots (300 um) (Figure 1). The size of the deposition area allows reducing collection times by increasing the concentration of particles in the 50-100ul volume of solvent used to extract the chemicals of interest.

Figure 1. Collection plate and sample spots

The sample collection plates have been designed to easily couple with commercially available autosamplers, reducing the extent of matrix and/or sample manipulation related artifacts, and automating the chemical analysis.

Laboratory testing was conducted at ADI (Berkeley, California, USA) and field performance was assessed by deploying the new system at Stockton, an inland area located in Northern California, and at San Gorgonio National Forest. $PM_{2.5}$ samples we collected for 1 hour for anion analysis (IC-ECD), and 12 hrs for polycyclic aromatic hydrocarbon (HPLC-FL). Parallel filter samples were collected for 48 hrs and used for comparison. System reproducibility and results comparison with a real-time EchoChem (PAS2000) were also evaluated.

Results

Experiments conducted in the laboratory with generated and ambient aerosols show particle collection efficiencies >95% down to 6nm.

System reproducibility was 4% and 5% for sulfate and nitrate measurements, respectively, and ambient concentration measured in the collected samples were comparable to the levels found on filters.

Anion concentrations varied significantly from day to day, with nitrate being the major component (Figure 2).

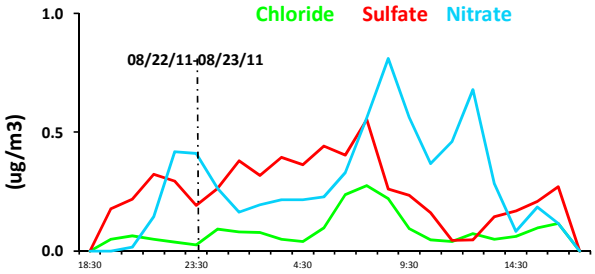

Figure 2. Hourly ambient concentrations of anions

Total PAH concentrations measured with the new collection system vary between 80-110% of those found on 48-hr filter collections. For individual PAHs, better agreement was observed for compounds mostly found in the particle-phase.

With a 12-hr time-resolution afforded by our sampler, we observed a clear day/night pattern in the ambient PAH concentrations. In general night time concentrations were higher than daytime values (figure 3).

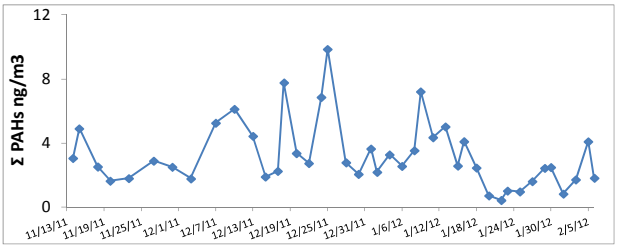

Figure 3. Temporal variability of particle-PAHs

An increase in ambient PAH concentrations was observed during the Christmas Holidays, when contributions from fireplaces added up to the common emission sources.

Diurnal and temporal variations are important when determining contribution of emission sources to ambient pollutants as well as assessing human exposure.

The temporal variability of total PAH concentrations observed with our collection system tracked the diurnal pattern measured simultaneously by an EcoChem PAS2000 sampler. This similarity with another widely used near-real system supports the validity of the new collector.

High Resolution Ion Mobility Spectrometer (HRIMS): a new instrument for aerosol nucleation studies

E. Montoya, S. López-Vidal, P. Dohányosová, E. Ramiro
RAMEM, SA. Madrid, Spain
emontoya@ioner.eu, www.ioner.eu

High flow, high resolution DMAs able to classify particles, clusters and even ions in the sub-5nm size range have received considerable attention in the last ten years as prefilters for MS and nanoDMAs and even as alternatives to Ion Mobility Spectrometers. Some prototypes have been developed in the lab but to our knowledge no commercial, compact, robust, and user friendly instrument is available yet. We will present the IONER® HRIMS, a bench-top, planar-parallel DMA-based mobility spectrometer. This instrument includes ionization, classification with high resolution (RP 40-80) DMA and electrical detection with high sensitivity. Species such as free ions, VOCs, clusters and particles in the sub-3nm size range can be mobility-classified and detected. Moreover, this instrument allows for a high versatility by changing different measuring conditions such as sheath and sample flowrates and temperatures, ion source (UV, radioactive, corona, electrospray, DBD). Applications of this instrument range from gas-to-particle conversion studies, ion aging, ions source characterization, but also more applied ones such as chemical trace detection thanks to multivariate analysis algorithms.

Figure 1: IONER® HRIMS instrument

As a way to test the instrument, a solution of tetraheptylammonium bromide (THAB) was electrosprayed (IONER® ES-3020) and the inlet slit of the DMA of HRIMS and introduced with a flow of air. The corresponding mobility spectra of THAB are shown in Figure 2. The spectra were measured at different values of the sheath gas in order to optimize the resolving power (RP). The result is shown in Figure 3 for the monomer ion THA^+. As it can be seen, the maximum RP obtained is around 45 at 160 l/min.

As an application example, standards of vapours of toluene were generated in a closed chamber. Concentration was calibrated by GC-MS. Figure 4 shows the mobility spectra of toluene.

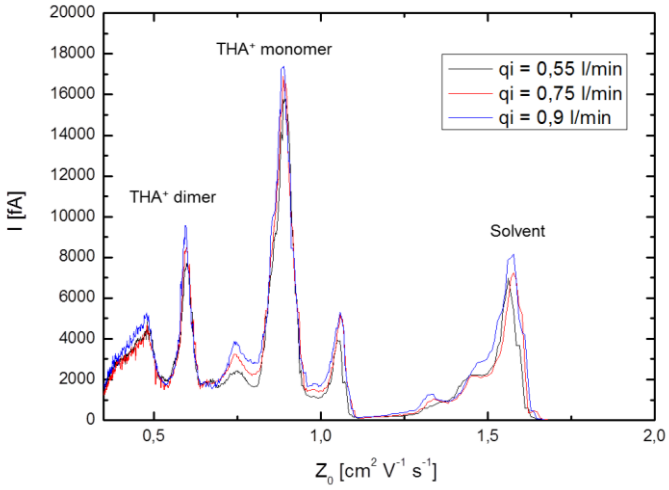

Figure 2: THAB mobility spectrum

Elemental carbon, (EC), is directly emitted into the atmosphere during incomplete combustion of forest fires, fossils fuels and biomass burning. EC particles strongly absorb solar radiation, heat the atmosphere and contribute to the global warming (e.g., Seinfeld, 2008; Jacobson, 2001, 2002; Crutzen and Andreae, 1990). The bulk of EC particles are associated with $PM_{2.5}$ and are transported over long distances. When EC is deposited onto snow surfaces, it may initiate melting. Unlike CO_2, the radiative forcing, RF, estimates of EC aerosols are highly uncertain because EC measurements are spatially and temporally sparse. The pre-industrial atmospheric EC, $[EC]_{atm}$, data will provide a valuable baseline for comparison with the industrial period and help to establish the background $[EC]_{atm}$. Currently long-term trends of $[EC]_{atm}$ are estimated based on fuel consumption inventories using emission factors (i.e., how much BC is emitted per g or kg of fuel burnt). These estimates have large uncertainties, which in turn induce large uncertainties in calculating its RF estimates.

EC is removed from the atmosphere mainly by precipitation and deposited in lake sediment. Husain *et al* (2008) showed that in an undisturbed lake $[EC]_{sed}$, is related to $[EC]_{atm}$, through the equation

$$[EC]_{sed} = K*[EC]_{atm} \quad (1)$$

where K is the deposition rate. If K is known $[EC]_{sed}$ can be used to calculate past $[EC]_{atm}$. We determined annual $[EC]_{atm}$ from monthly composites of daily samples collected from 1978 to 2007 at Whiteface Mountain, NY.

We also collected lake sediments cores from two remote high altitude lakes, West Pine Pond, (WP), and Deer Pond, (DP), near Whiteface Mountain. The sediment cores were sliced, freeze dried, and ages determined using ^{210}Pb dating. EC was chemically separated (Husain *et al*, 2008) in individual samples, and quantified by the thermal-optical method. The $[EC]_{atm}$ and $[EC]_{sed}$ for the 1978- 2007 was used in equation (1) to determine K, which in turn was used to calculate back $[EC]_{atm}$ from the lake sediments. The comparison of EC flux in WP and DP between ~1700 and 2005 agreed well; however after ~1950 the EC flux in DP showed low values compared with WP. The mean pre-industrial EC flux in WP for the period ~1700-1850 was 0.05±0.02 $gm^{-2}yr^{-1}$, in excellent agreement with 0.07±0.02 $gm^{-2}yr^{-1}$ from DP for ~1000-1850 periods. Also the pre-industrial EC flux from WP and DP was in excellent agreement with that obtained by Elmquist *et al* (2007), 0.07±50% $gm^{-2}yr^{-1}$ from ~11^{th} century to ~1850. This is a very important conclusion, where two sites almost ~6400 km apart gave the same pre-industrial EC flux. The mean $[EC]_{atm}$ estimated from WP for the period ~1700-1850 was found to be 62±22 ng m^{-3}, in excellent agreement with the value of 68±19 ng m^{-3} found from DP for the ~1000-1850 period. From the results of $[EC]_{atm}$ estimated from WP and DP, it could be concluded that the pre-industrial $[EC]_{atm}$ was stable around 65±29 ng m^{-3}.

Over the last decade, Mn and MnO_x nanoparticles has been extensively investigated due to their great importance in catalysis, electrochemistry, ion exchange materials, batteries and other areas (Si *et al.*, 2005; Han *et al.*, 2006). This work describes preliminary experiments producing manganese nanoparticles by metal organic chemical vapor deposition (MOCVD) using manganese(II) acetylacetonate (MnAA) as a precursor.

Particles were synthesized in an externally heated tube flow reactor with i. d. 25 mm and the length of heated zone 1 m. Experiments were performed in an inert atmosphere using nitrogen as a carrier gas (pyrolysis) as well as in oxidizing atmosphere at 2 and 10 vol. % of oxygen in the reaction mixture (oxidation). Particle production and their characteristics were studied in dependence on reactor temperature (T_R), precursor vapor pressure (P_{MnAA}), oxygen concentration (c_O), and reactor flow rate (Q_R). P_{MnAA} was controlled by the variation of the saturator temperature (T_S). The particle production was monitored by scanning mobility particle sizer (SMPS, TSI model 3936) and samples for particle characterization were deposited onto TEM grids using nanometer aerosol sampler (NAS, TSI model 3089) and on Sterlitech Ag filters. Particle characteristics were studied by HRTEM, SAED, EDS, XRD and XPS.

The SMPS monitoring showed that the particle production depends in particular on precursor concentration and also on the chemistry of precursor decomposition. Number concentration and mean particle size increase with increasing P_{MnAA} and more and larger particles/clusters are generated by pyrolysis than by oxidation. Number concentration also slightly increases with T_R and Q_R, while mean particle size decreases.

Particles produced by pyrolysis were typically agglomerated into clusters with primary particle size between 5 and 10 nm, and with clusters size increasing with increasing P_{MnAA}. Mixture of spherical and facetted particles was formed by oxidation. Size of spherical particles varied between 10 and 30 nm, facetted particles were larger, 20 – 50 nm. Both spherical and facetted particles were partially agglomerated, see Figure 1. Portion of facetted particles increases with increasing T_R and c_O.

Particles prepared by pyrolysis were XRD amorphous and selected area electron diffraction (SAED) patterns were rather week. HRTEM images revealed lattice fringes in the cores of particles, which were mostly indexed as cubic Mn. Particles produced by oxidation, were much more crystalline. Electron diffraction patterns consist of spots, which are difficult to index, and lattice fringes were visible through the whole size of particles. EDS analysis discovered Mn, O and C in the samples with much higher oxygen concentration in the particles prepared by oxidation. XPS analysis of the 5 nm thick surface layer of the samples showed carbon present in bonds C-C, C-H and C-O and manganese in bonds Mn-O. From the above mentioned we can suppose formation of Mn nanoparticles encapsulated in partially decomposed MnAA by pyrolysis and MnO_x nanoparticles by oxidation.

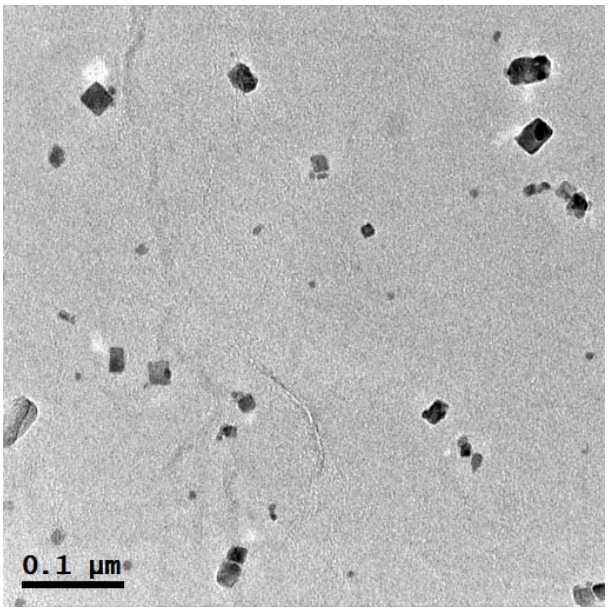

Figure 1. HRTEM image of particles prepared at T_R=800 °C, c_O=10 vol. %, P_{MnAA}=2.2 Pa, Q_R=800 cm^3/min.

This work was supported by the Grant Agency of the Czech Republic under grants 104/07/1093, P503/11/2315 and P503/12/G147. XPS analyses were performed by Dr. Josef Zemek, Institute of Physics AS CR, v.v.i. and XRD analyses by Dr. Jaroslav Maixner, Institute of Chemical technology, Prague.

Formation of secondary organic aerosol: OH initiated oxidation of dodecane in the presence of NOx

A. Gratien, M. Camredon, Y. Mohamed Yassin, B. Aumont, and J.F. Doussin

Laboratoire Interuniversitaire des Systèmes Atmosphériques, UMR-CNRS 7583, Université Paris-Est Créteil et Université Paris Diderot, Institut Pierre Simon Laplace, 94010 Créteil, France
Keywords: SOA, n-Alkanes, Atmospheric aerosols, Smog chamber, Aerosol formation, modelling
Presenting author email: aline.gratien@lisa.u-pec.fr

Secondary organic aerosols (SOA) are known to be harmful health and have an impact on the climate. Furthermore, the largest uncertainty in predicting climate change is the contribution of airborne particles, which impact climate in more complex ways.

However, the chemical transport models (CTM) fail in estimating SOA formation in the atmosphere. The main factors limiting the chemical accuracy of current and future models are limitations in our knowledge of processes involved in SOA formation and the development of parameterizations directly on the basis of experimental data.

This project aims at a better understanding of the processes involved in SOA formation in both gas and particle phase. The project aims also to build a SOA formation database by delivering parameterization that represents physical-chemical processes controlling SOA formation in CTM models.

The strategy put in place to achieve the objectives of this project is based a combination of explicit modeling with GECKO-A and smog chamber experiments with CESAM. Experiments adapted for the evaluation of models will be performed in CESAM. Comparisons at a molecular scale between GECKO-A and experiments performed in CESAM will be carried out to evaluate and ameliorate our understanding of SOA formation in the atmosphere. These comparisons will contribute to fill the lack of experimental data at the molecular scale for the evaluation of models, such as GECKO-A. GECKO-A will be updated and will then serve as a benchmark for the development of reliable SOA parameterizations for CTM.

A first step in the evaluation of models would consist in studying SOA formation from simplest structures, as alkanes (Presto et al. 2010; Chacon-Madrid and Donahue 2011; Ziemann 2011; Yee et al. 2012). The oxidations of dodecane by OH in the presence of NOx have been studied at 1 atm air in CESAM. The analytical device includes long path in-situ FTIR for the detection of gaseous secondary organic species. In addition, collecting air samples on Tenax solid adsorbent have been performed. The measurements of the SOA mass and SOA composition at the molecular level are performed by SMPS and gas chromatography – mass spectrometry, respectively. The figure 1 shows an example of experiment. Comparisons at a molecular scale between GECKO-A and experiments performed in CESAM will be presented and the atmospheric implications discussed.

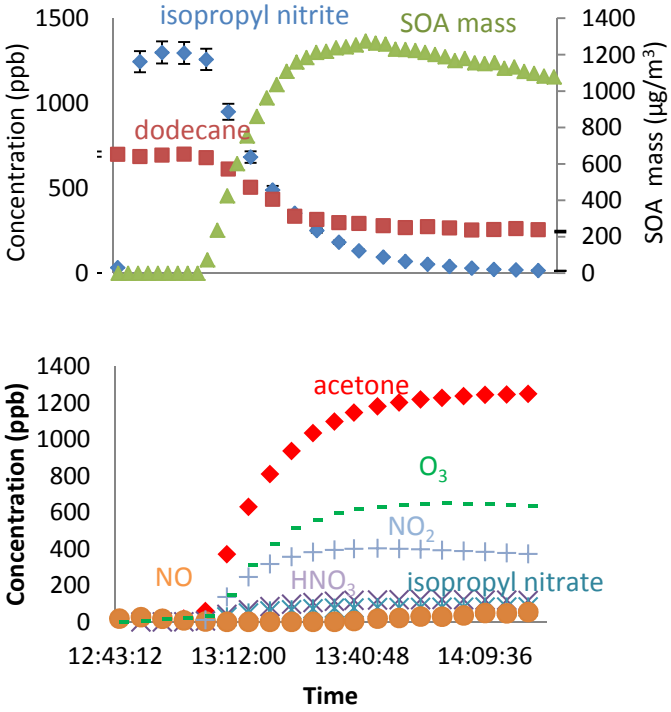

Figure 1. Time dependant concentrations and aerosol mass during an experiment of OH oxidation of dodecane

Some considerations about Langley method on the retrieval of spectral irradiance at the TOA and of the total atmospheric optical depth

M. Melgão[1], M.J. Costa[1,2] and A.M. Silva[1]

[1]Geophysical Centre of Évora, University of Évora, Évora, 7000, Portugal
[2]Department of Physics, University of Évora, Évora, 7000, Évora
Keywords: Remote Sensing, Optical Depth
Presenting author email: martamel@uevora.pt

Ground based instruments, soundings with atmospheric balloons and instruments on board of satellites are responsible for the monitoring of the atmosphere. Remote sensing is one of the techniques of measuring atmospheric quantities and it's used by several instruments. In this study we are concerned with a special instrument: spectral radiometer YES MFR-7 (MFR-7). This radiometer measures the diffuse and global spectral hemispherical irradiances. Also, the software instrument makes use of a method derived from the Beer-Bouguer-Lambert law (eq.1) – Langley method. The Langley method consists of using eq. 1 to compute the extra-terrestrial spectral irradiance at the top of the atmosphere ($I_{\lambda 0}$), providing the existence of some conditions: 1) clear sky, 2) low aerosol concentration and 3) a stable atmosphere. At the same time the total spectral optical depth (τ_λ) of the atmosphere can be obtained from the slope of the measured spectral irradiance at the surface, I_λ versus the relative air mass (effective path length), m, as shown in Fig.1.

$$I_\lambda = I_{\lambda 0}\, e^{-\tau_\lambda m} \qquad (1)$$

Optical depth retrieval via Langley regression is complicated due to cloud transits and other time varying interferences (Harrison, et al. 1994) and several conditions (presented above) limit the accuracy of the initial retrieval of the data.

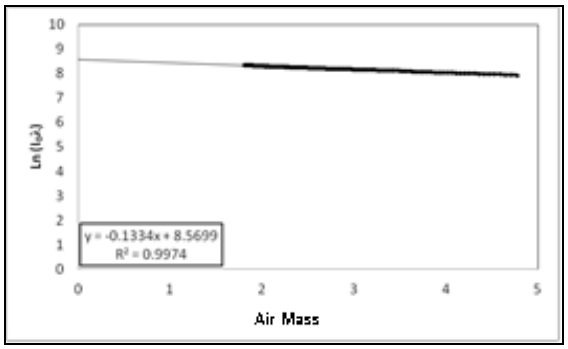

Figure 1. Example of Langley Method for the morning. Spectral channel: 415nm.

The aim of this study is to compare results of the Langley method obtained from the instrument's software with the ones calculated with our methodology (IDL software developed), which executes also a linear fitting of the data, as the one showed in fig.1. For this study we consider 6 years of data, 2003 to 2008 and 2010, although there are some missing data corresponding to periods where the instrument was disable. A particular motivation of the study is to check the reliability of the MFR-7 procedure; its associated error and several parameters associated to the method itself, for example if it's done for every available channel, in the morning or in the afternoon, when compared with the same results obtain independently.

In order to achieve those, we are analysing graphics as the one presented in fig.2, where the first results for the year 2010 can be observed, for the morning period and for channel 415nm. In this specific example, the afternoon period exists but it's very similar so it's not shown here.

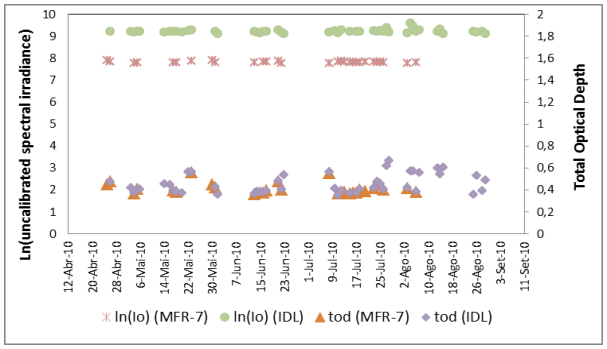

Figure 2. Time evolution series of total spectral optical depth (right axis) and the uncalibrated logarithm of the spectral irradiance derived at the top of the atmosphere (left axis), during the morning period, from the MFR-7 software and IDL software.

Figure 2 shows that $I_{\lambda 0}$ obtained with IDL software are superior to the one given by MFR-7 software and that the total spectral optical depth is similar in both cases. The differences observed probably rely on the used criteria. In the Langley method performed by IDL software, the condition imposed is that the linear correlation coefficient between $Ln(I_\lambda)$ and m (fig.1), was superior to 0.9. In the Langley method performed by the instrument software, several points are dismissed because, for example, cloud transit (could be corrected by speed up the time sampling), thus resulting in a lower number of points in the MFR-7. Considering this fact, a preliminary conclusion is that the filtering of the IDL routine is weaker than the one of the MFR-7 software, which can introduce greater error in the results. The difference between the two values of uncalibrated spectral irradiance is still open for discussion. Presently we still study those differences and which part of the MFR-7 algorithm is responsible for it.

Reduction of combustion alkali aerosols by addition of kaolin to pelletized biomass fuels

C. Boman, J. Fagerström, G. Gårdbro, E. Steinvall and D. Boström

Energy Technology and Thermal Process Chemistry, Umeå University, SE-901 87, Umeå, Sweden

Keywords: alkali, aerosols, combustion, biomass, kaolin, additive
Corresponding author e-mail: christoffer.boman@chem.umu.se

The use of new feedstocks for biomass fuels are pushing the market towards potentially more problematic raw materials with high ash content, e g forest logging residues, energy crops, cereals and industrial waste materials. Compared to stemwood fuels like sawdust, such raw materials generally contain higher concentrations of ash forming elements, where the alkali elements (K and Na), together with Cl, S and P, are of special relevance concerning the aerosol chemistry and formation of fine particles and deposits. The present focus on potential health related effects of combustion aerosols will lead to more stringent regulations of particle emission from small (residential) and medium scale (0.5-3 MW) stationary combustion sources within EU. Since these combustion units lacks advanced particle removal devices, cost effective primary measures (i.e. fuel and process related) will become more attractive to implement. Such fuel related measures (additives or co-combustion) may be used to change the ash transformation processes and the use of Al-silicates as additives during combustion of "problematic" biomass is rather extensively studied. Most common are studies of kaolin as an additive. Kaolin is a clay, mainly consisting of the mineral kaolinite, $Al_2Si_2O_5(OH)_4$. This mineral can remove gaseous alkali compounds by binding potassium and forming K-Al-silicates which have higher melting temperatures than the pure K-silicates and thereby reduce alkali release and aerosol formation [Boman *et al*., 2008; Boström *et al*., 2009; Bäfver *et al*., 2009; Tissari *et al*., 2008; Tran *et al*., 2004; Uberoi *et al*., 1990; Zeuthen *et al*., 2007]. Still, the effect on kaolin addition to different biomass fuels as well as a detailed understanding of suitable addition levels and the effects of different process parameters are still not elucidated. The objective of the present work was to determine the effect of the fuel additive sorbent kaolin on aerosol particle formation and emission during fixed bed combustion of two biomass fuels. In addition, the results will be discussed in comparison with data on alkali release from single pellet tests in a large-sample TGA set-up with same fuels and additive.

Two typical pelletized biomass fuel assortments were used; soft wood and wheat straw. Both fuels were co-pelletized with kaolin powder and the combustion experiments were performed in a typical underfed (fixed bed) residential burner (~10 kW) connected to a reference boiler. Combustion with one level of kaolin was compared to the pure fuels. The content of kaolin in soft wood was 3 wt-% and in wheat straw 7 wt-% (mixing proportions based on dry substance biomass). The kaolin levels were chosen based on earlier experience and chemical equilibrium calculations, and the levels should be enough to elucidate the reduction of alkali aerosols. The combustion performance was monitored by FTIR gas measurements (e.g. CO_2, H_2O, CO, NO/NO_2, HCl, SO_2 and CH_4) in flue gases to ensure good gas burnout and follow the effect of the fuel additive on relevant inorganic gas species. The temperature in the fuel bed (i.e. where the ash is formed) was measured by thermocouples, to better interpret relevant ash transformations on the grate. The aerosol particles were sampled in the flue gases at a temperature of ~150 °C and characterized regarding PM_{tot} mass concentration (standard filter sampling), mass size distribution (low pressure impactor, 0.03-10 µm), number concentration and size distribution (SMPS, 0.01-1 µm) as well as elemental composition (SEM/EDS) and inorganic phase distribution (XRD). In addition, the bottom ash and slag was collected and characterized regarding elemental, morphological and crystalline phase composition. This enables a more complete evaluation of the influence of the kaolin additive on the total ash transformation process.

Preliminary results indicate a clear reduction of alkali aerosol emissions by kaolin addition for both biomass fuels. Further detailed results on the effects on aerosol particle mass and number concentrations as well as ash transformation and aerosol chemistry will be presented from the combustion tests in the pellet burner and discussed in relation to data from single-pellet tests.

Morphology-Controllable of Porous Hyaluronic Acid Prepared using A Spray-drying Method

Asep Bayu Dani Nandiyanto, Takashi Ogi, and Kikuo Okuyama

Department of Chemical Engineering, Graduate School of Engineering, Hiroshima University, 1-4-1 Kagamiyama, Higashi Hiroshima 739-8527, Japan
Keywords: porous material, aerosol technique, spray route, drug delivery.
Presenting author email: asepbayudn@gmail.com

Recently, production of both powder and solution formulations of pharmaceuticals, especially for inhalation application, has received considerable interest. However, although current methods for this drug fabrication has been well-known, there are significant difficulties: particle size distribution, insufficient process control, high cost, complexity of the process, loss of chemical activity, and problems associated with scaling-up the process (Iskandar, 2009). With this reason, production of specific particle that sufficient for this purpose, and certainly, using an effective method are required.

Based on our experience in the synthesis of porous particles (Iskandar et al,, 2009, Nandiyanto et al, 2009, Nandiyanto et al, 2012), here, we reported the new design porous material, consisted multi-pore types with a good arrangement, was prepared via aerosol route. As a model of drug, we used hyaluronic acid (HA). In the synthesis procedure, HA powder (Kewpie Corp., Japan) was used to prepare aqueous solutions (mass concentration: 0.005-0.5 wt%). Polystyrene particle (PS, JSR, Japan; size = 100, 200, and 300 nm) was added to the aqueous HA, forming the suspension that was then used in spray drying. The mass ratio of HA to PS in the suspension was fixed at 1 to 4. The suspensions were then sprayed using a two-fluid nozzle spray dryer (SD-1000, Eyela, Tokyo Rikakikai Co. Ltd., Japan) at 120 °C (using heated compressed air as carrier gas). The solid particles were collected using a cyclone separator. To obtain porous particles, the collected composite particles were etched with an organic solvent—toluene (Sigma Aldrich, USA)—for one minute to dissolve the PS template particles. The morphology of the prepared particles was examined using a scanning electron micrograph (SEM, Hitachi, S-5000, 20 kV)

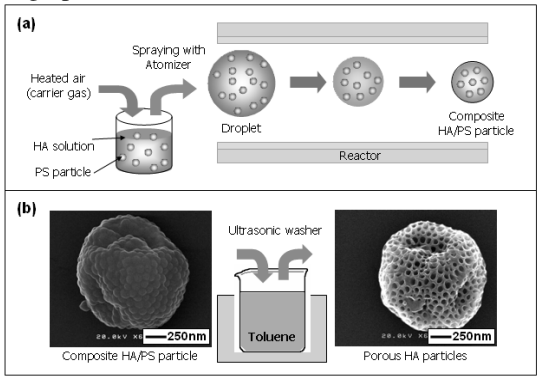

Figure 1. Schematic illustration diagram of the preparation method {(a) composite particle preparation and (b) etching process}

When the solution of HA and PS was spray dried, composite HA/PS particles were produced (Fig. 1a). In this process, heat was used to evaporate the solvent and template. To avoid the use of high temperature heating process, an advanced method that combines spray drying with template removal by dissolution was used to produce porous particles. Fig. 1b shows the morphology of the spray-dried particles before and after template removal. PS particles were arranged on the surface of the droplet, which formed as a result of spraying the solution, due to buoyancy and surface forces; HA solution filled the space. After drying, solid particles with raspberry-like arrangements were produced (Fig. 1b, left SEM figure). The effects of removal of the templating agent via etching that occurred when the primary particles were washed in toluene are shown in Fig. 1b, right SEM figure. PS particles were completely removed leaving holes, the diameters of which corresponded to those of the PS particles used in the process.

The effect of the changing parameters are shown in Fig. 2. The result showed that changing PS size led the production of particles with controllable pore size (Fig. 2a-c), while changing initial precursor resulted in the preparation of particles with controllable particle outer diameter (Fig. 2a,d,e).

Keywords: atmospheric aerosol, urban background.
Presenting author email: zdimal@icpf.cas.cz

Detailed knowledge of physical and chemical properties of atmospheric aerosol in the urban environment is becoming more important in last years as more adverse health effects of aerosol particles are known. According to the current Czech legislation, concentrations of selected gaseous pollutants and of $PM_{2.5}$ and PM_{10} aerosol fractions are monitored at selected sites. However, this monitoring gives only limited information on properties of measured aerosol, especially concerning the related health effects.

In order to improve this knowledge, a Prague Aerosol Supersite, Suchdol (PASS), has been completed during last years. Various instruments (see Table 1) have been added to the site during several EU and local projects. Recently, the instrumentation covers both physical and chemical properties of sampled atmospheric aerosol in a complex way.

The supersite is hosted by the Institute of Chemical Process Fundamentals (ICPF) located inside a Suchdol campus of the Academy of Sciences of the Czech Republic. This campus is placed in a suburban district of Prague, situated about 6 km NW from Prague's center and about 9 km NE from the airport on a plateau elevated 80 m above the Prague's downtown valley. There are no major sources of air pollution close to the campus except family houses (with local gas heating). The closest road with 10-15 thousands cars per day goes about 250 m eastward from the campus.

The PASS supersite includes aerosol equipment for on-line measurements and long term monitoring, as well as for short-period off-line measurement campaigns including impactor- and filter-based sampling followed by chemical analysis (IC, PIXE, RBS). Highly time-resolved elemental composition can be also measured using a 3DRUM impactor in three size fractions. Recently, the equipment has been extended by an HTDMA (ICPF home-made).

The PASS supersite is connected to the automated imission monitoring station AIM-ASUCA of the Czech Hydrometeorological Institute. The station provides basic information about meteorological conditions (temperature, wind speed and direction, relative humidity, UV intensity), concentrations of selected gaseous pollutants (NO, NO_2, NO_x, O_3, SO_2, CO), and $PM_{2.5}$ / PM_{10} concentrations.

Part of the long term data series obtained during completion of the PASS supersite were published in few papers (Schwarz et al. 2008, Putaud et al., 2010, and Řimnáčová et al., 2011). Results of few short term campaigns were published as well (Ondráček et al., 2011, Štefancová et al., 2010). These and other data files show advantages of such a site for investigations on contrasts between background and urban pollution levels, including various traffic and heating sources localized in different parts of the city.

Table 1. List of aerosol equipment at PASS.

Measured quantity	Measurement range	Instrument	Time resolution	Data available
Size distribution	10 – 470 nm now variable	SMPS 3034 (TSI) rebuilt at IfT	5 min	since 2007 since 2012
	0.52 – 10 μm	APS 3321 (TSI)	5 min	since 2007
Size distribution and chemical composition	50-800 nm	cTOF-AMS (Aerodyne)	1 min	since 2010
EC/OC	PM_{10}, $PM_{2.5}$, $PM_{1.0}$	EC/OC field analyser (Sunset)	2 hours	since 2009
Hygroscopicity	adjustable	HTDMA (ICPF)	about 1 hour	since 2012

Synthesis and Characterization of Pt/WO_3 Nanoparticles Photocatalyst Prepared by Flame Spray Pyrolysis

Takashi Ogi, Asep Bayu Dani Nandiyanto, Agus Purwanto, Kikuo Okuyama

Department of Chemical Engineering, Graduate School of Engineering, Hiroshima University, 1-4-1 Kagamiyama, Higashi Hiroshima 739-8527, Japan

Tungsten oxide (WO_3) is a visible-light-driven photocatalyst which has many potential applications: energy conversion devices, virus deactivation, and harmful pollutant degradation. Bare WO_3 shows very low photocatalytic activity under visible light irradiation. Many attempts have been made to improve the photocatalytic activity of WO_3. The addition of a co-catalyst, such as platinum (Pt), gold (Au), and silver (Ag), enhances the photodegradation activity of WO_3. Thus far, Pt has been the most powerful co-catalyst for high-activity WO_3 (Purwanto, 2011). However, the high cost of Pt is a primary impediment for a scale-up process.

Herein, in this study, the optimum condition of Pt amount was investigated for Pt/WO_3 nanocatalysts prepared by a flame spray pyrolysis (FSP) method (Widiyandari, 2012). This is a fast, continuous, and controlled aerosol process for the production of nanoparticles.

In this method, $H_2PtCl_6 \cdot 6H_2O$ was mixed with $5(NH_4)_2O \cdot 12WO_3 \cdot 5H_2O$ (ATP) in aqueous solution to produce a homogeneous precursor. A thorough mixing of the Pt and W components was expected to produce a better distribution of Pt in the Pt/ WO_3 nanocatalyst. The preparation of Pt/WO_3 was conducted with a CH_4 flow rate of 0.5 L/min, an O_2 flow rate of 1.1 L/min, and a nitrogen carrier gas flow rate of 2 L/min. The ATP concentration was 0.01 M, and the Pt content was varied from 0 to 0.5 wt.%.

Fig. 1 shows the concentration–time evolution of amaranth degradation by Pt/WO_3 at various levels of Pt content under solar simulated irradiation. The optimal level of Pt addition for high photocatalytic activity was 0.12 wt.%. This concentration was much lower compared with other methods (0.5–1 wt.%). From the XRD analysis, the spectra indicated that WO_3 was monoclinic. The characteristic peaks of Pt were not detected in the spectra due to the low fraction of Pt in the nanocatalyst.

Fig. 2(a) shows the TEM image of Pt/WO_3 (Pt = 0.12 wt.%). The prepared particles were nanorods with aspect ratios ranging from 2 to 5 (diameter 10–20 nm and length 20–50 nm). However, this image does not clearly represent the existence of Pt particles, which may have been due to the small amount of Pt. Further characterization indicated the stacking-fault in the HR-TEM images (Fig. 2(b)), which indirectly implied the existence of Pt. Pt serves as a pool for electrons which lead to the effective excited electron consumption. This results in an efficient charge separation and ensures high activity for Pt/WO_3. This investigation suggests that the optimal condition for Pt/WO_3 is reached at a Pt content of 0.12 wt.%.

Our results showed that FSP-made Pt/WO_3 nanocatalyst required a lower Pt fraction for an efficient photodegradation process compared to the well-known photodeposition method. This lower Pt fraction resulted from a stacking fault of Pt in the WO_3 matrix, as shown in Fig. 2(b). In the photodeposition technique, Pt was deposited onto the WO_3 surface. However, the reduced Pt was not all deposited onto the WO_3 surface. This implies that a higher concentration of Pt is needed for optimal photocatalytic activity. Thus, FSP offers a facile method to produce a Pt/WO_3 nanocatalyst which is a low fraction of Pt for efficient dye photodegradation.

TiO_2 Thin Film Morphologies Controlled by Aerosol Flame Deposition Process

Jinrui Ding and Kyo-Seon Kim*

Department of Chemical Engineering, Kangwon National University
Chuncheon, Kangwon-Do, 200-701, Korea
Keywords: Columnar Morphology, AFD Process, Photoelectrochemical Properties, TiO_2 Thin Films,
*E-mail: kkyoseon@kangwon.ac.kr

Nanostructured TiO_2 thin films have been extensively studied for use in solar energy applications, such as photosplitting of water and dye sensitized solar cells (Thimsen et al, 2008). The thin film morphology has been identified as an important, efficiency-limiting aspect of TiO_2 film characteristics. It is believed that TiO_2 thin films with one-dimentional morphology have potential to make a breakthrough in efficiency improvement for photoelectrochemical cell. Flame technology for material synthesis was highlighted recently by Strobel (2008) and Pratsinis (2010) to make "smart" nanoparticles for catalysts, sensors, biomaterials and so on. The Aerosol flame deposition process offers an inexpensive way to prepare nanostructured thin films from liquid precursor.

In this study, we prepared nanostructured TiO_2 thin films by aerosol flame deposition process. TiO_2 thin films with columnar morphology deposited on ITO conductive glasses were obtained. The influence of the various process parameters, such as precursor feed rate, depositon height, the total gas flow rate and substrate temperature, on morphology evolution of TiO_2 thin films were investigated, respectively. The structure properties were characterized by Scanning electron microscopy. The photoelectrochemical properties were tested by a Potentiostat (Pinceton Applied Research, Versastat 3).

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) grant funded by the Ministry of Education, Science, and Technology (No. 2009-0090428).

Ultrafine particles in the atmosphere can absorb and scatter radiation, thereby affecting the climate of the Earth at a local and a global scale (IPCC 2007). The scattering and absorption efficiency of atmospheric particles strongly depend on their ability to take up water (i.e., their hygroscopicity), which in turn is determined by their chemical composition.

In situ measurements of particle hygroscopicity and chemical composition were conducted at an urban background site in Patras from 8 to 27 June 2012. For the measurements we employed a Hygroscopic Tandem Differential Mobility Analyzer (HTDMA; Rader & McMurry, 1986) combined with a Cloud Condensation Nucleus Counter (CCNC; Roberts and Nenes 2005), and a High Resolution Aerosol Mass Spectrometer (HR-AMS; DeCarlo et. al., 2006). Dried aerosol particles having mobility diameter of 40, 60, 80, 100, and 120 nm were selected by the first DMA of the HTDMA system. Half of the monodisperse particle flow downstream of DMA-1 was conditioned at a relative humidity of 87±2%, while the other half was passed through the CCNC within which the supersaturation of the sample ranged from c.a 0.1 to 1%.. The HR-AMS measurements provided mass concentrations of ammonium, sulphate, chlorine, nitrate and organic ions. The volume fractions of common atmospheric chemical species were calculated using the ion mass measurements and the ion pairing algorithm described by Gysel et. al., (2007).

Table 1 provides a summary of the HTDMA measurements obtained over the entire period of our study. Most monodisperse-particle samples exhibited unimodal distributions following humidification, indicating that the particles are internally mixed. Almost a quarter of the samples corresponding to the smaller dry diameters selected by the first DMA (i.e., 40 and 60 nm) exhibited two modes of the growth factor distribution: one less and one more hygroscopic having growth factors of 1.07±0.03 and 1.11±0.04, respectively. As the dry mobility diameter of the particles increased the percentage of samples having bimodal distributions decreased, whereas the difference of the growth factors between the less and more hygroscopic populations increased (cf. Table 1).

Table 1: Summary of the HTDMA measurements performed at the suburban station in Patras from 8 to 27 June 2012. Key: d_{dry} is the mobility diameter selected by DMA-1; P_u and P_b are the relative frequencies of occurrence for unimodal and bimodal distributions, respectively; g_1, g_{21}, and g_{22} are the average growth factors ± one standard deviation for the measurements showing unimodal and two bimodal distributions, respectively.

d_{dry}	g_1	P_u (%)	g_{21}	g_{22}	P_b (%)
40	1.21 ±0.07	74.2	1.11 ±0.04	1.33 ±0.06	25.4
60	1.23 ±0.07	76.9	1.07 ±0.03	1.32 ±0.06	22.8
80	1.25 ±0.06	87.3	1.06 ±0.03	1.30 ±0.05	12.7
100	1.25 ±0.06	94.3	1.07 ±0.03	1.33 ±0.08	5.46
120	1.26 ±0.06	96.8	1.06 ±0.05	1.30 ±0.05	3.15

The HR-AMS showed that organic volume fractions accounted for almost half of the volume of the particles. The average fraction of ammonium sulphate volume fractions was of the order of 30%, whereas ammonium bisulphate volume fractions averaged at 12%. Considering the substantial amount of organic species present on the particles and assuming that they are hydrophobic, the particles predicted hygroscopic growth factor will be suppressed, as indicated by the HTDMA measurements.

Presenting author email : tiang-hong.gan@dsto.defence.gov.au

Introduction Diesel exhaust is classified as 'carcinogenic to humans' (Group 1) by the World Health Organisation. Characteristics defined for diesel particulate (DPM) exposure are complex, and include particle size, elemental carbon (EC), total carbon (TC) and other chemical species. In exposure regulations, EC content has been defined as 50% of TC, which is too simplistic, given the variation of EC and DPM with engine type, age, operating conditions, lubricants and fuel. Consequently EC in addition to other characteristics of DPM were investigated as chemical markers for a Euro 0, Japanese and several US built engines.

Experimental EC, DPM and particle size (0.3 μm – 20 μm), were monitored continuously in the personnel module of a Unimog truck powered by a Mercedes Benz OM 353.959 (Euro 0) engine. EC, organic carbon (OC), TC, inorganic ions and metals were also sampled using quartz and Teflon filters. Size fractionated characterisations were conducted using two Sioutas impactors under vehicle idling only. Field trials were conducted on test circuits in a rural area, free from vehicular pollution.

Results and Discussion Real time EC levels were found to correlate with DPM in the Unimog module for various vehicle operating modes, consistent with findings of filter and impactor samples. EC content of the Euro 0 engine was predominantly confined to particles < 0.25 μm size and mass averaged from 23% to 45% of TC (Fig 1), in agreement with the results of a 1986 Nissan engine (Kelly et al, 2003). A lower EC/TC is associated with incomplete oxidation of OC at lower exhaust temperatures (Ng et al, 2007).

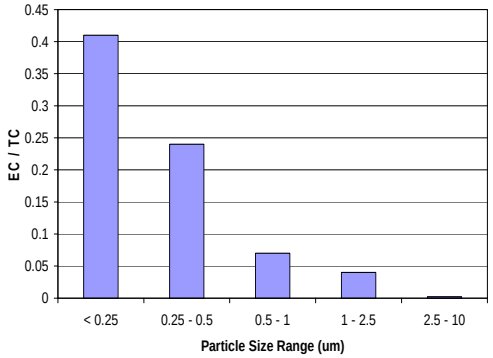

Fig. 1. EC/TC size distribution of Euro 0 diesel particulates under idling conditions.

EC/TC for the 1996 Cummins engine in a military Dodge Bobtail varied from 3% to 15% for various engine loads (Kelly et al, 2003). EC/TC for US commercial trucks fitted with Detroit, Cummins and Caterpillar engines (1996 - 2000) ranged from 3% to 83% for low and high engine loads respectively (Shah et al, 2004). Since EC is assumed as 50% TC for exposure compliance, these findings suggest DPM exposures can differ by up to an order of magnitude.

Toxicity of metals in diesel emissions are DPM size dependent especially in < 1μm and nanoparticles (Mayer et al 2010). Mass size distributions of the Euro 0 engine metals (Al, Fe, Mn and Ni) under idling conditions were found to be uniform from engine wear. By comparison unsized characterisation (Gautam et al, 2002) is less exposure informative.

Distribution of sulphate across the particle size range as the sole chemical marker of engine combustion (Kelly et al, 2003) has limited use, due to interference from other sources. In contrast, size distribution of lubricant minerals concentrated in the < 0.25 μm fraction (Fig.2) is definitive of diesel engine combustion.

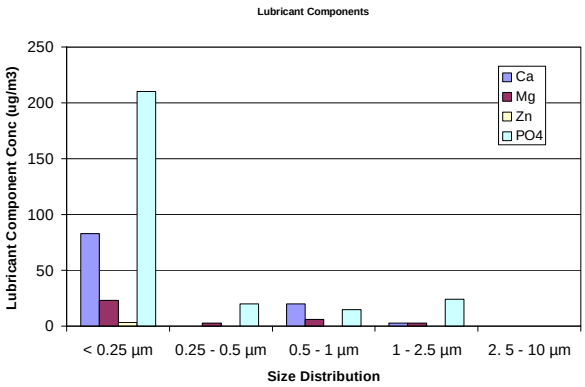

Fig. 2. Particle size distribution of Euro 0 engine lubricant minerals under idling conditions.

Conclusions Hence, in addition to elemental carbon (EC), DPM should be reintroduced as an exposure metric. For the Euro O engine localisation of DMP mass EC and lubricant minerals (<0.24 um size fraction) provides definitive evidence of diesel engine combustions.

Keywords: ultrasonic, droplet, viscosity, size distribution.
Presenting author email: sehrman@umd.edu

Ultrasonic atomization, developed for liquid atomization, plays an important role in applications including drug delivery, precursor transport and environmental improvement, with the advantages of tunable and relatively narrow droplet size distributions. In our experiment, copper nitrate/water/ethanol and copper nitrate/water/ethylene glycol precursor solutions were atomized by a 1.7 MHz ultrasonic nebulizer. The droplet size distribution and atomization rate were measured. The effects of nitrate concentration, cosolvent volume ratio and carrier gas flow rate on the droplet diameter and atomization rate were investigated. Results indicated that increasing either the concentration or the cosolvent volume ratio increased the viscosity and the droplet diameter, and at the same time decreased the atomization rate. Increasing the carrier gas flow rate increased the atomization rate, and had a limited effect on the droplet diameter.

Droplets with D50 around 5 µm were observed with a solution viscosity lower than 3 mm^2/s. Dimensionless diameter D and frequency Ω were defined as $D50/(\gamma^2\rho/\sigma)$ and $\omega/(\sigma^2/\rho^2/\gamma^3)$ separately, where ω is the ultrasonic frequency, γ is the kinematic viscosity of the solution, ρ is the solution density and σ is the solution surface tension. Linear behaviour of log(D) vs. log(Ω) indicated that droplets may be generated from periodic surface fluctuation on the wavelets formed by ultrasonic excitation of the fluid. As the viscosity became larger than 3 mm^2/s, a bimodal droplet size distribution was observed, with the first peak around 5 µm and the second one around 70 µm.

The formation process of droplets was also investigated using Shadowgraphy with a high-speed camera and laser illumination. Atomization process images of pure water and 40v% EG/water solution are shown in Figure 2-a, b. For the pure water system with low viscosity, all droplets were generated around the water cone, which was activated at the center of the generator. Droplets with diameters around 50 microns appeared to be generated by the breakup of water ligaments, while formation of the droplets with smaller sizes was likely due to the capillary waves on the solution surface. For the 40v% EG/water solution with a relatively larger viscosity, a cone at the center was activated, and droplets were mainly generated by the breakup of water ligaments with diameters around hundred microns. Investigation of the relationship between fluid viscosity and droplet formation mechanism is ongoing.

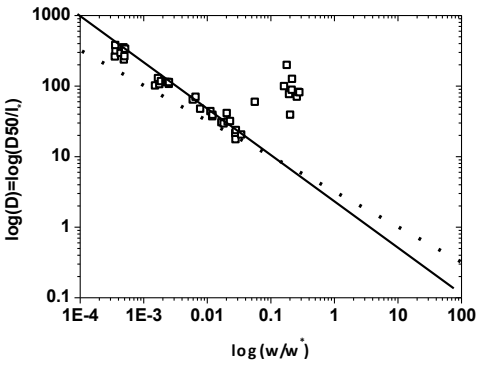

Figure 1. Correlation between dimensionless diameter and dimensionless frequency. Solid line corresponds to $D=2.79\Omega^{-0.602}$

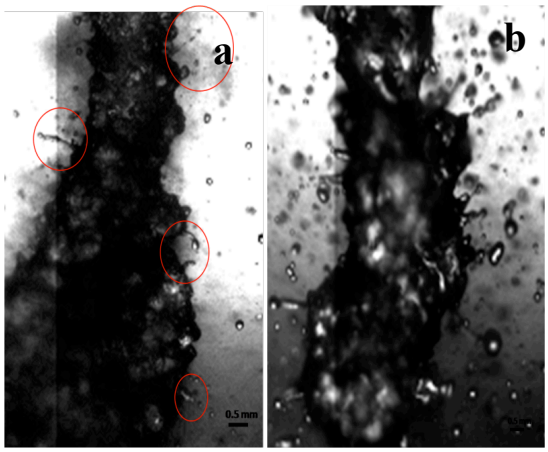

Figure 2. Images of the atomization process (a) water (b) 40v% EG water solution

Abstract: The objective of this study is to perform a spatial distribution of atmospheric pollutants concentrations in Portugal (mainland and archipelagos) in a total of 78 stations for a period 2006-2008 and to compare these results with the EU Directive. The data were measured within the Portuguese Environment Agency (APA) Air Quality Monitoring Network. The latter consists on several stations distributed in Portugal providing hourly data of the main atmospheric pollutants such as particulate matter, SO_2, NO, NO_2, CO, and O_3. Particulate matter results shows that 25% of the sampling stations exceeded the PM_{10} limit value of 40 mg/m^3 in 2006; in 2007 and 2008, the limit value was exceeded in 13% and 7% of the stations. Concentrations were higher in littoral where the main urban and industrial areas are placed in Portugal. In Lisbon PM_{10} concentrations were exceeded in 40 % of the stations in 2006 and 20% of the stations in 2007 and 2008; the stations are in the center of Lisbon near important traffic street. In 2006, except in Madeira island, Vermoim – north of mainland Portugal and Estarreja - center of mainland Portugal, all the stations presented $PM_{2.5}$ concentrations lower than 20 mg/m^3 (EU limit value). In 2007, only Vermoim and Estarreja presented concentrations higher than 20 mg/m^3. In 2008 all stations presented concentrations lower than 20 mg/m^3. In general, PM_{10} and $PM_{2.5}$ concentrations decreased from 2006 to 2008. Statistical significant tests are applied to establish differentiation between rural, urban and archipelago stations. The Portuguese data are compared with other European published data or originated by European Monitoring and Evaluation Program (EMEP). Mass trajectories as given by HYSPLIT (Hybrid Single-Particle Lagrangian Integrated Trajectory) model will be studied for days were the concentrations of the pollutants are significantly higher than the European legislation.

An update on ChArMEx (the Chemistry-Aerosol Mediterranean Experiment) activities and plans for aerosol studies in the Mediterranean region

The objective is to present an update of the Chemistry-Aerosol Mediterranean Experiment project (ChArMEx) with a focus on on-going aerosol research activities and future campaign plans.

ChArMEx is a French initiative aiming at developing and coordinating regional research actions for a scientific assessment of the present and future state of the atmospheric environment in the Mediterranean Basin, and of its impacts on the regional climate, air quality, and marine biogeochemistry. The target of ChArMEx is short-lived particulate and gaseous tropospheric trace species.

Through seven work packages, ChArMEx addresses: emissions and source apportionment; chemical ageing of air masses with a focus on the formation of secondary organic aerosols; transport processes and their effect on air quality; direct radiative forcing by aerosols and its consequences on the water budget and regional climate; atmospheric deposition of nutrients and contaminants; recent trends and variability in atmospheric composition; and the future evolution of atmospheric chemistry at the horizon of 2030 and 2050.

ChArMEx proposes a multi-scale model-satellite-field observation integrated strategy. The field observation strategy combines continuous monitoring in a network of background stations, and intensive campaigns including airborne measurements.

We briefly illustrate recent ChArMEx activities that include aerosol remote sensing climatology (Nabat *et al.*, and Chiapello *et al.*, 2012), 3-D modelling of African dust aerosol radiative impact, developing monitoring networks for aerosol chemistry (Sciare *et al.*, 2012), aerosol optical properties (AERONET), and dust deposition, performing intensive aerosol chemistry measurement campaigns at Majorca (Pey et al., 2012) and the Finokalia observatory in Crete (Nicolas *et al.*, 2012) and at our new background station at Ersa, Cape Corsica (Fig. 1) in 2011 and 2012, and other intensive field measurements during the Pre-ChArMEx/TRAQA-VESSAER campaign (11 June-13 July 2012) including (i) soundings with a new balloonborne OPC (Renard *et al.*, 2012), (ii) tentative assimilation of aerosol lidar data from ACTRIS monitoring network in southern Europe, (iii) aircraft observations over the NW Mediterranean basin with drifting balloons for tentative Lagrangian re-flight, and (iv) ultralight aircraft measurements over Corsica in conjunction with lidar profiling.

Fig. 1. The ChArMEx/CORSiCA atmospheric chemistry background station at the wind mill of Santa Catalina at Ersa, Cape Corsica (42.97°N, 9.38°E, alt. 533 m).

We finally present plans for a large field campaign in summer 2013 with aircraft and balloons in the western Mediterranean, and ideas for a cruise across the Mediterranean in May 2015. Future plans will be discussed at the 3rd ChArMEx International Workshop in early Nov. 2012 in Cargese, Corsica Isl. (registration at *http://charmex.lsce.ipsl.fr/index.php/third-intern-workshop*).

TiO_2 thin film structures prepared by controlling the particle formation and deposition in PCVD system

Hoang Hai Nguyen and Kyo-Seon Kim

Department of Chemical Engineering, Kangwon National University,
Chuncheon, Kangwon-Do, 200-701 Korea
Keywords: Plasma chemical vapor deposition, Thin film growth, Particle coating, Titanium dioxide
Presenting author email: kkyoseon@kangwon.ac.kr

The titanium dioxide (TiO_2) is one of the most focally studied photocatalysts for environmental applications due to its nontoxicity, chemical stability, low cost and active reactivity. In recent years, many studies have focused on TiO_2 thin film which can be used as gas sensors, solar energy cells, and self cleaning effects. In addition, there have been many methods to improve the activity of TiO_2 thin films such as increasing the ratio specific surface area by controlled structure and morphology of thin films.

TiO_2 films can be prepared by various methods, such as chemical vapour deposition, sputtering, ionized cluster beam, aerosol chemical vapour deposition and plasma chemical vapour deposition.

In this work, TiO_2 thin films were deposited on silicon wafer by Plasma Chemical Vapor Deposition (PCVD) system. Figure 1 shows the schematic diagram of PCVD system, which consists of the RF generator, precursor supplying system, vacuum system and plasma reaction chamber. We used titanium tetra-isopropoxide (TTIP) as the precursor of TiO_2 films, and N_2 pure gas or N_2 mixed with O_2 gas as plasma gas. The important process variables in this PCVD system are gas flow rate, precursor temperature, power and substrate temperature and we investigated the effects of these process variables on the morphologies of resulting TiO_2 thin films. Table 1 shows the ranges of experimental variables we investigated in this work. The standard bubbler temperature was 80°C, and the TTIP/ N_2 gas line was heated to prevent condensation onto the tube. The N_2/TTIP mixture was delivered into the chamber (buffer) where it was mixed with oxygen. The operation pressure was 3 Torr and substrate temperature was 150°C for all deposition experiments. The TiO_2 thin films were prepared for 20 min. The influences of initial TTIP concentration, oxygen flow rate were examined in detail.

In this study, we demonstrate that a simple, one-step PCVD system can be applied to prepare TiO_2 thin films with different controlled morphologies. The morphologies of TiO_2 were characterized by scanning electron microscopy to study the morphology, by X-ray diffraction to study the structure and SEM cross section to deduce the film thickness.

Table 1. Ranges of experimental variables to prepare TiO_2 thin film in this study.

Experimental variables	Ranges
Pressure	3 Torr
Power	20-70 W
Substrate temperature	150 °C
Precursor temperature	80 °C
O_2 flow rate	10 sccm
Carrier gas flow rate	5-50 sccm
Total gas flow rate	80-100 sccm
Distance	40 mm

Polarized Imaging Nephelometer for Field and Aircraft Measurements of Aerosol Phase Function

G. Dolgos[1,2], J.V. Martins[1,2]

[1]Joint Center for Earth Systems Technology, University of Maryland, Baltimore County, Baltimore, MD, 21250, USA
[2]Department of Physics, University of Maryland, Baltimore County, Baltimore, MD, 21250, USA

Keywords: Scattering matrix, Scattering coefficient, Optical instrumentation, In-situ measurements.
Presenting author email: gdolgos@umbc.edu

At the Laboratory for Aerosols, Clouds and Optics (LACO) at the University of Maryland, Baltimore County we have developed a new technique to directly measure the aerosol phase function and the degree of linear polarization of the scattered light. We designed and built a portable instrument called the Polarized Imaging Nephelometer (PI-Neph). The PI-Neph was successfully flown on dozens of flights as a part of the NASA Development and Evaluation of satellite ValidatiOn Tools by Experimenters (DEVOTE) project and the Deep Convective Clouds and Chemistry (DC3) project.

The LACO imaging nephelometer concept has been implemented as a portable instrument after laboratory proof of concept experiments (Dolgos et al, 2010). The aerosols that enter the PI-Neph are illuminated by laser light (wavelength of 532 nm) and scattered light is imaged by a stationary wide field of view camera in the scattering angle range of 2° to 178°. (in some cases stray light limited the range to 3° to 176°)

Figures 1 and 2 show data from the DEVOTE flight on 2011/10/17 aboard the NASA Langley B-200 aircraft. The aircraft was based at NASA Langley Research Center and flew over three AERONET stations that day.

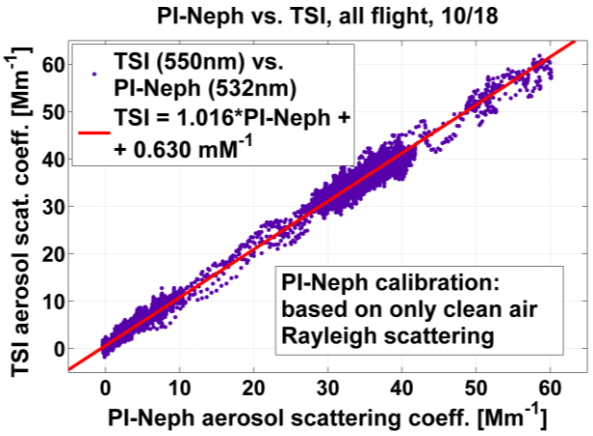

Figure 1. Scatter plot and the least squares linear fit showing the correlation between the independent measurements of the aerosol volume scattering coefficient by the PI-Neph and the TSI integrating nephelometer aboard the NASA Langley B200 aircraft.

The volume scattering coefficient is compared to parallel and independent TSI measurements and the spiral averaged phase function from the flight over NASA Wallops Flight Facility is compared to the ground based AERONET retrievals.

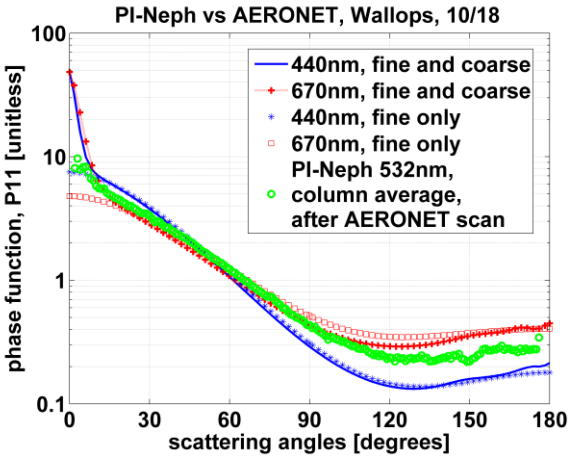

Figure 2. Comparison of the phase function measured by the PI-Neph aboard the NASA Langley King Air and retrieved from AERONET sky radiance measurements.

Results from this dataset showed good agreement between the PI-Neph measurements of volume scattering coefficient and the parallel TSI integrating nephelometer measurements, as well as between the PI-Neph measurement of phase function and the AERONET retrievals. The differences between the PI-Neph and the AERONET retrievals can be attributed to differences between the ambient size distribution and the one sampled inside the aircraft. Further analysis of the DEVOTE and DC3 flight data is underway.

At LACO our goal is to enable systematic in-situ and eventually inlet-free measurements of aerosol phase function that can be compared to AERONET and satellite retrievals to enhance the quality of our global view of aerosols from ground and space.

This work was supported by the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) mission, the NASA Langley Research Center DEVOTE project, and the DC3/SEAC4RS projects funded by NASA HQ.

Water diffusion in glassy aerosol investigated using a new Raman isotope tracer method

H.C. Price[1], B.J. Murray[1], J. Mattsson[2] and L.G. Benning[1]

[1]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK
[2]School of Physics and Astronomy, University of Leeds, Leeds, LS2 9JT, UK
Keywords: Atmospheric aerosols, glassy aerosol, diffusion, Raman spectroscopy, water soluble compounds.
Presenting author email: eehcp@leeds.ac.uk

The properties of aerosol containing water soluble organic compounds is much more poorly understood than aerosol containing inorganic solutes. Recently it has been suggested that atmospheric aerosol may be present in the form of amorphous solids and semi-solids at low relative humidity and even at room temperature (Virtanen et al., 2010). These highly viscous particles are thought to have low diffusion coefficients, leading to very long equilibration times, with profound effects on their interactions with water vapour and other chemical species (Koop et al., 2011).

Water uptake by amorphous solids on increasing humidity occurs slowly at the surface of a particle, proceeding to the interior of the particle more rapidly when this outer layer has softened the solid and increased the rate of diffusion. This plasticizing effect leads to considerable difficulty in determining the diffusion coefficient of water in a particle undergoing hygroscopic growth due to the non-linearity of the diffusion problem (Zobrist 2011, Bones 2012). A method which involves observing a tracer diffuse into a particle without a corresponding change in viscosity or size would be advantageous.

A technique has been developed whereby Raman spectroscopy can be used to give a quantitative measure of water diffusion into an ultra-viscous aqueous solution or amorphous solid droplet. A disk of solution is placed in a temperature and humidity controlled cell, with its circumference (but neither face) exposed to the surrounding gases. The droplet is allowed to come to equilibrium with the surrounding H_2O vapour, before switching to D_2O vapour of the same dewpoint. Raman spectra are taken at various radial distances as the D2O diffuses into the droplet. The ratio of the OD to OH stretch peaks gives an indication of the concentration of each isotope at any one time and position. By solving Fick's second law for diffusion into a disk, the coefficient of diffusion of heavy water can be determined over a range of water activities.

Results will be presented for raffinose solution droplets. These data show that below 30% RH, the 150 µm disk remained out of equilibrium for a period longer than 48 hours and the diffusion coefficient was determined to be $5x10^{-15}$ m^2/s. Using this diffusion coefficient a 1 µm diameter aerosol particle would have a diffusion half-life of 7 seconds at 30% RH. The implications for water retention in atmospheric organic aerosol will be discussed.

Presenting author email: monique.albert@tno.nl

Sea-spray aerosol considerably affects the climate, both directly and indirectly. The emission rate of sea-spray droplets per unit area of the sea surface is implemented in climate models through a sea-spray source function (SSSF). Recent formulations of the SSSF include a contribution of organic matter based on satellite observations of ocean colour (Gantt *et al*, 2012) Organic material substantially contributes to the composition of sub-micron sea-spray aerosols, especially in biologically active regions, where small sea-spray particles may be mainly composed of organic matter (OM) with a decreasing contribution as particle size increases (Facchini *et al*, 2008). The amount and type of organics in sea-spray aerosol have an impact on their scattering potential (Randles *et al*, 2004) and their ability to act as cloud condensation nuclei (O'Dowd *et al*, 2004; Fuentes *et al*, 2010). Starting from a first estimate of the total annual global emission of OM, we have performed a sensitivity analysis on used parameterizations and input data and found variability to a factor of 50%, which could be mainly assigned to the sea-spray source function that was chosen (Albert *et al,* 2012).

The uncertainties in current sea-spray source functions are still large (de Leeuw *et al*, 2011). Conventional sea-spray source functions are expected to be improved by including factors, complementary to wind speed, which better account for the effects of a suite of meteorological and oceanographic factors. We are currently exploring the use of global satellite-retrieved whitecap fraction, W, data (Anguelova *et al,* 2006) Figure 1 shows an example of a global W distribution for one day. An advantage of satellite data over traditional observations (photographic or video images) of W data may be a better representation of open ocean conditions across the world's oceans as opposed to local observations from ships or platforms. It should be stressed that the W data as used in our study are research products and are therefore not yet available as operational type of data used in global models. Therefore our study additionally serves to validate the satellite derived W data.

The goal of our study is to find an alternative W parameterization which can be used to replace the commonly used relationship derived by Monahan and Muircheartaigh (1980). Once we have optimized our new parameterization for global application we will validate the outcome of our sea-spray emission tool through application in the regional chemistry transport model LOTOS-EUROS (Schaap *et al.*, 2008). The outcome of LOTOS-EUROS will be compared with in situ measurements of Sodium concentrations. Preliminary results will be presented.

Plenary 3

Aerosols, clouds and climate

U. Lohmann[1]

[1] Institute for Atmospheric and Climate Science, ETH Zurich, Switzerland
Keywords: indirect aerosol effect, climate modeling, ice nucleation
Presenting author email: ulrike.lohmann@env.ethz.ch

Aerosol particles modify the radiation budget directly by scattering and absorption of solar and longwave radiation and indirectly by acting as cloud condensation nuclei and ice nuclei. The cloud albedo or Twomey effect of warm clouds refers to an increase in the cloud droplet number concentration for a constant liquid water content that increases cloud albedo.

In addition, the more and smaller cloud droplets in polluted clouds decrease the precipitation formation, presumably increasing cloud lifetime (cloud lifetime effect). Both effects partially set off greenhouse gas warming. In cirrus clouds the same shortwave effects occur as for water clouds described above, but in addition changes in the particle concentration also affect the longwave radiation.

Because clouds in mid-latitudes originate predominately via the ice phase, changes of the properties of ice nuclei maybe of crucial importance for the hydrological cycle. An increase in ice nuclei can result in a rapid glaciation of a supercooled liquid water cloud due to the difference in vapor pressure over ice and water. Unlike cloud droplets, these ice crystals grow in an environment of high supersaturation with respect to ice, quickly reaching precipitation size, and with that can turn a non-precipitating cloud into a precipitating cloud (glaciation effect). But if ice nuclei are chemically modified by anthropogenic material such as sulfates or organics, they may de-activate ice nuclei, which has an opposite effect.

In order to estimate these effects, global climate model simulations with present-day aerosol emissions are contrasted to those driven with pre-industrial aerosol emissions. The results differ substantially as shown in Figure 1.

Recently more emphasis is placed on aerosols acting as IN as more laboratory data on ice nucleation and how it can be parameterized in global climate models have become available. Also the role of bioaerosols as ice nuclei receives more attention. In this talk, I will discuss some of these indirect aerosol effects with emphasis on processes occurring in mixed-phase and cirrus clouds.

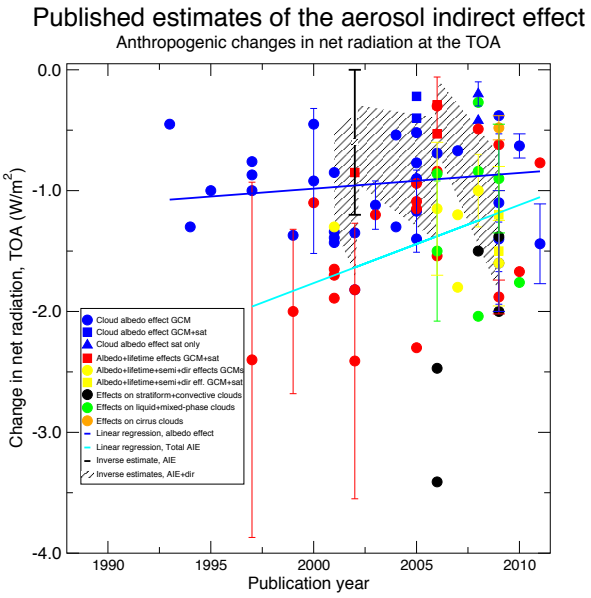

Figure 1. Model, satellite and inverse estimates of the aerosol indirect effects over the last two decades. For each method or effect considered, each symbol represents one published estimate (one paper one vote). Blue represents estimates of the cloud albedo effect from GCMs (dots), GCMs combined with satellite measurements (squares) and satellite estimates only (triangles). Red represents estimates of both the cloud albedo and cloud lifetime effect from GCMs (dots) and GCMs combined with satellite estimates (squares). The yellow dots represent estimates of the combined cloud albedo, lifetime, direct and semi-direct effects. Black dots represent the aerosol effects on stratiform and convective clouds and green dots represent estimates of aerosol effects on liquid and mixed-phase clouds. The black stippled area refers to inverse estimates. In case of multiple estimates per paper, the vertical bars denote the standard deviation. Updated from Lohmann et al, 2010.

Presenting author email: poulain@tropos.de

The impact of orographic clouds to the local aerosol chemical composition was measured during the Hill Cap Cloud Thuringia 2010 (HCCT-2010) field campaign, which took place in September/October 2010 at the Schmücke mountain ridge in the Thuringia forest (Germany). The main objectives of the HCCT-2010 project were to assess the effects of clouds on particle composition, gas phase oxidant budget, changes of hygroscopic properties and activation of aerosol particles. Three sampling sites were equipped: one on the top of the Schmücke Mountain, where clouds were sampled, and two valley stations located upwind and downwind of the summit. In total, four Aerodyne ToF-AMSs were deployed during the campaign. One at each valley station and two at the summit station: one downstream of a Cloud Virtual Impactor (CVI) for droplet residual analysis and one to measure interstitial particles. Based on air mass trajectories, gas tracer experiments and meteorological parameters, it is possible to identify periods during which the air mass of the three stations were connected. The overflow periods were divided in two subsections corresponding to the presence of cloud at the summit station (Full Cloud Events, FCE) and to the absence (Non Cloud Events, NCE) of cloud at the summit station. For these two categories of connected flow, the AMS results were compared in order to follow the cloud induced modification of the aerosol chemical compositions as well as modification of the chemical size distribution.

AMS results were successfully compared according to instrumental uncertainties and possible particle loss and dilution effects between the stations during the NCE periods and to the bulk chemical composition measured at the three stations show similar mass fraction. The comparison of the two valley stations is presented in Figure 1. Because the results measured at the three stations during NCE events were comparable, the same approach could be directly used to investigate aerosol cloud interaction and influence of clouds to local particles. Figure 1 also shows the first results of the comparison between the upwind and downwind station during several FCE periods. The scatter plots suggest a possible change on the bulk chemical composition of the particles corresponding to a small decrease of the particulate nitrate fraction as well as a tiny increase of sulfate. Details on the aerosol changes during the different cloud events including a comparison of the organic components as well as chemical size resolved will be presented.

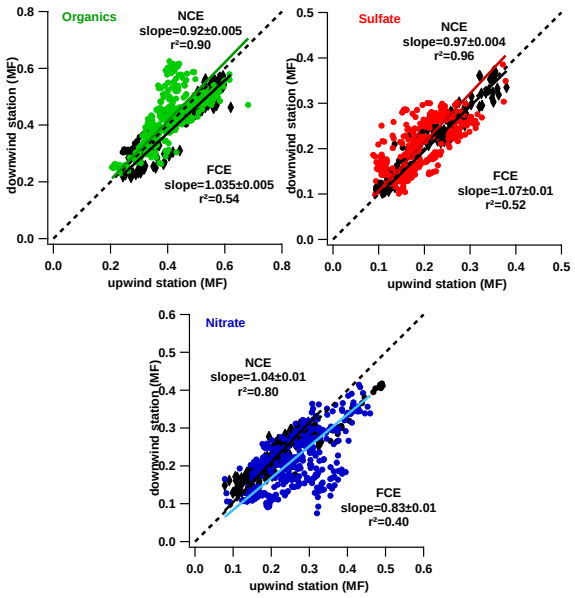

Figure 1: Scatter plots of the organics, sulphate and nitrate mass fraction measured at the upwind and downwind stations during NCE (black) and FCE (color). Regression slopes were calculated using orthogonal linear fitting.

Presenting author email: dominik@tropos.de

Clouds have a strong impact on physical and chemical processes in the atmosphere. Studying the interaction of aerosol and clouds under natural conditions is challenging, due to the height, as well as the spatial and temporal variability of clouds. Lagrangian-type field experiments, where a hill cap cloud is used as a natural flow-through reactor were successfully performed in the past to investigate different aspects of physical and chemical aerosol cloud interaction [*Bower et al.*, 2000; *Fuzzi, 1994; Fuzzi, 1997; Gallagher, 1999*; *Herrmann*, 2005].

In September/October 2010, the international cloud experiment "Hill Cap Cloud Thuringia 2010" (HCCT-2010) was performed at the Schmücke, which is part of a large mountain ridge in Thuringia, Germany. HCCT-2010 aimed at a better understanding of (i) the chemistry and microphysics within a cloud, (ii) chemical and physical modifications of aerosol particles by their passage through a cloud, (iii) the effects of clouds on the phase partitioning of oxygenated volatile organic compounds (OVOCs), and (iv) the effects of clouds on the budget of the main radical oxidants OH and HO_2.

In Figure 1 a scheme of the campaign area is given.

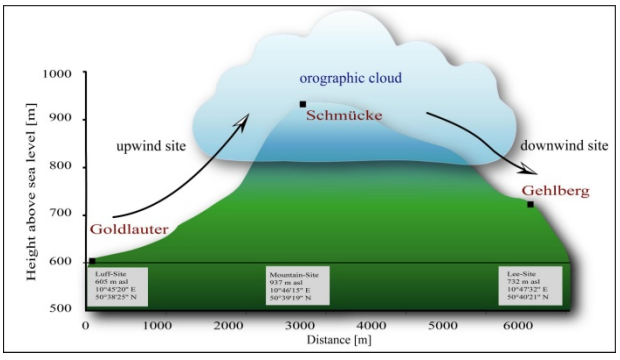

Figure 1: Scheme of the campaign area and the 3 sites.

Three measurement sites were set up: An upwind site to comprehensively characterize incoming air masses, an in-cloud site on the Schmücke summit to sample the different phases of a cloud, and a downwind site to study possible modifications of the aerosol after the cloud passage.

An extended pool of instruments was installed at the sites, including gas monitors, VOC and OVOC samplers, FAGE, SMPS, APS, HTDMA, CCNC, MAAP, CPC, filter samplers, impactors, MARGA, PILS, AMS, ALABAMA, a ceilometer, bulk and multi-stage cloud water collectors, CVI and interstitial inlet, PSAP, PVM, and FSSP.

A total of 370 hours of clouds could be captured at the summit station during the six weeks duration of the campaign. Certain offline samplers were operated only when meteorological observations predicted favourable flow connectivity between the sites, which was the case for a total of 73 hours during 12 so-called "full cloud events". A thorough investigation of meteorological conditions results from statistical analyses and several SF_6 tracer experiments revealed several top events, where a good flow connectivity between the three sampling sites can be assumed.

The study of physical and chemical parameters within these air masses led to interesting findings in scientific areas such as aerosol processing through clouds, chemical cloud composition, or the influence of clouds on the radical oxidants budget.

Within this contribution, an overview over the campaign will be given and some of the results will be highlighted.

Aerosol particles are known to influence the climate directly as well as indirectly. The indirect aerosol effect is amongst others determined by the efficiency of an aerosol particle to act as cloud condensation nucleus (CCN). The ability of a particle to be CCN active is a function of particle size, chemical composition and saturation ratio. In a cloud, interstitial particles and gases are entering the cloud droplets through in cloud scavenging and uptake. If the cloud evaporates, the scavenged mass (particles and gases) leads to larger, internally mixed and more hygroscopic particles. This mechanism is called cloud processing and is assumed to modify the chemical composition of CCNs during cloud passage.

A ground-based integrated study of chemical aerosol-cloud interaction was conducted in September and October 2010 in the Thuringian Forest in Germany in the frame of the Hill Cap Cloud Thuringia experiment (HCCT2010). Aim was to study possible cloud processing in the orographic clouds formed at Mount Schmücke. CCN measurements were performed at two study sites, i.e. upwind (station Goldlauter) and downwind (station Gehlberg), of the orographic clouds forming at Mount Schmücke. Measured were particle number and CCN size distributions, the latter for supersaturations (SS) between 0.07% and 0.4% utilizing a Cloud Condensation Nucleus Counter (DMT, USA).

From the size segregated CCN measurements, the critical diameter (D_{crit}), which is defined as the diameter at which 50% of the particles become activated to cloud droplets, was determined. From the resulting D_{crit}–SS-values, the hygroscopicity parameter κ was calculated (Petters and Kreidenweis, 2007). κ values were determined during so-called, full cloud (FCE) and non cloud events (NCE) at both sites, Goldlauter and Gehlberg. An event was defined as a time when the wind direction was such that an air mass from Goldlauter could be assumed to reach Gehlberg.

Table 1. Local meteorological parameters during FCEs.

Parameter	criterion
LWC	>0.1 g m^{-3}
wind direction	200°-250°
wind speed	2-12 m s^{-1}
Temperature	>0°C
Precipitation	0 mm

FCEs are characterized by the local meteorological conditions presented in Table 1 with an orographic cloud forming on Mount Schmücke, while there was no cloud/fog at the valley sites Goldlauter and Gehlberg. During NCE, no cloud/fog was present at any of the stations.

In Figure 1 κ values determined during the FCEs 11.3, 13.3, and 22.1 are shown. It can be seen that, downwind (Gehlberg) of the orographic clouds formed at Mount Schmücke, κ was higher for supersaturations between 0.07% and 0.2% than upwind of the clouds, i.e. in Goldlauter. This means, that while passing through the clouds, particles became more hygroscopic, respectively more CCN active during cloud passage. In contrast, in cases where no clouds were present at Mount Schmücke, κ featured the same values for both stations.

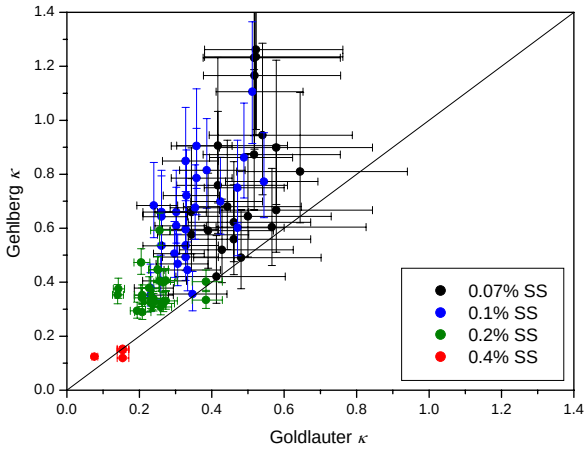

Figure 1. κ values during the FCEs 11.3, 13.3, and 22.1.

Interestingly, for 0.4% supersaturation, κ was found to be equal in Goldlauter and Gehlberg. The according D_{crit} ranged between 71 nm and 107 nm. This suggests that particles in this size range were not activated to cloud droplets, remained part of the interstitial aerosol, and were consequently not processed in the cloud. Hence, the supersaturation reached within the cloud was lower than 0.4% during the considered FCE. In connection with the findings described above, the supersaturation in the cloud at Mount Schmücke can be estimated to be between 0.2 % and 0.4%.

Relating particle hygroscopicity to chemical composition during HCCT-2010 field campaign

Z.J. Wu, L. Poulain, W. Birmili, M. Merkel, K. Dieckmann, M. Schäfer, D. van Pinxteren, S. Stratmann, H. Herrmann, A. Wiedensholer

Presenting author email: wuzhijun@tropos.de

Particle hygroscopic growth, number size distributions, and chemical composition were measured simultaneously at a low mountain range in central Germany (Thüringer Wald), during the HCCT-2010 (Hill Cap Cloud Thuringia 2010) field campaign which took place in September and October 2010. The main objective of HCCT-2010 was to perform a ground-based Langrangian-type experiment for investigating the influences of clouds on aerosol chemistry. Three sampling sites were equipped: one at the top of the mountain and two valley stations located upwind and downwind of the summit. This abstract focusses on the interactions between sub-micrometer particles and water vapor, as well as the role of chemical composition in particle hygroscopicity at the upwind site.

The hygroscopic growths at 90% for size-resolved particles derived from HTDMA measurements are converted into the hygroscopicity parameters κ (Petters and Kreidenweis, 2007) in order to eliminate the effect of particle size. The statistics performed over the entire sampling time period is shown in Fig.1. We can clearly see that the smaller particles are less hygroscopic than larger particles. Such size dependence of particle hygroscopicity can most likely be explained by an increasing fraction of organic compounds with decreasing dry diameter, which are shown by AMS measurements (Not shown in this abstract).

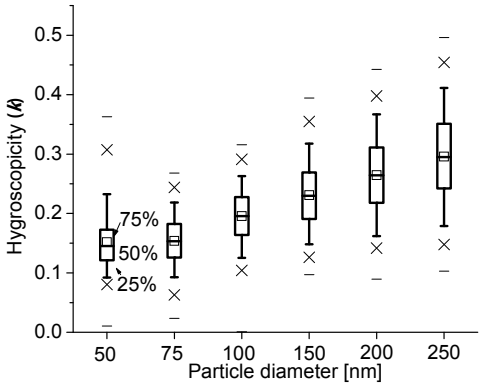

Figure 1: The size dependence of the hygroscopicity parameters κ

The predictions of particle hygroscopicity are performed using the detailed chemical composition provided by aerosol mass spectrometer (AMS) based on the Zdanovskii–Stokes–Robinson (ZSR) method. A good agreement between measured and predicted κ for 250 nm particle is found and illustrated in Fig. 2, indicating that the ZSR mixing rule combined with AMS data allows for accurate quantitative predictions of the mean growth factor of mixed atmospheric aerosol particles. We found that the agreement between prediction and measurement is very sensitive to the κ of organic fraction selected in the model due to the large contribution of organics to the total mass (lower panel of Fig. 2). Therefore, a further analysis on the relationship between finer organic structure and water vapor will be deployed in a hygroscopicity closure study. As a further topic, the relationship between the particle oxidation states and particle hygroscopicity will be also presented.

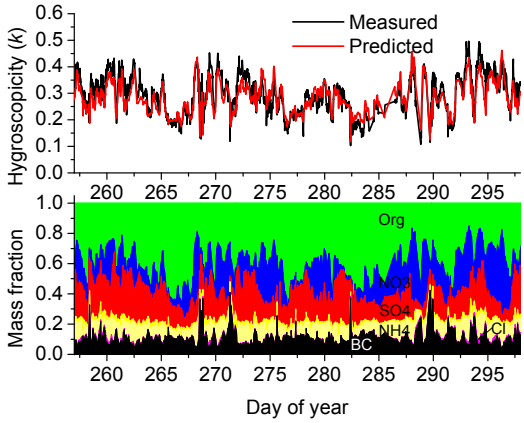

Figure 2: Time series of measured and predicted κ, as well as composition of non-refractory compounds as measured by AMS.

Aerosol-cloud interactions were studied during the Hill Cap Cloud Thuringia (HCCT) experiment which was conducted at the mountain "Schmücke" (938 m a.s.l.) located in the forest "Thüringer Wald" in Central Germany, in September and October 2010. Three sampling sites have been set up: one station upwind, one on the mountain top and one downwind. Here we report on results obtained at the mountain top station where cloud residual particles were sampled by a counterflow virtual impactor and subsequently their submicron fraction was analysed by two types of aerosol mass spectrometers: one Aerodyne C-ToF-AMS and one laser ablation single particle mass spectrometer (ALABAMA, Brands et al., 2011). The C-ToF-AMS was additionally equipped with a light scattering probe, enabling single particle analysis also with the AMS (Freutel et al., 2011). The interstitial aerosol was sampled through a 5-µm cut-off inlet and analysed by an Aerodyne HR-ToF-AMS.

Additional instrumentation included black carbon mass concentration (MAAP), particle size distributions (SMPS, OPC) and total number concentration (CPC) of the cloud residuals and the interstitial and out-of-cloud aerosol, as well as cloud liquid water content (PVM) and cloud droplet size distribution and concentration (FSSP).

During out-of-cloud periods, both AMSs were operated in parallel behind the interstitial inlet to ensure the comparability between the two instruments.

The results obtained with both instrument show an enhancement of nitrate in cloud residuals in comparison to the out-of-cloud aerosol sampled shortly before the or after the cloud event (Figure 1). The comparison of interstitial aerosol and cloud residuals from the same cloud events show the enhancement of nitrate even more pronounced. This nitrate enhancement might be due to a less efficient activation of small particles that contain a higher sulphate fraction, or possibly also to the uptake of nitric acid by the cloud droplets.

In general, most particles detected and analysed by ALABAMA were internal mixtures of organic and inorganic compounds. The ALABAMA data indicate a relative increase of soot-containing particle in the cloud residuals, which is confirmed a decrease of the interstitial black carbon mass concentrations during cloud events. The detected soot particles were always internally mixed with nitrate and/or organics, hence the activation can be explained by a inorganic or organic coating on the soot particles which initiates the activation. The laser ablation data also showed significant number of biological particles and of mineral dust, at least in certain cloud events.

The organic fraction of the out-of-cloud aerosol was found to have a slightly higher O:C ratio than the interstitial aerosol sampled during cloud events. This indicates that the more oxidized (aged) organic aerosol is preferably activated as CCN, but this effect on average was found to be rather small.

This presentation will summarize the results obtained with both types of mass spectrometers, with emphasis on particle mixing state, air mass origin and organic composition of the cloud residuals.

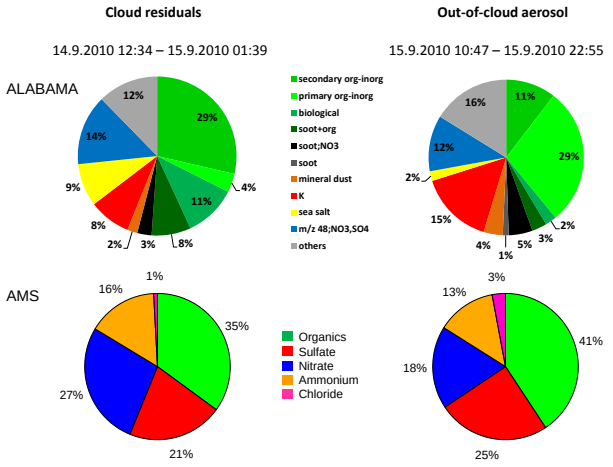

Figure 1. Comparison between composition of cloud residuals and out-of-cloud data for a selected cloud event (upper panel: ALABAMA, lower panel: AMS).

The chemical composition of cloud residual and background aerosol particles as well as the aerosol-cloud interaction was investigated during the field campaign Hill Cap Cloud Thuringia (HCCT) in September and October 2010 on the mountain site Schmücke (938m a.s.l.) in Central Germany. Either background aerosol was sampled by an interstitial inlet or orographic cloud droplets were sampled by a counterflow virtual impactor (CVI) which evaporates the cloud water. The remaining particles as well as the background aerosol particles were sized and analyzed by the bipolar Aircraft-based Laser Ablation Aerosol Mass Spectrometer (ALABAMA, particle size range 150 nm – 900 nm, Brands et al., 2011). Additionally the particle size distribution was measured by an optical particle counter (OPC) with a size range between 0.25 µm and 32 µm.

About 21 000 positive and negative mass spectra of cloud residual particles and about 239 000 of background aerosol particles were recorded. The size distributions measured by the OPC verify as expected, that the activated fraction shows a higher abundance of larger particles compared to the out-of-cloud aerosol.

A comparison of the averaged mass spectra shows a higher fraction of nitrate-containing particles as well as a lower fraction of organic and sulfate containing particles among cloud residuals. The mass spectra were separated by means of the fuzzy algorithm (Hinz et al., 2006) into clusters consisting of mass spectra with similar fragmentation patterns representing a certain particle type. This shows compared to the background aerosol composition that principally internally mixed particles containing secondary inorganic and secondary organic material and soot particles mixed with nitrate or organics serve as cloud condensation nuclei.

Depending on various meteorological conditions of cloud events and the air mass origin, cloud residual aerosol shows different composition (Figure 1). The main fractions are particles of organic and inorganic mixtures, potassium salts and internally mixed soot with nitrate. Furthermore variable fractions of mineral dust and sea salt particles are observable.

Difficulties arise in the case of mass spectra that contain only information on one polarity. These mass spectra, which amount to about 40% of the total recorded mass spectra, cannot be assigned definitely to one particle type.

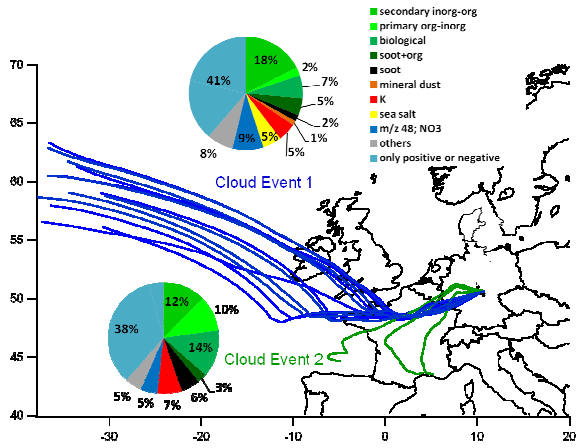

Figure 1. Comparison of cloud residual particle composition and HYSPLIT back trajectories (96 h, 500 m a.g.l., Draxler, 2012) for two different cloud events.

The impact of clouds on radical concentrations: Observations of OH and HO_2 during HCCT-2010

L.K. Whalley[1,2], I.J. George[1], D. Stone[1] and D.E. Heard[1,2]

[1]School of Chemistry, University of Leeds, Leeds, West Yorkshire, LS2 9JT, United Kingdom
[2]National Centre for Atmospheric Science, University of Leeds, Leeds, LS2 9JT, United Kingdom
Keywords: free-radicals, cloud uptake, heterogeneous loss
Presenting author email: d.e.heard@leeds.ac.uk

Clouds play a crucial role in the chemistry of the atmosphere, occupying, on average, ~ 15 % of the volume of the lower atmosphere (Lelieveld & Crutzen, 1990). Modelling studies have shown that aqueous phase chemistry in clouds can influence gas phase radical chemistry and in turn can cause significant reductions in the oxidative capacity (e.g. Lelieveld & Crutzen, 1991; Kreidenweis et al., 2003) and, hence, removal rate of VOCs. A number of aircraft projects have identified significantly reduced HO_2 concentrations when flying through clouds that exceeds the depletion expected due to the reduction in radiation alone (Olson et al., 2004; Commane et al., 2010). These experimental observations are relatively sparse, however, and until recently a comprehensive study to validate model predictions has been lacking.

Here we report measurements of OH and HO_2 radicals made during the HCCT (Hill Cap Cloud Thuringia) project that took place at Mt. Schmücke, Thuringia in Germany during September/October 2010. The University of Leeds Fluorescence Assay by Gas Expansion (FAGE) instrument was located at the summit of Mt. Schmücke and made near-continuous measurements of the radicals at the top of a 22 m tower. The site was regularly influenced by clouds throughout the measurement period and co-located measurements of liquid water content were made at the site enabling the influence of this microphysical parameter on the radical budget to be determined. On average, the photolysis rate of O_3 to form $O(^1D)$, the primary daytime source of HO_x radicals, was ~ 65 % lower in-cloud relative to the out of cloud observations. The HO_2 concentrations were significantly depleted in cloud, with concentrations ~ 90 % lower relative to the out of cloud observations; an OH signal above the noise of the instrument was not observed during cloud events. These results suggest that heterogeneous processes in clouds do perturb the gas-phase radical chemistry. Using a simple steady state analysis, to replicate HO_2 in-cloud observations, a first order loss rate of HO_2 to clouds = 0.2 s^{-1} is needed, suggesting a reactive uptake coefficient, γ, equal to 0.0125 at a cloud droplet surface area of 1.5 x 10^{-3} cm^2cm^{-3}. This value is consistent with HO_2 uptake coefficients determined for relevant aerosols in the laboratory using an aerosol flow reactor combined with FAGE detection of HO_2 radicals.

SPACCIM model studies on the multiphase chemistry occurring in orographic hill cap clouds during the HCCT-2010 field campaign

A. Tilgner, P. Bräuer, R. Wolke and H. Herrmann

Department of Chemistry, Leibniz-Institut für Troposphärenforschung,
Permoserstr. 15, Leipzig, 04318, Germany

Keywords: aerosol modelling, multiphase chemistry, aerosol cloud interaction, organic aerosols
tilgner@tropos.de

Tropospheric clouds and deliquescent particles are a complex multiphase and multi-component environment with simultaneously occurring gas and aqueous phase chemical transformations. Such aqueous phase chemical processes in cloud droplets and deliquescent particles are expected to proceed very efficient on short timescales and hence they are able to alter the chemical aerosol composition and the deduced physical properties on a global scale (Ravishankara, 1997). Besides the physico-chemical aerosol processing, chemical aerosol cloud interactions have significant effects on the whole multiphase oxidation budget.

In order to improve the still limited understanding of the aerosol-cloud interactions, Lagrangian-type field experiments, where an orographic cloud is used as a natural flow-through reactor, are used for studying such processes in more detail. In Sept./Oct. 2010, the Lagrangian-type cloud passage experiment HCCT-2010 (Hill Cap Cloud Thuringia 2010) was conducted at Mt. Schmücke in Thuringia, Germany to study aerosol cloud interactions (see Figure 1). As known from former cloud passage experiments, particularly associated model investigations (see e.g. Tilgner et al., 2005) including comparisons of model results with observations have considerably contributed to the interpretation of the measured field data.

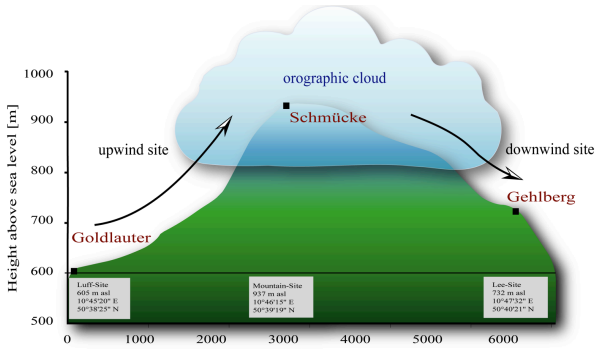

Figure 1. Schematic representation of the campaign area of the cloud passage experiment HCCT-2010.

In the present study, the parcel model SPACCIM (SPectral Aerosol Cloud Chemistry Interaction Model, Wolke et al., 2005) is applied to investigate the effects of multiphase cloud processing of tropospheric aerosol particles and trace gases resulting from a passage through an orographic cloud at Mt. Schmücke (Germany) during HCCT-2010. The applied model combines a complex microphysical and a detailed multiphase chemistry model with 11381 gas phase and over 3600 aqueous phase reactions. The chemical multiphase mechanism (MCMv3.1 (Master Chemical Mechanism; Saunders et al., 2003)/ CAPRAM3.0i-ext (Chemical Aqueous Phase RAdical Mechanism, Herrmann et al., 2005)) incorporates a detailed near-explicit description of the inorganic and organic multiphase chemistry based on time-dependent size-resolved aerosol/cloud spectra. The measured physical and chemical data at the upwind site provided the basis for the model initialisation under real environmental conditions.

First SPACCIM simulations have been carried out for few cloud events, which provided appropriate meteorological and overflow conditions fulfilling the cloud passage experiment requirements. Model results of the cloud passage simulation have been compared with experimental cloud water composition data at Mt. Schmücke (summit site) as well as gas and aerosol measurements at the downwind site in order to interpret the experimental data and to evaluate the model results. To this end, detailed analyses of the chemical multiphase system have been performed including chemical source and sink studies with special emphasis on radical and non-radical oxidants as well as important organic and inorganic chemical subsystems. For the fist time, modelled interstitial gas phase in-cloud HO_x concentrations were compared with measurements performed at the in-cloud summit site. Moreover, a central objective of the study was to assess in-cloud oxidations of important C2 and C3 organic compounds such as glyoxal and methylglyoxal.

Presenting author email: weigelr@uni-mainz.de

In-situ measurements with a 4-channel condensation particle counter (COPAS, Weigel et al., 2009) with different d_{p50} (50 % detection efficiency cut-off particle diameter) were conducted in the altitude range of 12.0-20.5km on board the M-55 *Geophysica*. One of four channels has a heated aerosol inlet line (at 250°C) which additionally allows for counting non-volatile particles.

Kiruna, North Sweden, was the operations base from where research flights towards the Arctic Winter Vortex (AWV) were performed during three scientific missions: EUPLEX (Jan.-Mar. 2003, 15 flights); RECONCILE, (Jan.-Mar. 2010, 13 flights); and ESSENCE, (Dec. 2011, 2 flights).

For potential temperatures $\Theta > 400$K the progression of the vertical profiles strongly depends on whether the measurements occurred in- or outside the AWV (Figure 1, left). Outside the AWV the particle mixing ratio N remains nearly constant with altitude while inside the AWV N increases with ascent.

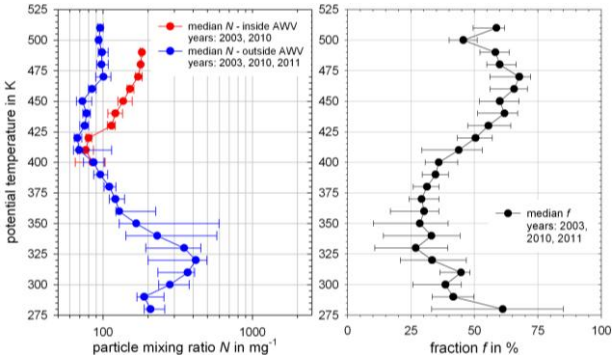

Figure 1. Vertical median profiles with 25- and 75-percentiles of particle mixing ratio N and the fraction f of non-volatile particles.

The fraction f of non-volatile aerosol in the AWV region is generally increasing at altitudes with $\Theta > 400$K from about 35% up to 70% at $\Theta = 475$K (Figure 1, right), which is high compared to f measured elsewhere in the stratosphere at same altitudes (cf. Borrmann et al., 2010). Hence, subsiding air masses inside the AWV entrain particles into the Arctic lower stratosphere from aloft. Up to 7 of 10 of these particles contain solid, not vaporizable material and were previously assumed to mainly stem from meteoritic ablations at mesospheric altitudes (Curtius et al., 2005).

During RECONCILE and ESSENCE particles were collected with an impactor at altitudes of $\Theta > 410$K. The chemical analysis of these aerosols with Environmental Scanning Electron Microscopy (ESEM) and Energy Dispersive X-ray (EDX) analysis techniques yields (apart from found residuals of the volatile nitric- and sulfuric acid compounds):

A) Non-volatile particles with $d_p < 500$nm mainly consist of soot, sometimes with bearings of lead.

B) Particles with $d_p > 500$nm (and $d_p < 6$µm) are partly amorphous, most likely of crustal material. In the same size range also molten spheres were found, alloy particles, metals or metaloxides and silicates.

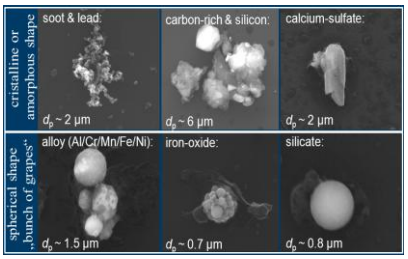

Figure 2. ESEM images of collected particles in the AWV region.

The fly-ash habit indicates that some particles were exposed to high temperatures for a sufficient duration.

These non-volatile particles in the AWV region provide condensation surfaces and thus could contribute to the formation of Polar Stratospheric Clouds (PSCs).

Geophysica missions were funded by the EC within the FP5 and FP7 (EVK2-CT-2001-00119and 226365-FP7-ENV-2008-1) and by the European Space Agency (ESA). Further support was provided by the Universities of Mainz and Darmstadt and the Max-Planck-Institute for Chemistry.

The viscosity and phase of atmospheric aerosols are key properties that help define aerosol reactivity and hence aerosol aging (Virtanen et al, 2010). The viscosity and phase are strongly linked to the water content of aerosols and hence the aerosol hygroscopicity. The ability of chemical species to diffuse into the aerosol core, or be limited to surface reactions, is closely linked to the aerosol viscosity. In particular, the bulk reactivity of fast lived species with a limited lifetime is often diffusion limited (Pfrang et al, 2011).

At present, there are no analytical techniques that can directly measure the viscosity and phase of atmospheric aerosol. This greatly limits the physical chemical understanding of these important atmospheric systems. In particular, a measure of viscosity would allow for direct probing of the glassy state of aerosols (Koop et al, 2011).

We are developing the use of Fluorescence Lifetime Imaging (FLIM) techniques, which have previously been used for investigating cell viscosity (Kuimova et al, 2009), to probe the viscosity of atmospheric aerosol. The FLIM technique works by the insertion of novel fluorescent probes (molecular rotors) into the aerosol systems of interest (Kuimova et al 2008). The fluorescent lifetimes of these probes are dependent on the viscosity of the surrounding environment because the fluorescence competes with intramolecular rotation. In a highly viscous environment the rotation of the rotors is significantly hindered and hence the fluorescence is strongly perturbed. This technique allows the viscosity of model aerosols to be measured whilst varying the environmental conditions such as relative humidity and temperature.

The use of different molecular rotors allows for the measurement of viscosity from 1-1000 centipoise, and the choice of rotor is important for ensuring precise measurements. Results on the viscosity of both inorganic and organic aerosol systems will be presented and the effect of relative humidity on aerosol viscosity will also be shown. The FLIM technique allows for the investigation of surface versus bulk characteristics of large supermicron particles. The variation of aerosol viscosity throughout the aerosol medium will be presented.

The FLIM technique shows great promise for aerosol research and potential future applications of the technique in this field will be highlighted. In particular, the technique will be extended to investigate the role of gas phase oxidant chemistry on aerosol viscosity, and the probing of glassy aerosol states.

There is mounting evidence showing that tropospheric secondary organic aerosol (SOA) may exist in a phase state other than liquid, namely semi-solid or solid amorphous (Virtanen et al., 2010; Cappa and Wilson, 2011; Vaden et al. 2011). The solid or semi-solid, high viscosity material may have significantly higher lifetime in an oxidizing atmosphere than low viscosity liquid due to mass transfer limitations in the particle bulk (Shiraiwa, 2011).

In this work we report a systematic study of the phase state of SOA particles produced by photo-oxidation of several volatile organic compound (VOC) precursors in a potential aerosol mass (PAM) flow tube reactor. The phase state of the particles was studied by their bounce behaviour upon impaction on a polished steel plate in a low pressure impactor (Saukko et al., 2012). The SOA oxidation level (O/C) was determined by an Aerodyne high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS)

The phase state for several types of SOA from different surrogate anthropogenic and biogenic precursors, produced at a wide range of oxidation conditions, were studied at a range of relative humidities. We report the solid or semi-solid phase state of SOA produced from cyclic and terpene precursors used in the study up to at least 50 % relative humidity. Furthermore, adding sulfur dioxide into the reaction chamber yielded liquefied particles, while particles formed from oxidation of pure organic precursor were solid or semi-solid. For a long-chain alkane precursor a liquid-like SOA at low oxidation level was produced, but upon increasing the oxidation level, the formed particles became more solid, which is shown in Fig. 1.

While the bounce behaviour of the particles had no single explaining factor for all experiments, the precursor molar mass was seen to correlate with more solid phase at higher humidities in cases with cyclic or terpene precursor.

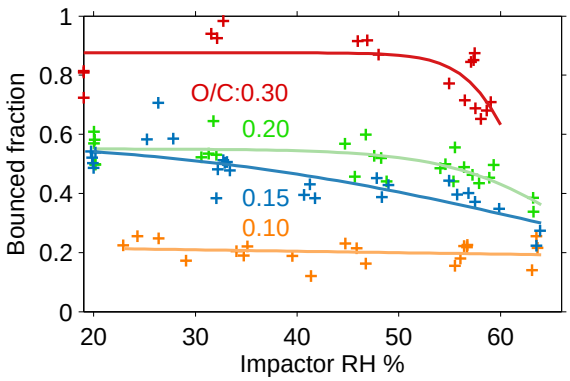

Figure 1: An increasing O/C level increases the fraction of bounced *n*-heptadecane-derived SOA particles at all humidities, while increasing humidity decreases the bounced fraction.

Clean Air for London (ClearfLo) is a large, multidisciplinary study of the London urban atmosphere aimed at understanding the relationships between surface meteorology, gas-phase composition and particulate matter at a city street site, a city background site (away from local traffic sources) and at rural locations that sample the outflow from the London urban area. During the winter intensive (January to February, 2012) we deployed a suite of instruments at a rural site southeast of London in Detling, UK. We present an overview of the chemical, physical and optical properties of the aerosol, focusing specifically on black carbon containing particles, as well as correlations with gas-phase tracers and aerosol precursors.

Data were collected through several co-located inlets mounted on a 9 m tower. Real-time particle instruments included an Aerodyne high-resolution time-of-flight mass spectrometer (HR-ToF-AMS), an Aerodyne soot particle mass spectrometer (SP-AMS), a multi-angle absorption photometer (MAAP), photo-acoustic soot spectrometers (PASS), a scanning mobility particle sizer (SMPS), cavity enhanced phase-shift particle extinction monitors (CAPS PMex), and a single particle soot photometer (SP2). Particle properties were measured with and without a thermal denuder in order to understand the effect of coatings on optical properties. Bulk particle chemistry was measured with filter samplers, a rotating drum impactor and a semi-continuous elemental and organic carbon analyzer.

Gas phase measurements included air mass tracers (CO, CO_2, O_3, NO_x) and volatile organic compounds using a proton-transfer reaction spectrometer (PTR-MS) and gas-chromatograph/flame ionization detector (GC/FID). The micro-orifice volatilization impactor chemical ionization time-of-flight mass spectrometer (MOVI-CI-TOFMS), a recently developed chemical ionization instrument that measures organic acids in both the gas-phase and the particle-phase, was also deployed.

Over the course of the campaign, sampled air masses were of local (A249 motorway 200 m south of the site), regional (London to the northwest, industrial areas north of the site, or Maidstone city southwest of the site) or more distant (continental European) origin depending on the direction of the prevailing winds. Figure 1 shows wind and CO data for an example of continental outflow (top panel) and regional London outflow (bottom panel). Results will be presented for each of these regimes. For the air masses identified as containing London outflow, the results are correlated with measurements at the ClearfLo winter intensive site in downtown London (North Kensington).

Aircraft measurements of gases and particles during CAREBeijing-2008 in surrounded Beijing areas

W.J. Zhang[1*], Z.P Bai[1], T. Zhu[2], W. Yang[1], B.H. Yin[1]

[1]State Key Laboratory of Environmental Criteria and Risk Assessment, Chinese Research Academy of Environmental Sciences, Beijing 100012, China

Corresponding author email: zhangwj@craes.org.cn

At present, the air pollution around Beijing area has become a complex problem with a combination of different types of sources: coal smoke, traffic emission, dust re-suspension, and so on. Additionally, the transport of particulates seems to be a large-scale regional pollution. It is of great value to conduct aircraft measurements of pollutants at different altitudes (Wang et al., 2008).

Measurements of gaseous pollutants, including ozone (O_3), sulfur dioxide (SO_2), nitrogen oxides (NO_X = NO + NO_2), carbon monoxide (CO), particle number concentrations (5.6-560 nm and 0.47-20 μm), and meteorological parameters (T, RH, P) were conducted during the Program of Campaigns of Air Quality Research in Beijing and Surrounding Region (CAREBeijing) from August 27 through October 13, 2008. The data of total 18 flights (70 h flight time) from the ground to 2100 m were obtained by a Yun-12 aircraft in the southern surrounded areas of Beijing (38ºN-40ºN, 114ºE-118ºE). This measurement was to characterize the regional variation of air pollution during and after the Olympics of 2008, the impacts of different transport direction and possible influencing factors.

Results suggested that four different groups of transport sources influenced the pollution level of pollutants with the consideration of the backward trajectory analysis, including: (1) the pollutant transport of the southern direction with higher pollutants level. The higher SO_2 concentration especially at 2100 m may be a good tracer for the sources from southern transport. The higher NOx concentration may be more from the southern or southeastern transport of ground pollutants; (2) the cleaner long-range transport of the northern or northwestern direction with lower pollutants level. The flights showed lowest concentration of gases pollutants, at all three different heights, which may indicate the contribution of deserted areas; (3) the transport from the eastern direction with characteristics of sea sources, i.e. middle level of gases pollutants and higher particle concentration. This may be due to the characteristics of the sea sources, lack of gases pollutants but more sea salt particles; (4) the transport of mixing directions, i.e. lower altitudes from the pollutant transport direction or local pollution but higher altitudes from the clean transport direction. Additionally, the relatively long-lived CO was shown to be a possible transport tracer of long-range transport of northwestern direction especially on the higher altitudes. Three factors influenced the size distribution of particles, i.e. air mass transport direction, ground source emissions and meteorological influences were also discussed.

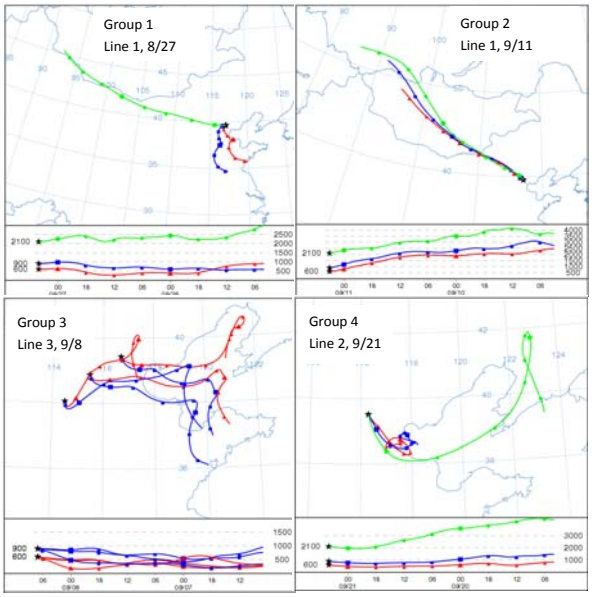

Figure 1. A 48 h back trajectories for the different group flights

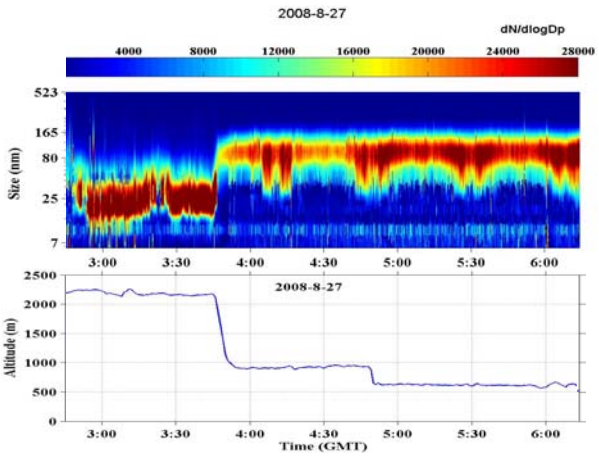

Figure 2. Variation of size distributions for 5.6-560 nm range with altitudes at different heights on Aug. 27 flight.

Single particle characterization using a high resolution time-of-flight aerosol mass spectrometer: Atmospheric observation in Nagoya, Japan

T. Mihara and M. Mochida

Department of Earth and Environmental Sciences, Graduate School of Environmental Studies, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464-8601, Japan
Keywords: urban aerosol, single particle analysis, mixing state, organic aerosol, aerosol mass spectrometry
Presenting author email: mihara.toshiyuki@d.mbox.nagoya-u.ac.jp

Introduction

Physical and chemical properties of single particles (e.g., refractive index and hygroscopicity) are important for various atmospheric processes, such as scattering and absorption of solar radiation and cloud droplet formation. Chemical composition controls the properties; however, knowledge on single particle composition is still very limited. In this study, we investigated the composition of single particles in the urban atmosphere using a high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS). The mass spectra of the particles were analyzed to explore the association of chemical components in single particles, and the temporal alternation of the aerosol mixing state.

Experiment

Measurements of atmospheric aerosols were performed in the urban area of Nagoya, Japan, from 31 October to 5 November, 2010. The aerosols were introduced to the HR-ToF-AMS and a scanning mobility particle sizer (SMPS) to measure the single particle composition and the size distribution, respectively. Prior to the measurement using the HR-ToF-AMS, the atmospheric aerosols were passed through a PM1 cyclone, three diffusion-dryer-type scrubbers (filled with activated carbon, silica gel, and molecular sieves), an aerosol neutralizer, and an aerosol humidifier (85% RH). The HR-ToF-AMS was operated in the mass spectrum (MS) mode, the particle time-of-flight (PToF) mode, and the brute-force single-particle (BFSP) mode alternatively. The unit mass spectra of size-resolved single particles were measured using the BFSP mode. In the analysis of the mass spectra collected using the BFSP mode, the baseline spectrum were subtracted to exclude the contribution from background gaseous species and to obtain the spectra originated from particles. Single particle detection events were extracted from the data using the threshold that is defined as the sum of the average and nine times the standard deviation of the baseline spectra. We regard that the particle was detected when the maximum of the sum of particle-related signals (i.e, those at mass numbers greater than or equal to *m*/*z* 30, but excluding *m*/*z* 32 and *m*/*z* 40) was above the threshold. The BFSP data were analyzed using the fragment table in the AMS analysis software (Squirrel, http://cires.colorado.edu/jimenez-group /ToFAMSResources/ToFSoftware/) to calculate the mass concentrations of sulfate, nitrate, and organics. These concentrations were compared with the concentrations measured in the MS and PToF modes, which were obtained using the AMS analysis software (Squirrel, Pika, Apes, PET).

Results and discussion

Particles were detected for 7,926 cycles in the 1,031,695 recorded cycles, whose diameter was in the range from 1 to 5,624 nm. The median diameter was 406 nm, and particle counts at <40 nm, which may not be real, was only 0.5 %. The pattern of the time series of the single particle counts were similar to that of the particle number concentrations measured using the SMPS. The mean concentrations of organics, sulfate, and nitrate in single particles were, respectively, 0.23, 0.05, and 0.05 μg m^{-3}. These values were one fifth of the mass concentrations measured in the MS mode. The delta analysis (Mihara and Mochida, 2011) was applied for the single particle mass spectra to assess the degree of oxidation of organics. The relationship of the proportion of organic mass with Δ values of 3, 4, and 5 in the total organic mass to the proportion of organic mass in the detected total mass (organics, sulfate, nitrate, ammonium, and chloride) was similar to that to the proportion of m/z 44 in the total organic mass (f44) (Aiken *et al.*, 2008). The results indicate that less oxygenated organics were more abundant in the particles with large fractions of organics. Oppositely, more oxygenated organics were abundant in the particles with large fractions of nitrate and sulfate. Alteration of the mixing state of aerosol was evident from the time series of the relationship of the proportion of organic mass with Δ values of 3, 4, and 5 in the total organic mass to the proportion of organic mass in the detected total mass; the internally-mixed condition changed to the externally-mixed condition from the evening of 4th to the noon of 5th of November. Although this analysis need processing of a large amount of data, this method makes it possible to analyze the chemical composition of single particles down to the size range (≥100 nm) that are not easy to analyze with the help of a laser scattering technique.

Long term measurements of chemical composition of ambient ions

Heikki Junninen[1], Mikael Ehn[2], Siegfried Schobesberger[1], Gustaf Lönn[1], Tuukka Petäjä[1], Douglas R Worsnop[1] and Markku Kulmala[1]

[1]Department of Physics, University of Helsinki, Finland, [2]Airmodus Oy, Helsinki, Finland,

Keywords: Ambient ions, APiTOF, mass spectrometry
Presenting author email: Heikki.Junninen@helsinki.fi

Atmospheric aerosol formation consists of a complicated set of processes that include the production of nanometer-sized clusters from gaseous precursor vapours and their subsequent growth. Charge is known to change clustering energies and also the ions themselves might play a role in new aerosol formation. Since the very first steps of aerosol formation are still unclear also the role of ions is unresolved for certain. Long term parallel measurements with ion spectrometer and particle size distributions show that the fraction of ions participating in the particle formation is varying depending on ambient conditions and the chemical environment. These measurement techniques, however have had a low mobility resolving power and an ion cluster composition could not been determined.

Here we present recent achievements on developing instrumentation to detect the composition of ambient cluster ions in the masses up to 2000Th. The instrument is an Atmospheric Pressure Interface Time-of-Flight Mass Spectrometer (APi-TOF, Junninen et al 2010) with mass accuracy <20ppm and resolving power 3000Th/Th. The instrument can be operated on remote location unattended or remotely controlled. This makes possible long term measurements and time series analysis. Majority of the peaks can be associated with a confidence to elemental composition and further to molecular composition of atmospheric ions. The data analysis has been performed using a new tool for analysing large datasets of time-of-flight mass spectrometry data, tofTools.

The APi-TOF was sampling continuously in field station (SMEAR II, Hyytiälä, Finland) for 7 months from May to November 2010 covering seasons late spring, summer and autumn.

Recently, alpha-pinene oxidation experiments in plant chamber (Ehn et al. 2012) have shown remarkable similarities with spectrum measured in ambient boreal atmosphere. Among other negative clusters the time behaviour and seasonal variability these novel extremely oxidised organic C10 compounds will be presented and their time series will be correlated against other precursors of aerosol formation. General features of time seasonal behaviour can be seen in figure 1, where an average difference spectrum between summer and fall is presented. During light hours in summer time the spectrum is dominated by malonic acid its cluster ions while dark hours by extremely oxidized organic compounds. This will be the first time such a long term measurement of newly identified compounds will be presented.

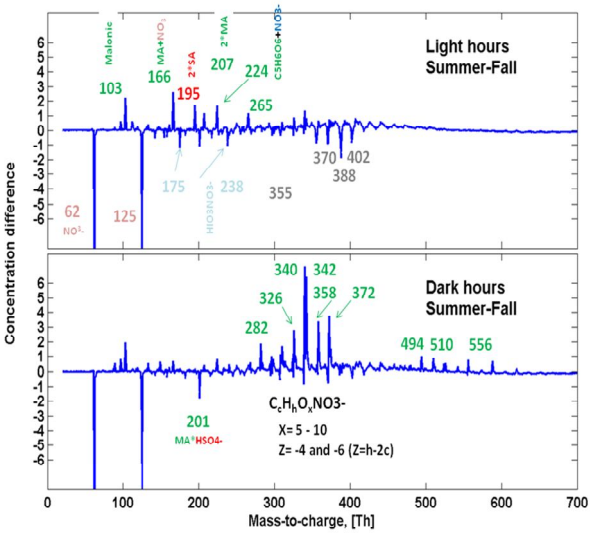

Figure1. Difference spectrum of summer and fall separated to light and dark hours. Positive peaks are dominant in summer while negative ones during fall.

Using a new unified model to revisit the relationship between aerosol size and composition

D. Topping[1,2], A. Buchholz[2] and M. McFiggans[2]
[1]National Centre for Atmospheric Science, University of Manchester, Manchester, UK
[2]Centre for Atmospheric Science, University of Manchester, Manchester, UK

Presenting author email: david.topping@manchester.ac.uk

Introduction

Aerosol particles, spanning orders of magnitude in size, are a complex mixture of many chemical compounds from both anthropogenic and biogenic sources. Despite this complexity, the present belief is that the relative importance of composition is second order to size and that the two remain uncoupled. Unfortunately, the theoretical tools which the community use as basis for such views, developed in the early 1930s, is not applicable to particulate composition we find in the atmosphere. Basic absorptive equilibrium partitioning models largely neglect the influence of curvature, leading to errors in predicted composition and volatility for conditions in which size is likely to play an important role. This includes the growth of very small particles and cloud activation potential. Similarly, empirical evidence often suggests it is not possible to reconcile water uptake in sub- and super-saturated environments using current instrumentation. This asks the question whether our knowledge of hygroscopicity derived using such tools is truly representative of behaviour in the atmosphere. Key to these problems is that the organic fraction of aerosol particles is comprised of multiple semi-volatile fractions. To attempt to address these problems we have developed a diameter depedent iterative equilibrium model that can predict partitioning between the gaseous phase and multiple condensed phases. We then apply it to two specific cases.

Case 1: CCN activation

As the particle is subject to changing environmental conditions, such as increasing/descreasing RH, the compounds comprising this fraction will re-partitioning between the gas and condensed phase accordring to their volatility, thus changing the particle size and chemical characteristics (figure 1). Existing theoretical tools cannot account for this. In this study we present new modelling and experimental work, carried out under the NERC funded programme ACID-PRUF, designed to reconcile the true effect of partitioning of all semi-volatile material on CCN activation potential, thus cloud droplet number. We show that the neglected effect of semi-volatile condensation as an aerosol particle approaches cloud activation has larger effects on activation potential than any other composition dependent phenomena included in equilibrium models. This directly challenges the widely held belief that size and composition remain uncoupled.

Case 2: Composition of ultrafine particles

The same numerical framework used in the previous section can be applied to study the predicted composition of ultrafine particles. It is still unclear what type of organic compunds may contribute to the initial stages of growth. Whilst insists from a non-dynamical model might be slightly resitrcted, in this study we apply this new iterative single particle modelling approach to ultrafine particles, first presenting an analysis on the type of organic compounds expected to contribute to their initial growth. Using output from state-of-the-art gas phase degradation mechanisms, with compound numbers ranging from 10^3 – 10^6, we are able to include the effect of non-ideality for each compound and account for depletion from the gas phase. We will show that the sensitivity to the surface energy of the particle increases as the size decreases, influencing the volatility boundaries required for aerosol growth.

Future outlook:

The development of a unified model enables the prediction of complex phenomena that might otherwise be limited by the numerical framework or availability of empirical data. With this in mind, we will also briefly show that the inclusion of non-ideality allows prediction of liquid-liquid phase separation, with subsequent effects on the equilibrium composition.

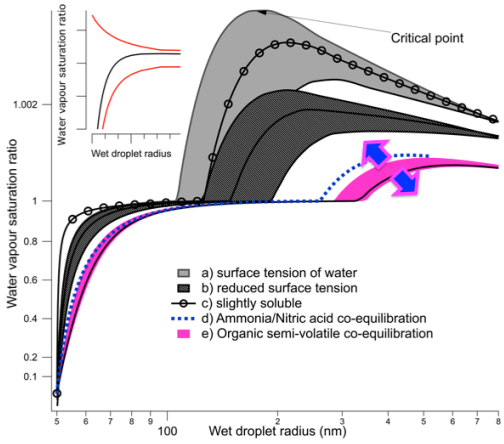

Figure 1. Traditional Kohler theory (grey areas) and the potential impact of organic co-condensation on CCN activation potential (cerise area). The up/down arrows highlight the effect of increasing or decreasing number concentrations respectively.

Session WG02S5O. Urban Aerosol Chemical and Physical Properties (II)

Comparative study of ultrafine aerosol within a city

I. Salma[1], T. Borsós[1], Z. Németh[1], P. Aalto[2] and M. Kulmala[2]

[1] Institute of Chemistry, Eötvös University, H-1525 Budapest, P.O. Box 32, Hungary
[2] Department of Physical Sciences, University of Helsinki, FIN-00014 Helsinki, P.O. Box 64, Finland
Keywords: DMPS, urban aerosol, number concentration, diurnal variation, atmospheric nucleation.
Presenting author email: salma@chem.elte.hu

Particle number size distributions were determined in the near-city background, city centre, street canyon and road traffic tunnel environments in Budapest. Measurements were performed by a flow-switching type differential mobility particle sizer (DMPS) in an electrical mobility diameter range of 6–1000 nm in 30 channels, with a time resolution of ca. 10 min.

Daily average particle number concentrations are shown in Table 1. Median daily concentrations varied by a factor of 33 from the background to the tunnel. The median and maximum number concentrations increased monotonically and substantially with the intensity of road traffic, which implies that the major source of particles is vehicular emission. The maximum measured concentration of 465×10^3 cm^{-3} was obtained in the tunnel. Mean contribution of ultrafine particles to the total particulate number and its standard deviation for the listed environments were (76±9)%, (79±6)%, (86±3)% and (85±2)%, respectively, which indicates that the combination of the primary emissions and atmospheric nucleation maintains more or less constant ultrafine contribution.

Mean diurnal variation of particles averaged by the time of day for the different environments exhibited similar structure. They contained three concentration peaks. The first peak occurred between 7:00 and 10:00 local time, and it was explained by vehicular emissions during morning rush hours. The third peak showed up in the evening between 19:00–22:00, and it was also related to traffic emissions but it was shifted from afternoon rush hours (that occurs between 16:30 and 18:00 in Budapest), mostly as a result of the daily cycling in meteorological parameters. The second peak appeared around midday for residential environments, and it was related to new particle formation and consecutive growth. The importance of atmospheric nucleation was clearly revealed by the diurnal variation of the mean ratio of ultrafine particles to the total particulate number, which exhibited a huge midday peak for the nucleation days, and no peak for the days without nucleation.

Table 1. Minimum (N_{min}), median (N_{med}) and maximum (N_{max}) daily number concentrations of aerosol particles in various environments in Budapest. The unit is 10^3 cm^{-3}.

Environment	N_{min}	N_{med}	N_{max}
Near-city background	1.25	4.3	10.1
City centre	2.7	11.8	20
Street canyon	4.9	23	41
Road tunnel	3.7	143	392

New particle formation occurred on 27% of all days in the city centre on a yearly scale. Its frequency showed an apparent seasonal variation. There were significant differences between the environments as far as nucleation frequency is concerned. It was the largest for the near-city background, and it was the smallest for the street canyon. No nucleation event was observed at all in the tunnel. Particle growth was usually finished within 1 day. Growth processes that were developing for two days were identified in the background. One of them is shown in Fig. 1. Special types of banana curves were also identified.

This work was supported by the Hungarian Scientific Research Fund under grant K84091.

Summer ammonia measurements in a densely populated Mediterranean city

Atmospheric ammonia (NH_3) is among the most abundant nitrogen compounds in the atmosphere and it plays an important role in: a) neutralisation of atmospheric acids to form ammonium salts, as ammonium sulfate ($(NH_4)_2SO_4$) and ammonium bisulfate ($(NH_4)HSO_4$) from sulfuric acid, ammonium nitrate (NH_4NO_3) from nitric acid and ammonium chloride (NH_4Cl) from hydrochloric acid, and b) eutrophication and acidification of the ecosystem by nitrogen (N) deposition (Flechard *et al.*, 2011). Overall, agriculture is estimated to contribute for 94% to the total NH_3 emission in Europe with livestock being the largest category in its emission inventory (EEA Report, 2011). Other sources of NH_3 include animal excreta, biomass burning, industries, coal burning, human breath, sweat and smoking, pets, sewage systems, wastes and vehicle emissions (Sutton *et al.*, 2000). Globally these sources form a minor part of the emissions but they might be relevant locally playing the greater role in ammonia emissions. At urban level for example there is a growing concern related with the emissions of ammonia after the introduction of gasoline-powered vehicles equipped with three-way catalytic converters and diesel-powered vehicles adopting selective catalytic reduction (SCR) system.

Measurements of ambient concentrations of gas-phase ammonia were performed in Barcelona (NE Spain) in summer between May and September 2011. Two measurement sites were selected: one in an urban background traffic-influenced area (UB) and the other in the historical city centre (CC). Levels of ammonia were higher at CC (5.6 ± 2.1 μg/m^3 or 7.5 ± 2.8 ppbv) compared with UB (2.2 ± 1.0 μg/m^3 or 2.9 ± 1.3 ppbv). This difference is attributed to the contribution from non-traffic sources such as waste containers and open markets more dense in the densely populated historical city centre. Under high temperatures in summer these sources had the potential to increase the ambient levels of ammonia well above the urban-background-traffic-influenced UB measurement station. The levels of NH_3 measured in Barcelona, especially high in the old city, may contribute to the high mean annual concentrations of secondary sulfate and nitrate measured in Barcelona compared with other cities in Spain affected by high traffic intensity. In Madrid (around 3 millions inhabitants) for example considerably lower concentrations of NH_3 have been observed compared with Barcelona. These high NH_3 concentrations in Barcelona may explain the increase of around 4 μg/m^3 in the mean annual concentrations of fine PM ($PM_{2.5}$) measured in Barcelona compared with Madrid. Finally, the concentrations of ammonia measured in Barcelona may also be the reason for the nucleation episodes involving NH_4HSO_4 formation which have been observed in Barcelona and which caused high levels of ultrafine particles (Reche *et al.*, 2011).

Ancillary measurements, including PM_{10}, $PM_{2.5}$, PM_1 levels (Particulate Matter with aerodynamic diameter smaller than 10 μm, 2.5 μm, and 1 μm), gases and black carbon concentrations and meteorological data, were performed during the measurement campaign. The analysis of specific periods (3 special cases) during the campaign revealed that road traffic was a significant source of NH_3. However, its effect was more evident at UB compared with CC where it was masked given the high levels of NH_3 measured in the old city. The relationship between SO_4^{2-} daily concentrations and gas-fraction ammonia ($NH_3/(NH_3+NH_4^+)$) revealed that the gas-to-phase partitioning (volatilization or ammonium salts formation) also played an important role in the evolution of NH_3 concentration in summer in Barcelona.

Seasonal variations of black carbon and number size distribution in Paris (France)

J. Sciare[1],T. Petäjä[2], J. Hakala[2], K. Lehtipalo[2], E. Herrmann[2], R. Sarda-Estève[1], J.B. Nicolas[1], N. Bonnaire[1] and P.P. Aalto[2]

Presenting author email: jean.sciare@lsce.ipsl.fr

Motivations. Road traffic and domestic wood burning emissions are two major contributors of particulate pollution in our cities. Because they are strong emitters of ultra-fine (soot containing) particles and are composed of highly toxic elements, these two incomplete combustion sources have important adverse health impacts, including increased morbidity and mortality from cardiovascular and respiratory conditions and lung cancer. A better characterization of soot containing aerosol sources (and their impact on aerosol number size distribution) in our major cities may provide useful information for policy makers, in the context of tackling air pollution issues affecting human health with additional benefits for climate change.

Experimental. As part of the EU-FP7 MEGAPOLI and the French ANR-MEGATOX & PRIMEQUAL-FRANCIPOL projects, seasonal variations of black carbon (BC) and number size distribution (NSD) were investigated at a background urban site of Paris (Laboratoire d'Hygiène de la Ville de Paris, LHVP, Paris, XIIIth district). Black carbon measurements in fine aerosols (PM2.5) were performed continuously for 2.5 years (July 2009 – December 2011) and achieved using a seven wavelength aethalometer (Magee Scientific, USA). Absorption measurements were corrected from the Weingartner et al. (2003) algorithm and source apportionment of BC between fossil fuel and biomass burning combustion source was obtained using the Aethalometer model developed by Sandradewi et al. (2008). The aerosol size distribution was measured in the same location with a flow switching Differential Mobility Particle Sizer (DMPS) over a period of one year (Aug. 2009 – Aug. 2010). In the flow switching DMPS, one Differential Mobility Analyzer (DMA) is operated with different sheath flows for a wider size range (6-800 nm). Also the total aerosol number concentration was measured with a Condensation Particle Counter (TSI CPC 3772) deployed in the DMPS by bypassing the DMA.

Results and discussion. Temporal variations of Black Carbon from wood burning (BC_{wb}) and fossil fuel (BC_{ff}) are reported in Figure 1 and clearly show distinct patterns. BC_{ff} is mainly dominated by traffic emissions and, for that reason, do exhibit a poor seasonal pattern. On the other hand, seasonal variations of BCwb are much more pronounced () and can be explained by domestic wood burning emissions which can be detected here for a period covering 7 consecutive months (October-April).
The sub-micron aerosol number size distribution had both diel and seasonal patterns, mainly governed by local emissions, boundary layer meteorology and long-range transport. The total number concentrations were typically higher during winter-time due to increased emissions and decreased vertical mixing.
Estimates of the PM contribution of traffic and domestic wood burning sources will be provided in the presentation as well as their impact on aerosol number size distribution will be discussed from previous observations performed in other European cities. Import of Black Carbon over the region of Paris will be addressed using similar (Aethalometer) measurements performed in parallel over a 1-year period at a rural site located at approximately 70km North-East of Paris center.

In Europe, the daily average values of ambient PM_{10} mass concentrations may not exceed the threshold of 50 µg/m³ more than 35 times per year (council directive 2008/50/EC) at governmental air quality sites. Many cities, however, find it hard to comply with this limit value. In Germany, low emission zones were established in many cities as part of a wider bundle of regulatory actions. The "green" low emission zone in Leipzig limits access to the city mainly to EURO4 equivalent of Diesel passenger cars as well as light and heavy duty vehicles. The main goal is to limit the direct tail pipe emissions, especially near traffic hot spots.

In Leipzig, a scientific cooperation between the Leibniz Institute for Tropospheric Research (IfT) and the Saxon State Office for Environment, Agriculture and Geology (LfULG) has analyzed possible beneficial impacts of the low emission zone. The Leipzig low emission zone, which covers most of the area of the city, was established on March 1, 2011. Black carbon and particle number size distributions have been determined continuously since June 2010 at 5 measurement sites (three IfT, two LfULG) in addition to the standard PM_{10} and $PM_{2.5}$ mass concentration measurements. The five measuring stations comprise two street sites (Leipzig-Mitte and Leipzig-Eisenbahnstrasse), two urban background sites (Leipzig-West and Leipzig-IfT) as well as a regional background site (Melpitz).

All stations are equipped with mobility particle size spectrometers such as a Twin Differential Mobility Particle Sizer (TDMPS) or a Scanning Mobility Particle Sizer (SMPS) to determine the particle number size distribution in the sub-µm size range. In Melpitz and Leipzig-Mitte, additional Aerodynamic Particle Sizer (APS) measure the number size distribution of coarse particle. At all stations, a Multi-Angel Absorption Photometer (MAAP) is used to determine the light absorption coefficient at 637 nm, which is converted into a black carbon mass concentration by using a mass absorption coefficient of 6.6 m²/g.

Figure 1 depicts the evolution of black carbon mass concentration in Leipzig between July 2010 and February 2012. The upper Figure illustrates the black carbon mass concentration at the street site Leipzig-Mitte and an urban background site, which exhibit significant short-term and seasonal variations. The lower graph visualizes the street site increment at Leipzig-Mitte, which was calculated as the difference between street site and background black carbon concentration.

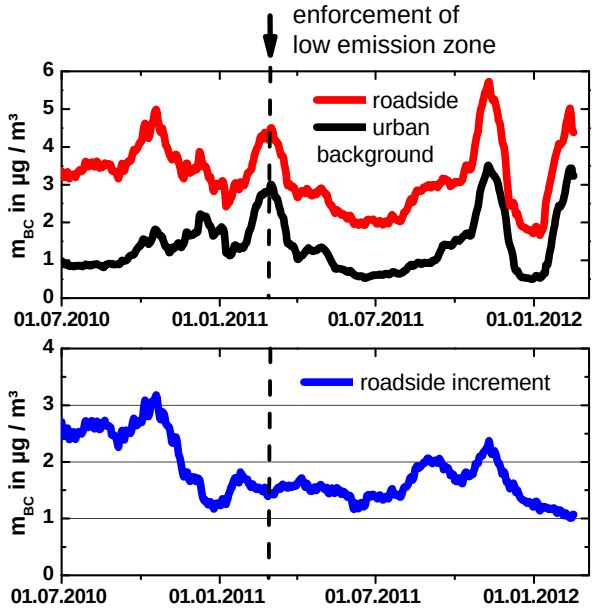

Figure 1: Upper graph: Black carbon mass concentrations at. two sites in Leipzig between July 2010 and February 2012. Red: street site Leipzig-Mitte; black: urban background site. Lower graph: roadside increment (i.e. background subtracted) at the roadside site Leipzig-Mitte.

The essential observation is that the street site increment shows a significant downward trend of 2010. The high levels of summer 2010 (24 h average), which exceeded 2µg/m^3 frequently, were hardly reached after this date. The reduction of the street site increment is approximately 25% in the black carbon mass concentration. However, this reduction corresponds to an black carbon mass concentration of 0.5-1.0 µg/m^3 only, which is modest compared to the overall PM_{10} level.This first analysis reveals beneficial effects of the low emission zone in Leipzig. It needs to be mentioned that black carbon accounts only for few percent of the PM_{10} mass concentration, but it is associated with adverse health effects. Black carbon caries especially heavy metal and polycyclic-aromatic hydrocarbons. Therefore, the benefits of the low emission zone might go significantly beyond the mere benefit of the associated reduction of the PM_{10} mass concentration. Furthermore, we will present the change in ultrafine number concentration at the street site due to the low emission zone.

Wintertime urban background measurements of PM_1, particle lung-deposited surface area, black carbon and particle number concentrations

Particulate matter (PM) is known to cause adverse health effects when inhaled. Currently, air quality standards are in force for PM_{10} and $PM_{2.5}$. However, epidemiological and toxicological findings suggest that the driving characteristics for health effects are more strongly related to the sub-micron particles (Pope and Dockery 2006). This particle fraction can be characterised by different metrics. Besides the mass concentration of PM_1, which is dominated by particles larger than 300 µm, the lung-deposited surface area (LDSA, mainly 20-400 nm) and the particle number (dominated by ultrafine particles (UFP) with diameters below 100 nm) might be used. Further, the black carbon (BC) content is currently discussed as a particularly health relevant metric (Jansen et al. 2011) related to traffic and domestic wood burning which are important urban air pollution sources.

In a joined measurement campaign IUTA and ISSeP investigated the relationships between these metrics. Measured metrics and instruments deployed were: Number size distribution (SMPS two systems, ca. 10-800 nm, and Grimm spectrometer, 0.265-31µm), LDSA,(NSAM, 20-1000nm),, BC (2-wavelength aethalometer, PM_{10} inlet), PM_1 (TEOM-FDMS), meteo.

The measurements took place in Mülheim, Ruhr area, Germany, close to the LANUV air quality network site STYR. This urban background site is characterised by influences from a motorway located ca. 250 m to the North-East, the second important wind direction besides the predominant south-westerly winds

The campaign was carried out between Feb. 6th and March 2nd). At the beginning of this period cold Siberian air masses dominated the weather in entire Germany. After 5 days the wind changed to usually predominant south-westerly direction, and temperature rose to values above freezing and, surprisingly, PM_{10} and BC concentrations increased significantly (fig. 1).

From SMPS measurement the concentrations for the number of UFP (dp<100 nm) and >UFP (dp 100-800 nm) were calculated. The light absorption coefficient obtained from the aethalometer was converted to BC concentrations (µg/m³) with a sigma of 16.6 (880 nm) and 39.5 (370 nm). Delta-C values were calculated from BC data corrected as described in Wang *et al.* 2011.

Table 1: Pearson correlation coefficients between metrics (as available at time of abstract submission)

	PM_1	UFP	>UFP	LDSA	BC1
PM_1	1	-0.087	0.819	0.753	0.716
UFP		1	0.191	0.466	0.274
>UFP			1	0.935	0.721
LDSA				1	0.835
BC1					1

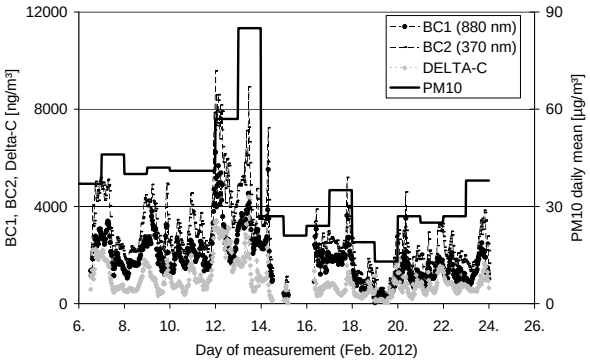

Figure 1: Time series of PM_{10} and BC concentrations

Delta-C data from aethalometer measurements (fig.1) indicate a significant influence of wood combustion which supports recent findings from levoglucosan analysis (Pfeffer *et al.* 2012). From correlation analysis (table 1) the five metrics reveal to provide rather complementary than redundant information.

Further evaluation of the full dataset (size distribution, LDSA, PM_1, BC, PM_{10}, NOx, meteo) for an indicative source apportionment following the approaches of Wang et al. 2011 as well as instrument intercomparisons will be presented.

This work was partly executed within the InterReg IV A project PM Lab. IUTA acknowledges financial support by the North Rhine Westphalia State Agency for Nature, Environment and Consumer Protection (LANUV)

Soot externally mixed with Asian dust particles in the submicron range in the marine atmosphere

K.I. Lieke[1], D. Zhang[2], K. Kandler[3], S. Weinbruch[3], and M. Bilde[1]

Keywords: soot, Asian dust, mixing state.
Presenting author email: kirstenlieke@gmx.de

Wide-spreading natural dust and anthropogenic soot in the atmosphere from the Asian continent are two important aerosols due to their influences on climate change, air quality, and ecosystem development. However, the available information does not provide clear knowledge on their mutual status in the outflow from the continent although they have been extensively studied. Here we show, with case data obtained in south-western Japan, that there were substantial amounts of soot particles in dust plumes arriving at Amakusa. In contrast to dust particles appearing in the size range of 1 to 30 µm geometric diameter, soot particles appeared in the submicron range of 0.5 µm and smaller. The observed soot particles were frequently isolated from dust particles and appeared in different morphologies as well as mixing state with secondary aerosol, most likely sulphate. These results indicate that anthropogenic soot externally mixed with dust particles in dust plume in the downstream offshore areas of the Asian continent and they could function as a place for sulphate formation in the submicron range.

Sampling and analysis

Samples of atmospheric particles were collected at Araoteke, a hill on the west coast of Amakusa peninsula, Japan (32.3550N and 129.9833E, 347 m a.s.l.) between 16 March and 18 March 2010. Weather reports issued by the Japanese Meteorological Agency indicated that a strong lower pressure system with fronts passed the desert and Gobi areas in north-western China, became loaded with dust on about 13 March and moved eastward. The low pressure system passed eastern China and the Korean peninsula on 14 and 15 March, and its centre arrived at the observation site in the afternoon on 15 March. On 16 and 17 March, the observation area was covered by a high pressure system following the low pressure system, Asian dust was reported at south-western Japan. Continuous records of an optical particle counter at the site revealed that the dust lasted until the afternoon of 18 March when a weak low pressure system arrived at the site. Therefore, the samples collected in the observation period were from the same dust event.

Samples were collected with a set of miniature cascade impactors on substrates suitable for electron microscopy. 3 Imapactor stages were used in the devices, covering a wide range in size: Particles from 40 nm up to tens of µm average diameter were collected. Single particle analysis was performed with an FEI ESEM Quanta 200 FEG and a FEI TEM CM200 at Darmstadt University of Technology. The instruments were equipped with energy-dispersive X-ray detectors for chemical analysis of elements with an atomic number larger than 5.

Results

During the spring dust episode, soot is found on all four samples of the dust event (listed in table 1, 11-3 is of a non-dust period). Soot is dominating the small particle size range. The size of primary soot spheres is 40-50 nm in average, showing typical graphitic layers under high resolution magnification in the transmission electron microscope. Lattice distances between 3.9 and 8 Å were measured in different soot particles. Combustion particles exist in different mixing states: pure different sized soot agglomerates in form of chains and balls; soot attached to secondary aerosol; soot encapsulated in secondary aerosol and internally mixed tar balls and fly ashes. The secondary aerosol was likely $(NH_4)_2SO_4$ and/or H_2SO_4.

Conclusions

Our results indicate that soot is transported with the dust from China. The large branched forms might arise from biomass burning, although the collapsed and internally mixed forms are occurring more frequently and thus proof that other sources as industrial plants and ships are contributing as well. A verification of sources and source apportionment is subject to further studies.

All over it is shown, that soot contributes significantly to the aerosol particles in the sub 500 nm size range in Asian dust plumes arriving at the Japanese coast in spring.

Sources and processes affecting coarse aerosols at street canyon and urban locations in London, UK

David C Green and Gary W Fuller

MRC HPA Centre for Environment and Health, King's College London, London, SE1 9NH, UK
Keywords: Coarse aerosol, traffic emissions, Aerosol Particle Sizer.
Presenting author email: david.c.green@kcl.ac.uk

Introduction

Aerosols in the range 2.5 – 10 µm in aerodynamic diameter have important implications for health (WHO, 2003). They are also an important component of the wider PM_{10} fraction and are consequently subject to regulation (EU, 2008) and policies to control their emission (GLA, 2010). Many of the sources and processes which contribute to the production of these particles are independent of those governing the smaller size fractions and are therefore worthy of independent investigation.

Methods

Measurements of coarse aerosol (0.5 - 20µm) where made using the TSI 3321 Aerosol Particle Sizer (APS) at an urban background site and a street canyon site in London between July 2010 and October 2011. Aerosols were sampled at ambient temperature and humidity through a ¾" stainless steel tube protected from rain ingress by a TSP inlet. The instruments were collocated at the background site for a period of 10 days to ensure they were comparable. Regular sample flow and HEPA filter checks were undertaken and the instruments were calibrated regularly using PLS by the manufacturer.

An assessment was made of the 2.5 – 10 µm mass from the difference between PM_{10} and $PM_{2.5}$ mass measurements using the FDMS. Chemical composition, traffic and meteorological measurements were also available to determine the sources and processes affecting the concentration.

Measurements from the APS were converted to volumetric equivalent diameter using the method provided by Peters (2006). This was used to isolate the 2.5 – 10 µm mass fraction and to calculate the effective density when compared to the mass measurement.

Results and discussion

The difference between the urban background and street canyon locations (the traffic increment) was calculated for hours when both measurements were available. The mass concentration was calculated based on the mean effective density (1.8 gcm^{-3}) when the volume concentration was compared to the mass concentration measured using the FDMS. This is slightly higher than previous studies at the Marylebone Road site (1.5 gcm^{-3}) which examined the merged SMPS and APS datasets during a campaign (Beddows, Dall'osto et al., 2010) and a little lower than the densities of around 2 gcm^{-3} found during studies of coarse aerosol in the US (Peters, 2006).

Figure 1 shows the particle number and mass concentration spectra from each site and the traffic increment. The particle number concentration increment is dominated by the single sub 1 µm mode while the mass concentration increment is dominated by the >2.5 µm particles. This mass increment appears to be multi-modal, indicating that a number of different sources and processes influence this metric. By comparing the diurnal variation in the calculated APS 2.5 – 10 µm mass to the FDMS mass measurements, the density was shown to vary with time of day; this is also consistent with a multi-source hypothesis.

Highly time and size-resolved trace elemental composition of aerosols during CalNex-LA 2010

Keywords: trace elements, XRF, PM and source apportionment, aerosol emissions
Presenting author email: suzanne.visser@psi.ch

Size-resolved measurements of trace elemental composition provide a highly specific technique for the identification of primary aerosol sources. The utility of such measurements is enhanced by sampling with high time resolution and coordination with other aerosol composition measurements. Here we present highly time and size-resolved measurements of trace elements as part of the CalNex-LA field campaign. CalNex-LA 2010 focuses on complex interactions between climate change, atmospheric conditions, and pollution sources (local and global) on air quality in California and the eastern Pacific coastal region. The high time resolution enables identification of sources highly variable in time like shipping via vanadium, and traffic via iron.

Sampling was performed at a ground-based urban site (California Institute of Technology, Caltech) in Pasadena, CA, USA. Particulate matter (PM) was collected from 15 May to 16 June 2010 with a 3-stage Rotating Drum Impactor (RDI). The RDI stages enable particle size segregation in the ranges 10-2.5 µm, 2.5-1.0 µm and 1.0-0.1 µm (Richard et al., 2010). A high sampling time resolution of 2-h was applied, instead of more common 24-h sampling times. Simultaneous measurements of e.g. wind speed and direction, and organic aerosols help separating local from regional sources with fresh and aged air masses, respectively.

The trace elemental composition of the collected aerosols was determined with Synchrotron Radiation induced X-Ray Fluorescence Spectrometry (SR-XRF) at SLS (Paul Scherrer Institute, CH) and at HASYLAB (Deutsches Elektronen-Synchrotron, DE). With the high 2-h time resolution, SR-XRF allows quantification of ambient elemental concentrations with a detection limit on the order of a few pg. Calibration is performed using a standard containing known concentrations of the elements of interest. The SR-XRF analysis provides a quantitative time series for elements with atomic number 13 (aluminium) to 82 (lead). Fig. 1 shows the time series of the 3 stages for iron (Fe). The main source of Fe in the coarse fraction is typically mineral dust, while traffic emissions are important for the smallest sizes (Bukowiecki et al., 2005; Richard et al., 2011). The diurnal variations with elevated concentrations during the day also indicate anthropogenic influences. The higher and more variable values for the coarse fraction in June are probably caused by dry, sunny conditions resulting in increased dust resuspension by traffic.

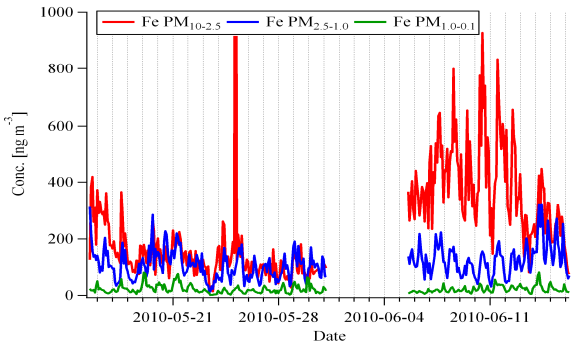

Fig. 1. Time series of size-segregated 2-h Fe conc. measured by RDI-SR-XRF during CalNex-LA 2010.

Fig. 2 shows the relative elemental contribution to the 3 stages averaged over the entire campaign. A high Cl fraction in $PM_{10-2.5}$ and $PM_{2.5-1.0}$ can indicate sea spray, as identified previously in Los Angeles with Na and Mg by Pakbin et al. (2011). The extreme S fraction, a known marker for secondary sulphate in $PM_{1.0-0.1}$, is in line with Richard et al. (2011). This fraction points at secondary and aged aerosol transported from LA to the sampling site in Pasadena. Further source identification during this campaign will be done with Positive Matrix Factorization.

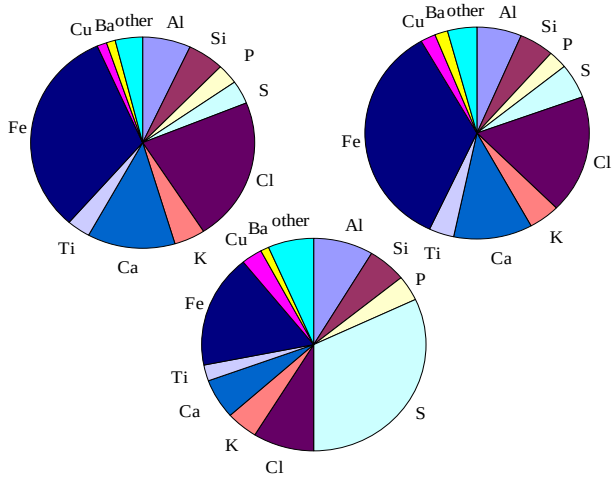

Fig. 2. Relative contribution of elements to $PM_{10-2.5}$ (left), $PM_{2.5-1.0}$ (right) and $PM_{1.0-0.1}$ (centre) identified by RDI-SR-XRF during CalNex-LA 2010.

Session WG07S3O. Gas phase synthesis of nanoparticles

Nanostructured catalytic layers for fuel cell electrodes prepared by electrospray

S. Martin, B. Martinez-Vazquez, P.L. Garcia-Ybarra and J.L. Castillo

Dept. Fisica Matematica y de Fluidos, Facultad de Ciencias UNED, Madrid, Spain
Keywords: Electrospray, Deposit morphology, Nanoparticles, Fuel cell
Presenting author email: smartin@dfmf.uned.es

The electrohydrodinamic atomization or electrospray has demonstrated to be a suitable technique for micro- and nano-thin-film deposition (Martin *et al*., 2005; Jaworek and Sobczyk, 2008). In our laboratory, the electrospraying of liquid suspensions containing catalytic nanoparticles is being successfully used in the production of porous catalytic layers for proton exchange membrane fuel cell (PEMFC) electrodes (Martin *et al*., 2010a, 2010b). One of the factors limiting the wide use of PEMFCs is the cost of the catalyst (platinum) in the electrodes. The goal of this study is to determine the electrospraying working conditions for obtaining electrodes with a low catalyst loading without compromising the fuel cell performance.

The electrospray deposition method enables the generation of nanostructured catalytic layers whose building blocks are clusters (of a few catalyst particles each) with a characteristic size of approximately 100 nm disposed in a dendritic arrangement (see Fig. 1).

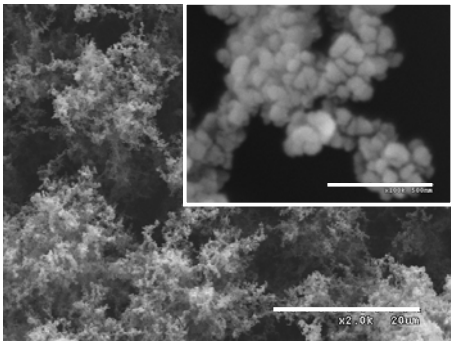

Figure 1. Dendritic structure of a catalyst layer with 0.01 $mg_{Pt}cm^{-2}$ Pt loading. The micron bar is 20 μm long for the main image and 500 nm for the inset.

This arrangement produces catalytic deposits with the appropriated morphology for PEMFC electrode preparation. On the one hand, the small size of the catalyst clusters leads to a high dispersion of the catalyst. On the other hand, the dendritic arrangement of the catalyst clusters results in a highly porous deposit with an enhanced permeability and increased electrochemical active surface area (Castillo *et al*., 2012).

The electrospray technique allows the preparation of efficient PEMFC electrodes with ultra-low platinum loadings (0.01 $mg_{Pt}cm^{-2}$). The conditions for achieving uniformly thin layers with the electrospray working in a stable cone-jet mode will be discussed. Figure 2 shows the fuel cell performance for several electrodes prepared under the same electrospraying parameters. The catalyst utilization (power per gram of platinum) delivered by these electrodes lies in the interval 30-35 kW g_{Pt}^{-1} what, to the best of our knowledge, represents the maximum platinum utilization reported up to now for any catalyst deposition method. Indeed, these results overcome in more than 50% the highest utilization achieved by sputtering (Cavarroc *et al*., 2009) and it is 3 times the Pt-utilization in our previous work (Martin *et al*., 2010b).

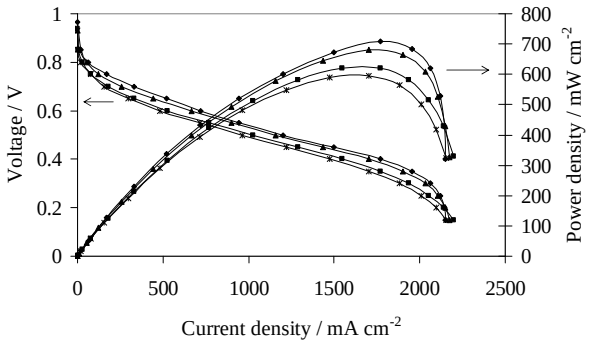

Figure 2. Fuel cell current-voltage and power density curves for electrodes with a Pt loading of 0.01 $mg_{Pt}cm^{-2}$.

The latter results were achieved using a fuel cell with small (5 cm^2) square electrodes. The scaling up to get 50 cm^2 square electrodes (delivering the same power density) will be discussed. In this way, the electrospray deposition method may be used to cover the entire range of required electrode sizes: from automotive or stationary applications down to portable units.

[3] State Polytechnical University, Polytechnicheskaya 29, 195251, Saint-Petersburg, Russia
Keywords: nanostructure, synthesis, tetrapod, ZnO, UV sensor.

Zinc oxide (ZnO) is a direct wide band gap (3.37 eV) semiconductor material with a large exciton binding energy (60 meV). It has gained significant attention because of the unique optical, piezoelectric and magnetic properties, as well as capability of band gap tuning (Rackauskas *et al.*, 2009). Non-catalytically grown ZnO nanostructures can be observed in various morphologies such as nanowires, nanobelts, nanobridges and nanonails, nanoshells, tetrapods. The latter is one of the most gorgeous structures with many promising applications in solar cells, lasers, field emitters, UV and gas sensors.

Zinc oxide tetrapods (ZnO-Ts) were discovered in smoke from zinc-smelting plants and first studied in chemical vapor deposition systems. ZnO-Ts were produced in the lab scale through hydrothermal process, vapor synthesis from ZnO and C mixture, or directly from Zn powder, when tetrapods are collected on reactor walls or filtered at the outlet. Direct synthesis of ZnO-Ts from the metal vapor has obvious advantages of low temperature process and high yield, still the control of uniform concentration is rather difficult.

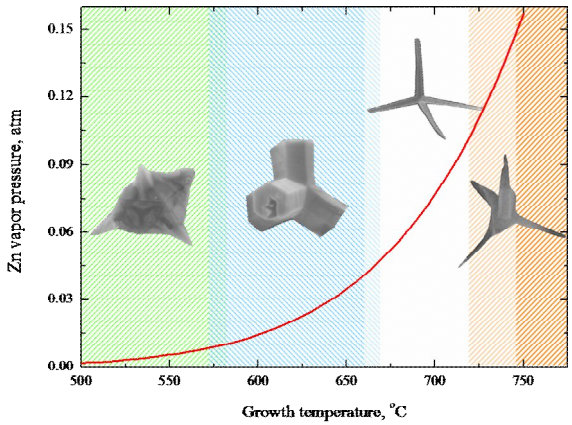

Figure 1. ZnO-T morphology at different temperatures and vapor pressures. Tetrapods shown are not in the scale.

In this work, we designed and constructed a vertical flow reactor for the controlled synthesis and collection of ZnO-Ts. In order to find favorable synthesis conditions, we varied the growth temperature and Zn vapor pressure. The overall trend of ZnO-T morphology change is summarized in Fig. 1. From our experimental data one can see that highly anisotropic structures were obtained above 650 °C (Rackauskas *et al.*, 2012). In order to modify the band gap and transparency of ZnO-Ts, we introduced magnesium vapor during the tetrapod growth.

Applicability of the produced ZnO-T structures was examined by fabricating transparent and flexible UV sensors. Flexible transparent UV sensor (Fig. 2) was made by drying droplet of ZnO-T solution in ethanol between two transparent single-wall carbon nanotube (SWCNT) film contacts, on a polyethylene terephthalate (PET) substrate. SWCNT electrode fabrication is described elsewhere, shortly,a one step process was used, filtered SWCNTs without any post processing were transferred from a filter by pressing it onto PET substrate. To obtain high optical transparency, sample synthesized at y_{Mg} = 2.3% and SWCNT electrodes with 95% transparency were used. UV sensing experiments were made under UV intensity of 30 μW/cm^2 at the wavelength of 365 nm. Inset in Fig. 2 shows a UV sensor response to the illumination. Initial current 0.032 pA increased to 1.45 pA under the UV illumination, which is 45 fold change. Response time to 90% of current change was 0.9 s.

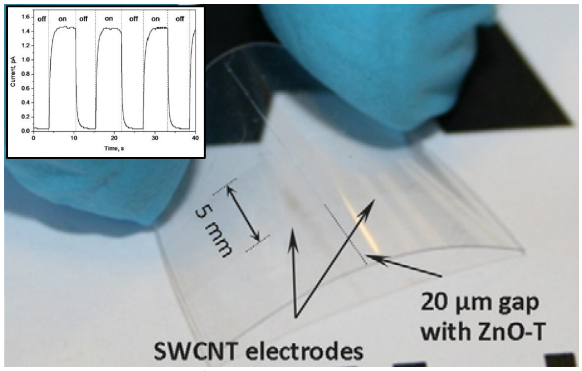

Figure 2. A photo of ZnO-T UV sensor. Inset shows the sensor response to excitation at 365 nm.

Synthesis of germanium-silicon hybrid particles in an aerosol reactor

C. Mehringer[1], R. Körmer[1], B. Butz[2], E. Spiecker[2] and W. Peukert[1]

[1]Institute of Particle Technology, Friedrich-Alexander-University Erlangen-Nuremberg, Cauerstr. 4, 91058 Erlangen, Germany
[2]Center for Nanoanalysis and Electron Microscopy (CENEM), Friedrich-Alexander-University Erlangen-Nuremberg, Cauerstr. 6, 91058 Erlangen, Germany
Keywords: nanoparticles, material synthesis, silicon, germanium.
Presenting author email: c.mehringer@lfg.uni-erlangen.de

Nanocrystalline silicon (Si) and germanium (Ge) are promising materials for the application in printable electronics (Holman et al, 2010). Nanoparticles (NPs) of these materials can be dispersed in organic liquids and deposited as thin functional films. As a prerequisite for the functionality of the film, good contacts between individual particles are necessary. A thin germanium layer around a silicon core might be a suitable composite material, because germanium has a much lower melting point, i.e. sintering is enhanced in comparison to Si, and Ge protects Si from oxidation.

A reactor system with two consecutive hot-wall reactors is used in the experiments. The first reactor stage is used for synthesis of Si NPs with defined properties from monosilane (Körmer et al, 2010). After the first reactor the aerosol is quenched by additional argon. Prior to the second reactor stage, monogermane is fed into the system. In the second reactor stage Ge is deposited on the Si NPs at temperatures between 500°C and 700°C. At the reactor exit the aerosol is quenched by nitrogen. The particles are collected with a membrane filter or sampled via a low pressure impactor by deposition on TEM grids or silicon wafers.

The structure of the nanoparticles is investigated by STEM analysis. Figure 1 shows a z-contrast image of representative particles synthesized at certain process parameters with a monogermane partial pressure of 0.08 mbar (Inset shows higher magnification). Under these reaction conditions Si particles with a faceted Ge patch are formed. This can be explained by energetically favoured sites for the initial island growth. Due to the slight misfit between the crystal lattices the Ge grows preferentially on itself and only partially around the Si core.

Figure 2 shows a HRTEM image of particles formed at reaction conditions with 0.83 mbar monogermane partial pressure, where the Ge patches cover an increased fraction of the Si particles´ surface. It is obvious, that the Si core, as well as the Ge patch is crystalline. Further, it can be seen that the Ge patch is no longer faceted. This fact is a hint to the growth mechanism of the patch. Starting from a wetting layer an initial Ge seed forms at the Si surface, which grows to a faceted patch. Further growth leads to relaxation and an altered form of the patch.

The progress on the synthesis of the germanium-silicon hybrid particles will be demonstrated, regarding the influence of the process parameters on their morphology and growth.

Thermostability of flame synthesized core-shell TiO_2/SiO_2 nanoparticles and its photocatalytic activity

Qi, Fei[1], Moiseev, Anna[2], Deubener, Joachim[2], Weber, Alfred P.[1]

[1]Institute of Particle Technology, TU Clausthal, Leibnizstrasse 19, 38678, Clausthal-Zellerfeld, Germany
[2]Institute of Non-metallic Materials, TU Clausthal, Zehntnerstrasse 2a, 38678, Clausthal-Zellerfeld, Germany

Keywords: thermostability of anatase, core-shell nanoparticles, photocatalytic activity.

Nanosized TiO_2 is a well-established material used for development of environmental photocatalytic technologies and self-cleaning coatings as well as catalyst support. The anatase content and anatase particle size are crucial factors for its catalytic performance. For the application of nanosized TiO_2 at elevated temperatures (over 400 °C) the classical sintering problem of anatase particles must be avoided.

In the present study binary TiO_2/SiO_2 nanoparticles were synthesized by oxidizing $TiCl_4$ and $SiCl_4$ at about 900 °C in $CH_4/O_2/N_2$-premixed flame reactor described in detail in [1]. Tetrachlorosilane precursor was fed directly into the flame at different flow rates condensing as a SiO_2-layer on the surface of TiO_2 crystallites (ca. 18 nm) to build so-called core-shell particle morphology. The thermostability of anatase phase in synthesized products was studied in the temperature interval from 900 to 1200 °C. The photocatalytic activity of calcined samples was tested by degradation of dichloroacetic acid (DCA).

Fig. 1 shows the stability of anatase phase at different calcination temperatures dependent on Si/Ti-ratio in TiO_2/SiO_2 materials. For a certain minimum SiO_2-content the resulting fraction of anatase reaches a maximum for each calcination temperature. With increasing calcination temperature the necessary silica content increases, while the resulting fraction of anatase is reduced.

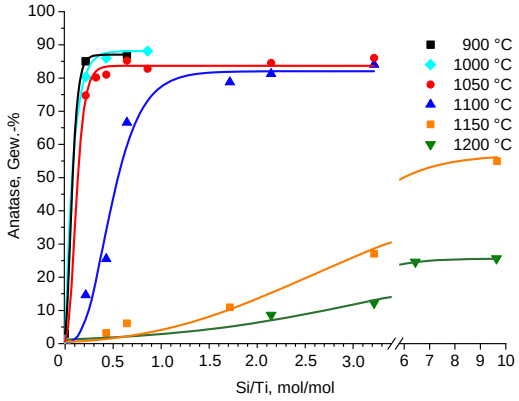

Fig. 1 Stability of anatase phase in core-shell particles versus Si/Ti-ratio at 900 - 1200 °C

Fig. 2 shows the oxidation rate of DCA, mgTOC/(l·min), versus Si/Ti-ratio. It was found that particles calcined at 1100 °C remained still notably photocatalytically active. Moreover, the samples calcined at 900 °C with Si/Ti-ratio up to 0.2 mol/mol exhibited the highest activity.

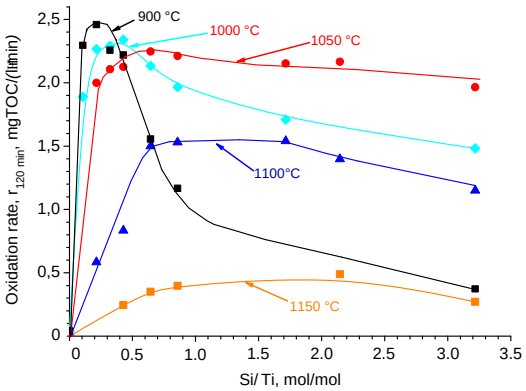

Fig. 2: Photocatalytic oxidation rate of DCA with calcined powders

Fig. 3 presents the binary TiO_2/SiO_2 powders after calcination procedure. The silica layer remained intact up to about 1050 °C. In the temperature range between 1050 and 1100 °C dramatic changes occurred in the material's morphology: cracks in the SiO_2-shell as well as coarse TiO_2 crystallites become now well observable by TEM. Calcination at 1150 and especially at 1200 °C nearly completely destroyed the protective effect of SiO_2-shell so that the TiO_2 particles sinter uninhibitedly rapidly to a µm-size.

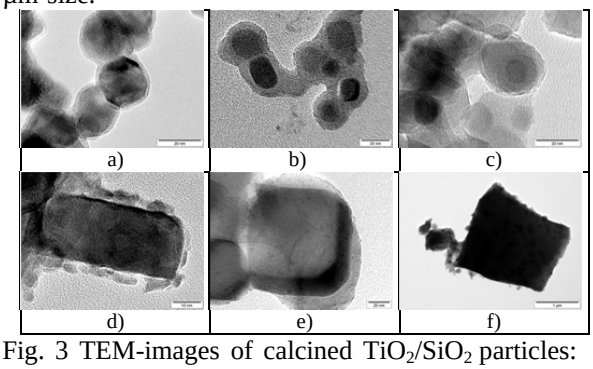

Fig. 3 TEM-images of calcined TiO_2/SiO_2 particles: a) - f) 900, 1000, 1050, 1100, 1150 and 1200 °C

Synthesis of aluminium nanoparticles with the aid of a customized atmospheric plasma spraying system

E. Daskalos[1], H. Mandilas[1], G. Karagiannakis [1] and A. G. Konstandopoulos[1,2]

[1]Aerosol &Particle Technology Laboratory, CPERI/CERTH, P.O. Box 60361, 57001, Thessaloniki, Greece
[2] Dept. of Chemical Engineering, Aristotle University, P.O. Box 1517, 54006, Thessaloniki, Greece
Keywords: atmospheric plasma spraying, aluminum nanoparticles, metallic nanoparticles
Presenting author email: emdaskal@cperi.certh.gr

The present study investigates the proof-of-concept feasibility to synthesize aluminium (Al) nanoparticles (NPs) from micron-sized Al powder with the use of a customized DC arc type Atmospheric Plasma Spraying (APS) technique. This technique facilitates synthesis of NPs via rapid sublimation of the precursor micrometric metallic particles (size ranges employed were 20-45 and 45-150 μm) and their subsequent re-nucleation. The process took place inside a sealed mantle/reactor system, which was designed and manufactured in-house. The reactor system equipped all necessary instruments for pressure, temperature and oxygen content measurements and provided the necessary inert environment (argon) to avoid any oxidation of the metal during plasma spraying. An additional argon flow, injected downstream of the plasma, promoted rapid quenching of the gasified metal. The particles formed were collected on a quartz filter. Typical production rate achieved was at 2gr·min^{-1}.

Post-characterisation of synthesised particles was performed via X-Ray Diffraction (XRD), Specific Surface Area measurement (BET), Transmission Electron Microscopy (TEM) coupled with Energy Dispersive Spectroscopy (EDS) and ThermoGravimetric Analysis (TGA) under air. It was found that the synthesised powders comprised metallic Al monocrystalline NPs of almost spherical shape. The NPs possessed a 2-5 nm oxide coating layer. By regulating the conditions inside the mantle, a variety of different size distributions was obtained.

Table 1. Overview of main properties of Al NPs synthesised

Exper. No	Average Primary Particle Size (nm)	Crystallite size (nm)	BET (m^2/gr)
1	31	23	51.33
2	47	49	27.20
3	68	67	20.60
4	82	57	18.07

Comparisons with respect to size distribution results of prepared samples provided strong indication that the effect of increasing precursor feed rate from 1 g·min^{-1} to 2 g·min^{-1} was more profound than that of decreasing precursor particle size from 45-150 μm to 20-45 μm. A more solid picture, however, emerged from a similar comparison for the synthesis runs performed with and without argon-accelerated quenching. It was evident that faster quenching led to smaller primary particles and narrower particle size distributions.

The size distribution and surface area features of Al NPs synthesised via the current system were found to be similar to those of Al NPs produced through similar plasma type systems. Dolbec *et al* (2008) produced Al NPs ranging from 25 to 100 nm (mainly dependent on quench rate) in size, using an inductively coupled plasma system under mild vacuum conditions. The mean size of Al NPs produced via H_2 plasma-metal reaction was reported at 46 nm by Liu *et. al.* (2003), while their BET surface area was measured at 48 m^2/g. Laser ablation of Al in liquid resulted in NPs production with a mean size of 30 nm (Kumar *et al*, 2010).

The amount of synthesised NPs deposited directly on the filter accounted to around 20% of the total quantity produced per experiment. The remaining quantity was deposited on the inner walls of the reactor/mantle (primarily) and near the APS gun (secondarily). Powder not deposited on, or near, the filter suffered from undesirable moderate-to-severe sintering phenomena as it failed to pass through the rapid quenching area of the reactor. The latter ascertainment implied the necessity for improvement of the current design in order to ensure that virtually all of the synthesised powder undergoes rapid quenching.

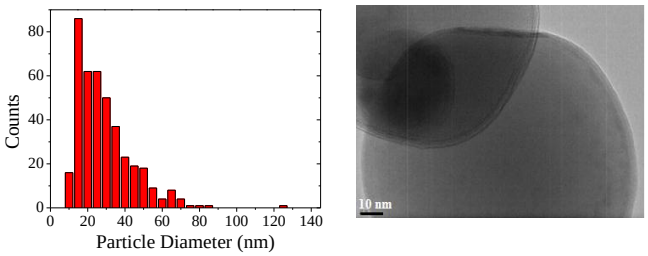

Figure 1. Representative size distribution of primary particles and HR-TEM image of Al NPs synthesised

Synthesis of Magnesium Hydride by Spark Discharge in Argon/Hydrogen Mixtures

T.V. Pfeiffer[1], A. Anastasopol[2], S.W.H. Eijt[2], and A. Schmidt-Ott[1]

[1]Nanostructured Materials, Department of Chemical Engineering, Faculty of Applied Sciences, Delft University of Technology, 2628 BL 136, Delft, the Netherlands
[2] Fundamental Aspects of Materials and Energy, Department of Radiation, Radionuclides & Reactors, Faculty of Applied Sciences, Delft University of Technology, 2629 JB 15, Delft, the Netherlands
Keywords: spark discharge, hydrogen storage, nanoparticles; generation, metal hydrides.
Presenting author email: t.v.pfeiffer@tudelt.nl

Hydrogen storage in metal/metal hydride systems is relevant as a safer alternative to high-pressure cryo-compressed storage. Magnesium based metal hydrides have the advantage of being relatively cheap, and having been studied extensively. An efficient process for the large scale production of metal hydrides is still lacking.

Previously we reported on spark discharge of magnesium in a mixture of 5% hydrogen / 95% argon. Nanoparticles of MgH_2 were formed, which showed low temperature hydrogen desorption. Apart from the typical β-MgH_2 phase, a significant amorphous fraction was found. This study aims to elucidate the formation of magnesium hydrides in hydrogen/argon mixtures, both in context of hydrogen storage properties and scale-up.

Hydrided magnesium nanoparticles were formed *in situ* by spark discharge using two electrodes of metallic magnesium 1.5 mm apart, and 1.0 SLM of 0-100% H_2 in Ar as carrier gas (figure 1). Production rates were determined from the mass collected on PVDF membrane filters over 5-17 hours. The structure of the as produced powders was investigated using XRD and TEM. Hydrogen storage properties were evaluated using Thermal Desorption Spectroscopy and a Sieverts apparatus.

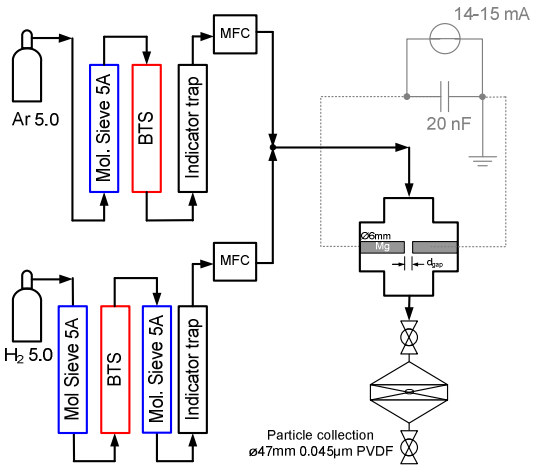

Figure 1. Spark discharge setup.

Increasing the hydrogen concentration in the carrier gas increases the breakdown voltage, and with it the power input into the spark. Power input levels off at 28 W for concentrations of 50% H_2 and up. Energy efficiency improves with increasing H_2 concentration: more mass is produced at the same plasma power input. When 100% H_2 is used, the nature of the plasma changes and the discharge becomes silent. The yield drops down to 5 ng/J, due to the absence of heavy Ar^+ ions in the ablation process. While the use of hydrogen is mostly limited to the production of hydrides, using less reactive gases that are heavy or have a large breakdown voltage, such as Ar, Xe or SF_6, in order to improve ablation efficiency could be more generally applicable.

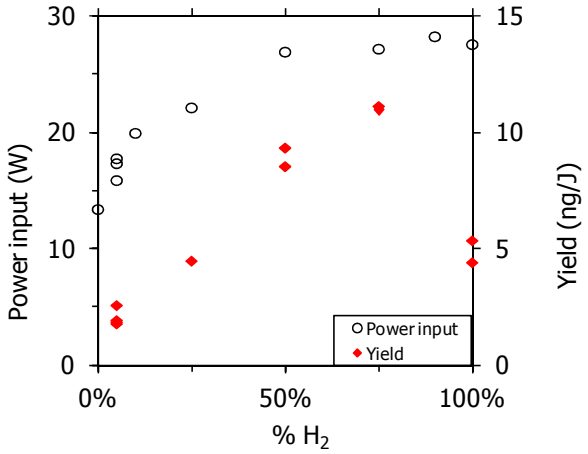

Figure 2. Power input and energy yield for various hydrogen concentrations.

For all samples, XRD shows the presence of nano-crystalline Mg, MgO and β-MgH_2. All samples produced with H_2/Ar mixtures have large amorphous fractions, but samples produced in 100% H_2 contain highly crystalline MgH_2 domains >100 nm. TEM confirms that the particles are surrounded by ~1-2 nm MgO shells. Sievert's analysis yields a decrease in desorption enthalpy to ~ 60 kJ/mol H_2 and increased equilibrium pressures at low temperatures, indicative of the nanostructure in the material.

The gas composition in spark discharge can be tuned to affect crystallinity and particle size of MgH_2. Power input and energy efficiency can also be affected, which is beneficial for larger scale production.

We acknowledge financial support by Agentschap NL, grant EOSLT07052.

Keywords: Aerosol spray pyrolysis, Nanoparticles, oxides, Particle deposition..
Presenting author email: j.f.m.m.gaury@tudelft.nl

Electrostatic Spray Deposition (ESD) is a method that combines Electrohydrodynamic atomization (in short electrospraying) and electrostatic deposition to form nano- or micro-structured materials. In this all-in-one-step technique that takes place in a controlled atmosphere, a precursor solution is pumped through a nozzle on which a high voltage is applied. As a result, the liquid jet breaks-up into micron-sized droplets under the influence of electrical forces and are deposited onto a substrate by the electrical field. By heating the substrate, one can enhance evaporation of the solvent and oxidation of the particles resulted from the solution during their flight from the nozzle to the substrate (cf. Figure 1).

By varying the operating conditions of the systems one can produce thin films having a wide variety of morphologies with building-block particles that range in size from the micrometer to the nanometer scale (Hartman and al, 2000). Despite the fact that temperature is the main parameter in the aerosol drying process and consequently in the morphology design of the film, a lot of other parameters should be taken into account such as the spraying parameters (voltage, flow rate, the nozzle to substrate distance) and the precursor properties (conductivity, surface tension, density, pH, etc).

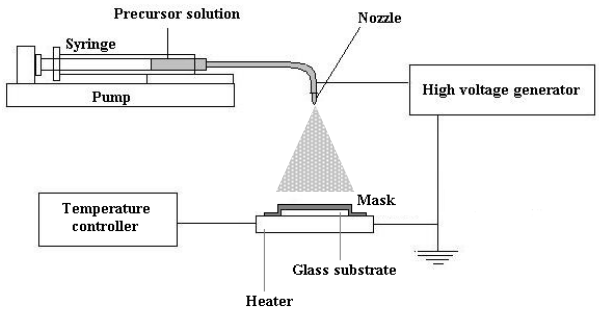

Figure 1. Schematic diagram of the Electrostatic Spray Deposition set up.

The ESD process has found valuable applications in the production of Metal Oxide Semiconductors (MOS), as well as thin films for Solid Oxide Fuel Cells (SOFC), Li-ion battery materials, or gas sensors. In this paper we demonstrate the fabrication of WO_3 films doped with niobium or tantalum using ESD. The modification of the spraying parameters offers the possibility to tune the morphology of our thin films in order to meet the requirements of building sensitive NO_x gas sensors. Doped and undoped samples have been produced and characterized by different techniques (e.g. SEM, TEM, EDX, XPS). Imaging analysis showed that we obtain homogeneous thin films, with highly porous morphologies and high surface to volume ratio, thereby offering a very efficient surface coverage that thereby enhances the gas sensing response.

The resulted Nb- and Ta-doped WO_3 thin films have dense, grain-like, flower-like or tree-like morphologies when the substrate temperature is increased from 250 to 400 °c. Reticulated structures have also been observed by using solvents with different boiling points. Based on the existing literature about the ESD theory (Hartman and al, 2000), droplet sizes have been estimated in the micrometer range and compared to the imaging spectroscopy performed on the films, showing particle sizes of about 150 nm. To explain this difference and the formation of the tree-like morphology, we developed a qualitative model (cf. Figure 2) in which the as-generated droplets undergo additional break-ups into smaller droplets by reaching the Rayleigh limit due to solvent evaporation (Tang and Gomez, 1994).

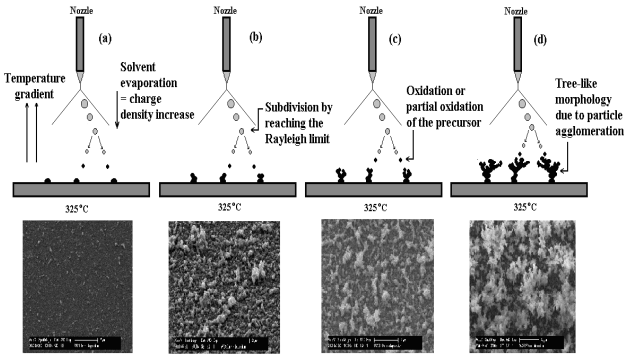

Figure 2. Deposition model and corresponding SEM pictures of WO_3 particles prepared at 325 °C, with a precursor flow rate of 0.2ml/h deposited for (a) 1; (b) 5; (c) 10 and (d) 20 minutes.

Nanomagnets with controlled size distribution are produced by continuous hydrogen reduction technique and coated in-situ by carbon or copper. Cobalt chloride is the precursor for the magnetic cobalt core of the particles. Copper chloride and ethene are applied as precursors for copper and carbon shells, respectively. The synthesis technique is presented in detail in previous articles (Forsman et al. 2008; Koskela et al. 2011). The copper layer can be oxidised ex-situ without oxidising the cobalt core. The magnetic cobalt cores are well protected against oxidation occurring over time or in elevated temperatures. The coating affects the optical and the electrical properties of the magnets and can be functionalised (Eiroma et al. 2011). The produced core-shell particles were characterised extensively with XRD, XRF, TEM, SAED, BET, TGA and squid magnetometer.

The number average diameter of the carbon coated cobalt core-shell particles (Co+C particles) varied between 17 and 78 nm (figure 1). The standard deviation of the particle size distribution increased with average particle diameter from 7 nm to 37 nm, while the specific surface area decreased from 27 to 7 m^2/g. The mass concentration ranged from 8 to 13 g/m^3 in these experiments. The number average diameter clearly correlated with the concentration of ethene in the reaction flow.

According to XRD and XRF data, the Co+C particles are very pure and well crystallized. The carbon mass fraction in the particles is 3-9 wt-% depending on ethene concentration. TGA analysis showed that oxidation of the Co+C particles started at 200°C. This indicates that the Co particles are uniformly coated with carbon.

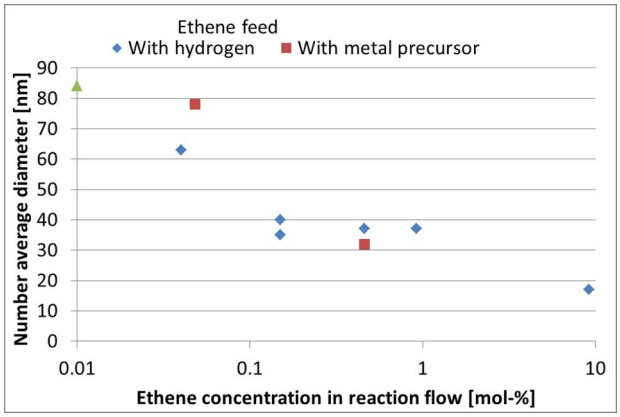

Figure 1. Number average diameter of particles as a function of ethene concentration in the reaction flow.

The mass fraction of copper in the copper coated cobalt particles (Co+Cu particles) was 31-92 wt-% according to XRF. XRD data showed that directly after production, both Co and Cu were in metallic form. After controlled oxidation of Cu, cobalt still remained metallic. The number average diameter of the Co+Cu particles ranged from 54 nm to 84 nm.

The saturation magnetization of the Co+C particles was close to that of bulk Co ($M_{s,\ bulk}$ = 159 emu/g) with the exception of the smallest (D_{ave} = 17 nm) particles. In that case, a large saturation magnetization of 239 emu/g was measured. This might indicate that the Co cores induce a magnetic moment in the C shell. Reports on induced ferromagnetism in C have attracted significant interest in recent years and this phenomenon still is a topic of intense scientific debate (Coey et al. 2002; Kusakabe and Maruyama 2003; H.-Ch. Mertins et al. 2004). In our experiments, we only observe an enhanced saturation magnetization for the smallest Co particles. In all studied Co+C samples hysteresis was low.

The saturation magnetization of Co+Cu particles was similar to bulk Co when normalized to Co weight. In comparison to Co+C particles, significant hysteresis was observed.

Session WG09S1O. Aerosol Modelling: Atmospheric Applications

Secondary organic aerosol formation during summer 2010 over Central Europe

B. Langmann[1], K. Sellegri[2] and E. Freney[2]

[1] Institute of Geophysics, University of Hamburg, KlimaCampus, Hamburg, Germany
[2] Laboratoire de Meteorologie Physique, CNRS, Universite Blaise Pascal, Aubiere, France
Keywords: three-dimensional modeling, secondary organic carbon aerosol formation
Presenting author email: baerbel.langmann@zmaw.de

Introduction

Until recently, atmospheric models systematically underestimated measured OC aerosol mass concentrations in the atmosphere by a factor of up to 10 and more. Jimenez et al. (2009) proposed the concept of aging of organic vapors, thereby producing less volatile and higher oxygenated organic vapors with atmospheric mass concentrations comparable to sulfate. Based on these ideas, Yu (2011) developed a promising modeling strategy where the aging of organic vapors is considered and in addition to the traditional two compound thermodynamical gas-particle partitioning a third low volatile organic vapor is formed which kinetically undergoes condensation on pre-existing particles.

Model description

Here we use the regional three-dimensional atmosphere-chemistry-aerosol model REMOTE (Langmann et al., 2008) with the aerosol dynamics and thermodynamics module M7 (Vignati et al., 2004). The standard M7 has been extended by Anntila et al. (2010) by a thermodynamical two compound SOC aerosol formation mechanism. This one was further extended based on Yu (2011). We consider three classes of organic vapors where the low-volatile one is formed by aging form the more volatile ones. The low-volatile organic vapor is assumed to condense kinetically on pre-existing particles, while for the medium- and semi-volatile organic vapors the thermodynamical approach of Anntila et al. (2010) is used.

Model results

REMOTE model results over Central Europe are compared with measurements from a campaign at Puy-de-Dome, France during June 2010. Sulfate and chlorine aerosol mass concentrations are very well captured in the model simulation results - finally also organic carbon aerosol mass concentration. For illustrating the sensitivity of OC model results on SOC parameterizations, Fig. 1 shows results for the original two compound thermodynamical approach for isoprene only by Anntila et al. (2010) (grey line) and model results with additional VOC precursor gases (yellow line). Taking into account the SOC gases as additional trace species in the model, which undergo transport and removal (green line) leads to a considerable, however still insufficient increase in comparison with the measurements. The red line shows results from the simulation where aging of the most volatile SOC gas to the semi volatile SOC gas has been considered, finally generating OC aerosol mass concentrations in the range of the measurements. Taken into account the aging of the semi volatile SOC gas to the low volatile SOC gas (black line) does not modify OC aerosol mass concentrations much in comparison to the first aging step.

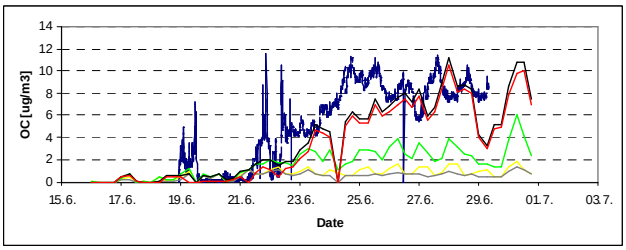

Fig. 1: AMS-measured (dark blue line) and modeled near surface OC mass concentration during June 2010 at Puy-de-Dome, France. Grey line: according to Anntila et al. (2010); yellow line: more VOC precursor gases; green line: SOC gas transport and removal; red line: 1. aging SOC gas; black line: 2. aging SOC gas - see text for more explanation

It should be noted however, that considerable differences in the aerosol size distribution are determined between the model simulations taking into account the first and second step of SOC gas aging. Due to kinetic condensation of the low volatile SOC gas, nucleation mode particles (up to 5 nm) grow into the aitken mode particle range (5 nm – 50 nm) which further grow into accumulation mode particle range (bigger than 50 nm).

Regional modelling of the tropospheric multiphase system using COSMO-MUSCAT: 2D-sensitivity-studies

R. Schrödner[1], A. Tilgner[1] and R. Wolke[1]

[1]Institute for Tropospheric Research, Leipzig, 04318, Germany
Keywords: Aerosol cloud interaction, Multiphase chemistry, Modelling (regional), Cloud microphysics.
Presenting author email: roland.schroedner@tropos.de

Clouds play a major role in the atmosphere due to their influence on the Earth's radiative budget, on the hydrologic cycle and on the tropospheric chemical composition (e.g. Ramanathan et al., 2001). Cloud lifetime is driven by the dynamics of the atmosphere at the synoptic scale and, in close interaction, by microphysical processes (e.g. nucleation of cloud droplets and ice crystals, condensation and evaporation, collision/coalescence processes, freezing, sedimentation of hydrometeor) on the small scale.

These processes depend on the chemical composition of particles and cloud droplets. In addition, microphysical processes redistribute chemicals among the various reservoirs: gaseous, particulate, liquid and ice phases. Clouds favor the development of "multiphase chemistry" since they are an ideal reaction medium for this: (1) clouds support very efficient photochemical processes inside droplets; (2) certain homogeneous chemical reactions within clouds can be usually faster than the equivalent reactions in the gas phase, and reactions such as those involving ionic species, can be important; (3) finally, interactions between the aqueous and solid phase can contribute additionally to chemical processes in clouds (for example dissolution of soluble particulate species). The evaluation of multiphase chemistry versus overall tropospheric chemistry and its role in the Earth's radiative budget is challenging since microphysical and chemical processes occurring at different time scales within clouds are still poorly known.

The model system COSMO-MUSCAT consists of MUSCAT (Wolke et al., 2004a) and the forecast model of the German Weather Service (DWD) COSMO (Schättler et al., 2008). Both models are coupled online. MUSCAT was extended to consider cloud-chemical processes (chemical aqueous phase reactions and phase transfer processes) on the regional scale replacing the former aqueous phase parameterization.

Based on the increasing kinetic and mechanistic knowledge on chemical aqueous phase reactions in the last two decades, advanced aqueous phase chemical mechanisms such as the Chemical Aqueous Phase Radical Mechanism (CAPRAM) are continuously developed (Tilgner and Herrmann, 2010). CAPRAM is an almost explicit mechanism which describes relevant chemical aqueous-phase conversions of both inorganic and organic compounds. A reduced version of the mechanism, applicable for 3D chemistry transport models was created (Deguillaume et al., 2009).

With the advanced model system, 2D-sensitivity-studies (air streaming over a mountain) have been conducted for an urban and a remote case. The comparison of two different mechanisms (simple inorganic (INORG) and detailed organic mechanism CAPRAM) have revealed agreements but also interesting differences for important chemical subsystems e.g. in the modeled multiphase HO_x budget and pH whereas the simple mechanism leads to always less acidic cloud droplets than CAPRAM. Invesigation of reaction fluxes show that this is due to additional organic acidification in CAPRAM. The difference in pH leads consequently to different regimes for e.g. the S(IV)-oxidation.

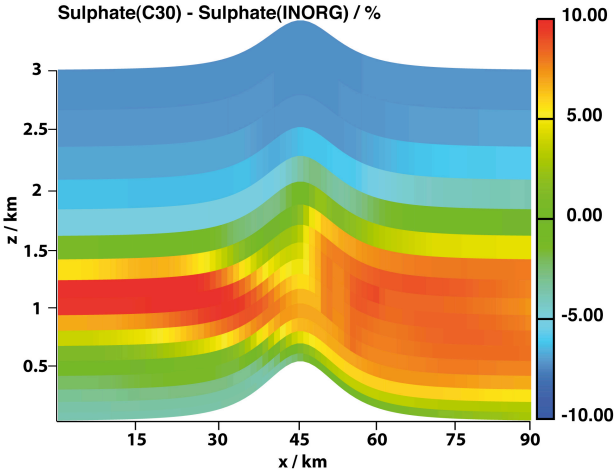

Figure 1. Height profile in x-direction of the simulated mass of S(VI) simulated with CAPRAM compared to the run with INORG. The cloud is located left of the mountain (red and yellow area). Species stream in from the left-hand side.

Simulating the impact of controlled sea salt emissions on cloud optical properties in the Southeast Pacific

K. Lundgren, T. Schad, M. Bangert, B. Vogel, A. Ferrone, and H. Vogel

Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany
Keywords: climate engineering, Southeast Pacific, cloud formation, regional modelling.
Presenting author email: kristina.lundgren@kit.edu

Currently it is discussed in which way climate change can be delayed by using different methods known under the term climate engineering. One of the suggested methods involves the controlled emissions of sea salt particles with the purpose to increase the albedo of marine clouds. Previous investigations have suggested that the Southeast Pacific is the most favourable region for climate engineering with sea salt (e.g., Korhonen *et al.* 2010). The Southeast Pacific is known to be characterised by a persistent layer of stratocumuli clouds with high coverage near the coast of Chile and Peru. The reason for its existence is a result of a highly complex chain of interactions between several processes. Due to the complexity of the system and the fact that several of the processes happen at small un-resolved scales, that need to be parameterised, atmospheric models encounter difficulties in capturing this cloud layer in a realistic way.

In this study, we investigate the impact of controlled sea salt emissions for the Southeast Pacific with the regional scale online-coupled model system COSMO-ART (Vogel *et al.* 2009). Natural sea salt emissions are calculated as function of the wind speed and sea surface temperature. For the investigation of sea salt climate engineering, we add controlled sea salt emissions to the natural sea salt emissions following Korhonen *et al*. (2010). We use detailed two-moment cloud microphysics including six hydrometeor classes (Seifert and Beheng, 2006) that are coupled to the aerosol particles by a comprehensive parameterisation for aerosol activation (Barahona *et al*., 2010). The activation parameterization accounts for the competition of different aerosol particles for water vapour during their activation and considers the effect of giant CCN such as sea salt.

The first step is to reproduce the cloud cover in the region realistically with the model. Numerical simulations are performed for a time period in October-November 2008, in which the VOCAL-REX campaign took place (e.g., Bretherton *et al.* 2010). The simulated effective cloud droplet radius is compared to the effective radius that was retrieved from satellite observations during the VOCAL-Rex campaign (Fig. 1). Apart from a region along 20°S, where a too low temperature inversion suppressed the cloud droplet formation, the simulated effective radius compares well with the observed effective radius of water. Values in the order of 13-17 µm dominate in the satellite retrieved effective radius, and the corresponding values in the simulation are approx. 11-19 µm. The artificial sea salt emissions lead to strong increases in number density in the order of 200%, below the temperature inversion. . The effect on the effective cloud droplet radius these imposed sea salt emissions will be presented at the conference.

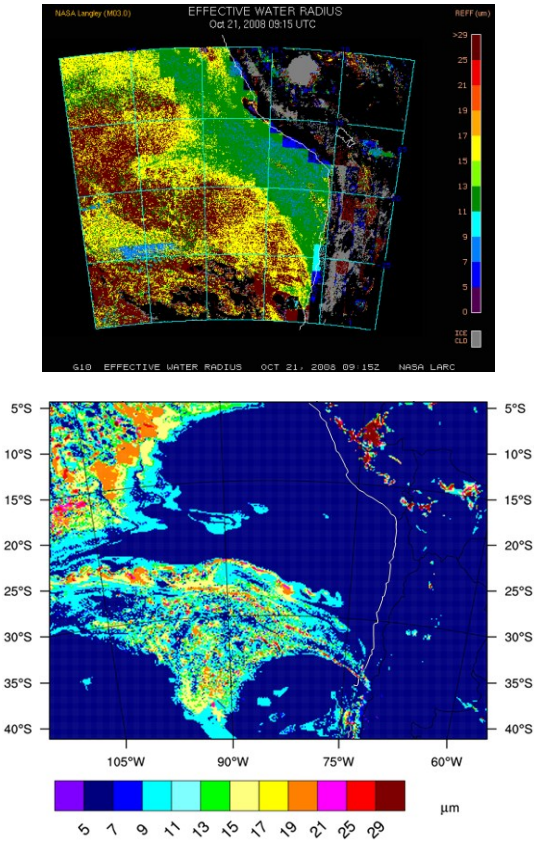

Figure 1. Observed and simulated effective radius at 21 October, 2008. Measurements are achieved from the VOCAL-Rex Field Catalog (www.catalog.eol.ucar.edu).

The Atmospheric Boundary Layer (ABL) is the lowest part of the troposphere which is directly influenced by the Earth surface. Factors like the season, the orography, the time of the day and the weather act over the ABL.

The determination of the ABL height is decisive for pollution dynamic studies and weather forecasting modelling. Radiosoundings, typically used for this purpose, are launched in a 1-2/day basis, at best. Then they cannot provide a suitable evolution of the ABL along the day.

Higher concentrations of aerosols are usually present in the ABL respect to those are in the Free Troposphere (FT). This fact is used to estimate the ABL height by means of lidar measurements. Indeed, a sharp difference in backscatter signal is found by 'crossing' from BL to FT altitude. In addition, since lidar systems can be in full-time operation, they appear to be the most appropriate instrumentation for a continuous ABL top detection.

There are different methods to calculate the ABL top height from lidar signals. They are based on two approaches: 1) the vertical distribution of the aerosol concentration, as used by the Derivative Methods (DM) (Flamant, 1997), i.e. the Gradient Method (GM) and Logarithm Method (LGM), and the Wavelet Covariance Transform (WCT) (Brooks, 2003); and the statistic analysis as used by the Centroid/Variance Method (VM) (Hooper and Elorata, 1986). A new procedure combining both these approaches is also used in this work: the Cluster Analysis (CA). The goal of this work is the comparison of the results obtained from the application of each one of those methods to lidar measurements. Differences found are analysed in order to establish the most reliable method for ABL top height determination.

Daily measurements are performed by a Micro Pulse Lidar (MPL) system in routine operation at the subtropical station of AEMET/Sta. Cruz de Tenerife Observatory (SCO, 28ºN 16ºW, 52 m a.s.l.). Raw signal profiles are acquired with 1-min integrating time and vertical resolution of 75 m. Then, these 1-min profiles are averaged over 10 minutes, obtaining thus 6 profiles/hour (144 profiles/day). This study is focused on two scenarios: dusty and non-dusty cases. An example of the ABL top height calculated by the GM, VM, WCT CA methods is shown in Figure 1 for a dusty case (9 November 2005). The same by the LGM and IPM methods is shown in Figure 2.

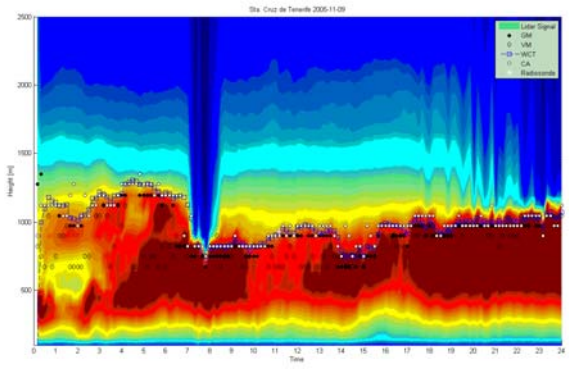

Figure 1. Daily range-corrected lidar signal on 09 November 2005, where the temporal evolution of the ABL top height calculated by GM, VM, WCT and CA methods (see legend) is shown. Radiosounding ABL estimation (11:00 UTC) is also included (white star) for reference.

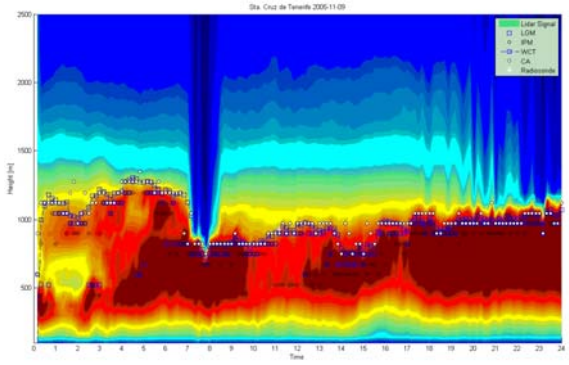

Figure 2. The same as Figure 1, but ABL top height is calculated by LGM, IPM, WCT and CA methods (see legend).

Results show that ABL heights determined by CA, WCT and LGM methods present the lowest differences respect to the radiosounding reference. VM provides a higher dispersion at the beginning and the end of the day. IPM shows, in general, lower height values than those obtained by all other methods.

The impact of the NAO on aerosol concentration levels in Europe

P. Jiménez-Guerrero[1], S. Jerez[2], J.P. Montávez[1] and R.M. Trigo[2]
[1]Department of Physics, University of Murcia, 30100 Murcia, Spain
[2]IDL, Universidade de Lisboa, Portugal
Keywords: aerosols, modeling, regional climate, NAO.
Presenting author email: pedro.jimenezguerrero@um.es

It is now widely accepted that the North Atlantic Oscillation (NAO) corresponds to the main mode of large-scale atmospheric circulation variability affecting the climate of the Atlantic and European sector. Positive phases of NAO promote the westerly winds in northern Europe and the northerly winds in the south-western Mediterranean basin. On the contrary, negative phases of NAO enhance (weaken) the zonal circulation and associated low-pressure systems in southern (northern) Europe.

Aerosols dispersion, deposition, transport and generation are intimately related to the predominant atmospheric conditions. Hence, the aforementioned NAO-impacts on climatic variables should display considerable signatures in terms of aerosols concentration levels. However, it is difficult to a priori establish them since (1) the aerosols response to the atmospheric conditions is highly non-linear, and (2) the NAO-impact on the various atmospheric variables could induce impacts of opposite signal, ones enhancing while others diminishing the concentration of aerosols. Therefore, the main objective of the present study is to characterize and quantify the NAO-impact on the aerosols concentration levels over Europe related to the well-known responses of its climate, identifying the prevailing underlying atmospheric processes.

The assessment is built on a 25-km resolution simulation performed with the CHIMERE chemistry transport model spanning from 1970 to 1999 and covering the whole European continent. The meteorological inputs were taken from a hindcasted climate simulation performed with the mesoscale model MM5 driven by the ERA40 reanalysis. The study is based on monthly values of aerosols total levels and their chemical composition. The monthly values of the NAO index are obtained from the Climate Prediction Center from the National Oceanic and Atmospheric Administration (NOAA). The analysis is mainly based on both, the correlation patterns depicting the temporal correlations between the evolution of the chemical variables and the NAO index, and the composites of the differences in the various aerosols concentration levels between positive and negative phases of NAO (>0.5 and <-0.5).

Results

The results show clearer changing signals during wintertime. A strong dipole north-south is depicted by the simulations. Months characterized with negative NAO values are associated with enhanced precipitation and positive temperature anomalies in southern Europe while northern European sectors present climatic anomalies of opposite signal. These patterns of anomalies reverse during months dominated by positive values of the NAO.

Therefore, a noticeable negative impact on ground-level aerosol concentrations (especially over southern Europe-Mediterranean area) is associated to the negative NAO phase, as clearly observed for the total levels of aerosols and most of their chemical components, such as sulphate, other secondary aerosols -not shown- and organic matter (Fig. 1). This is consequence, among others, of the higher precipitation associated to the negative values of NAO over the Mediterranean. However, this general behaviour for most aerosol species is not observed for those aerosols whose emissions depend on the wind module. The enhanced zonal circulation during negative phases of NAO promote the levels of sea salt aerosols, whose emission rate is a function of the surface wind speed raised to the power 3.41.

These results prove the structural role played by the NAO mode and would likely rebound on enhancing the short-term predictability of aerosols concentration levels over the entire European continent. Furthermore, the long-term future projections of air pollution could be reinterpreted and deeper understood taking into account these insights and possible trends in the NAO series.

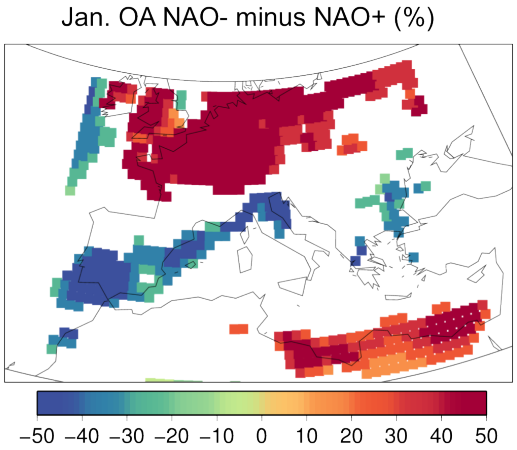

Figure 1: Difference (%) in the organic aerosols levels between January climatologies depicting NAO- minus NAO+.

Presenting author email: risto.makkonen@helsinki.fi

The biosphere emits large quantities of biogenic volatile organic compounds (BVOCs), both in terms of number of species and emitted mass. For the quantification of the indirect effect of secondary organic aerosol (SOA) it is essential to know the size-dependent partitioning of the semi- and low-volatile organic compounds. By using thermodynamic equilibrium partitioning, the organic compounds condense according to available organic mass in the aerosol phase, which can not support the observational evidence of nanoparticle growth by organics. Also, the increase in condensation sink can hinder new particle formation. While organic compounds are globally important for providing particle growth, recent observations have shown that organic compounds can also affect the atmospheric nucleation rates directly (Metzger *et al*, 2010; Paasonen *et al*, 2011). Finally, the magnitude of the indirect effect is largely determined by the spatial distribution of the cloud condensation nuclei (CCN) concentration increase and cloud cover.

We study SOA formation from BVOCs with the global aerosol-climate model ECHAM5.5-HAM2. Biogenic monoterpene emissions are distributed evenly to the boundary layer, and the oxidation products are assumed to condense to the particle phase during one timestep. The partitioning is done by using the condensation sink of the aerosol population. We study aerosol formation mechanisms including sulphuric acid only, and sulphuric acid together with organics (Paasonen *et al*, 2011). In all nucleation schemes, organics can participate in particle growth already from 2 nm size. Three SOA precursor cases are applied: no BVOCs, and emissions of either MEGAN2 or LPJ-GUESS models. The global monoterpene emission of MEGAN2 (∼80 Tg/yr) exceeds that of LPJ-GUESS (∼30 Tg/yr), but most of the emission difference is located in the tropics. Regionally, the two models vary in terms of emission rates and intra-annual variation.

Turning on BVOC emissions and SOA formation increases CCN(0.2%) in the tropics and in Northern high latitudes above 40°N. The increase is over 20% in large areas in South America and the boreal forest regions. The global increase in the CCN(0.2%) concentration due to biogenic VOCs is about 1.5% with MEGAN2 emissions and 0.5% with LPJ-GUESS emissions. At the same time, there is an increase in the condensation sink, which leads to overall decrease in the simulated nucleation rates. While the global average total particle concentration is slightly decreased, there is some increase over boreal forests where the condensation sink is still low even with BVOC emissions turned on.

The application of the two BVOC emission models allows us to study the sensitivity of the particle concentrations to the underlying assumptions of biogenic properties. The differences in simulated CCN concentrations reflect the differences in the BVOC emission: emissions of LPJ-GUESS lead to generally more CCN between 0°N and 50°N, while MEGAN2 emissions produce more CCN in the tropics and northern high latitudes. Globally, MEGAN2 emissions lead to an increase of 0.5% in CCN(0.2%) concentration compared to LPJ-GUESS emissions. In all simulations, the decrease in nucleation rates together with an increase in particle growth rates lead to mixed results regarding total particle concentrations.

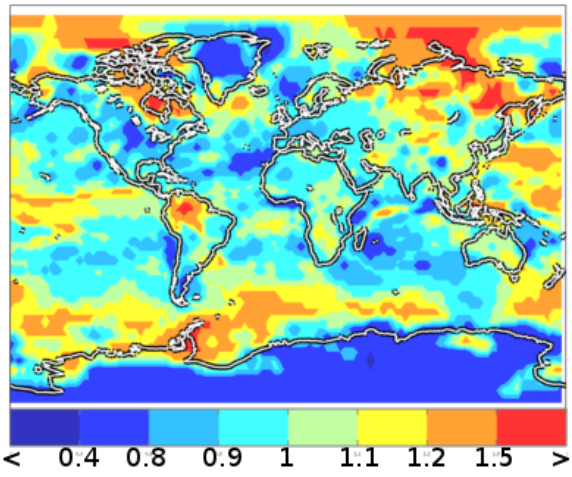

Figure 1: Ratio of CCN(0.2%) with MEGAN2 BVOC emissions to CCN(0.2%) without BVOC emissions.

Solar radiation management with high speed civil aircrafts and sulfur-enhanced fuel

Presenting author email: anton.laakso@fmi.fi

Geoengineering methods aim to increase the reflectivity of the Earth or remove greenhouse gases from the atmosphere as means to slow down global warming. One of the promising methods that have been suggested is injection of sulphate aerosols to the stratosphere. In the atmosphere, sulphate aerosols reflect solar radiation back to the space and thus cool the climate. Because of the stability of the stratosphere the lifetime of the sulphate aerosol is 1-2 years, when in the troposphere it is only a few days. Thus much smaller sulphur emissions would be required to obtain a similar cooling with stratospheric aerosol than with tropospheric sulfate aerosol.

Numerous methods have been proposed for delivering sulfate aerosol precursors. One of the methods that has been proposed but has not been sufficiently studied is using high-speed civil transport (HSCT) aircrafts and sulphur-enhanced fuel to emit aerosol precursors in a jet exhaust stream (Rasch, 2008). If aircraft fuel contained 1 weight per cent of sulfur, it would eventually generate roughly 4 Tg of sulphate aerosols. This method can be assumed to have relatively low cost since stratospheric sulfate production would be a by-product of civil air transport.

This study is performed with the global aerosol – climate model MAECHAM5.5-HAM2, a middle atmosphere version of ECHAM5.5-HAM2 (Stier et al. 2005). MAECHAM5 is integrated with a spectral truncation of 63 (T63) and 47 vertical levels up to 0.01 hPa and IPCC AR5 historic emission of air traffic has been used. For the geoengineering purpose, some of the flights are assumed to fly in the stratosphere.

Five-year long simulations have been made for six different cases: a control run for current flights and current fuel sulphur concentration and stratospheric flights with current sulphur concentration, with five times the current sulphur concentration (which is the current legal limit for aircraft fuel sulphur concentration), with 50 times the current sulphur concentration and with five times the sulphur concentration, but 5% of emissions are assumed to be converted as SO_4 (50 nm) immediately in the plume. To estimate the effect of future flight paths, we have used Representation Concentration Pathways (RCP) from IPCC Report 5 and in this case used five times the current sulphur concentration.

Results show that if stratospheric flights and current fuel content is used, the effect to the radiative forcing is insignificant. Also 5 x sulphur content has small effect to the aerosol radiative forcing, -0.11 W/m^2 by using current flight paths and -0.35 W/m^2 by using estimated air traffic for year 2050. If we enhance fuel sulfur concentration to 50 times the current concentration, the global aerosol radiative forcing at the surface is -0.9 W/m^2, but because commercial aircrafts fly mostly in the northern hemisphere, the effect of sulphate aerosols is much stronger in the northern hemisphere (-1.20 W/m^2) than in the southern hemisphere (-0.61 W/m^2). Thus if HSTC aircrafts were used for geoengineering, the aircraft fuel concentration would need to be enhanced much over the current legal limit for fuel sulphur concentration and some other delivering method would need to be used in the southern hemisphere to get similar effects for both hemispheres. If 5% of fuel sulfur emissions of the aircraft are assumed to be emitted as primary SO_4 particles, the effect to the aerosol radiative forcing is almost equal to the case where all sulphur is emitted only as SO_2.

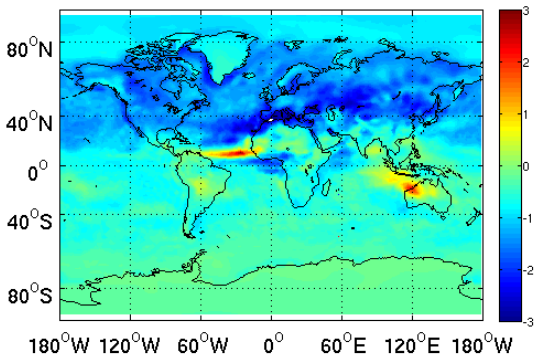

Figure 1: Radiative forcing when 50 x SO2 concentration is used

Modelling of particle number size distribution over Europe with chemistry transport model LOTOS-EUROS

Astrid Manders[1], Antoon Visschedijk[1], Hugo Denier van der Gon[1], Bas Henzing[1], Martijn Schaap[1].

[1]TNO, Department of Climate, Air and Sustainability, P.O.Box 80015, 3508 TA Utrecht, the Netherlands

Keywords: Particle size distribution, Aerosol modelling
Presenting author email: astrid.manders@tno.nl

There is a growing awareness of the significance of aerosol particles with diameters smaller than about 1 micron for human health as well as for their climatic impact. Particle number distributions are therefore gaining attention, both in measurements and modelling.

To study the particle number distribution over Europe with the regional chemistry transport model (CTM) LOTOS-EUROS, the model was extended with the aerosol dynamics module M7 which accounts for aerosol ageing effects (condensation, coagulation, hygroscopic growth) in 7 lognormal modes (Vignati et al.2004).

Model simulations with LOTOS-EUROS were performed using two different (anthropogenic) emission databases:

- MACC 2005 emissions. The first contains traditional PM2.5 and PM10 mass emissions (Kuenen et al., 2011). To be able to use these emissions, mass had to be redistributed over the species and size ranges used in M7.
- PN emissions. This database is the recently developed size-resolved particle number emission database for Europe. This database covers particles with dry diameters between 5 and 250 nm, distributed over 12 size bins (Denier van der Gon et al., 2010)

Modelling results are compared to EUSAAR SMPS/DMPS data for several European sites (Asmi et al. 2011).

Fall/winter concentrations, which are dominated by anthropogenic emissions, are modeled more realistically than spring/summer concentrations for which biogenic emissions and nucleation play a more important role. The PN inventory leads to a better correspondence with observations than the MACC inventory, showing the added value of the PN emission inventory.

In summer modeled Aitken mode concentrations tend to be underestimated as compared to measurements, in particular for the PN inventory. This may be due to a poor representation of SOA formation and an incomplete representation of SIA, combined with an underestimation of nucleation in the model.

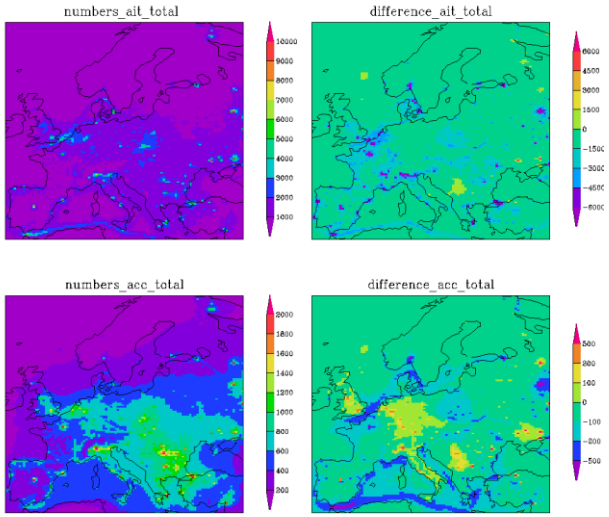

Fig. 1 Annual mean concentrations for Aitken and accumulation mode when using the PN emissions(left) and the difference with an-nual mean concentrations using the MACC emissions (PN-MACC)

Presentation

At the conference, it will be shown how the two emission databases are used in LOTOS-EUROS. The differences in the emission databases that are relevant for aerosol modeling are discussed.

Plenary 4

Secondary organic aerosol formation through aqueous chemistry: atmospheric evidence, chemistry, partitioning and prediction

B. J. Turpin[1]

[1]Department of Environmental Sciences, Rutgers University, New Brunswick, New Jersey, 08901, USA
Presenting author email: turpin@envsci.rutgers.edu

Organic aerosol, much of which is formed in the atmosphere (secondary), is a major component of fine particulate matter. The generally poor understanding of the formation of secondary organic aerosol (SOA) is a source of uncertainty in predictions of atmospheric aerosol concentrations and properties that affect climate, visibility and health. It is well accepted that SOA forms when semivolatile products of gas-phase photochemical reactions partition into preexisting particulate organic matter (SOA_{om}). SOA_{om} has been studied extensively through smog chamber experiments conducted at low relative humidity (RH). While clearly important, gas-phase chemistry and partitioning fails to explain several key atmospheric observations, including high O/C ratios, vertical profiles, correlations with sulfate and aerosol water, droplet mode size distributions, oxalate formation and formation of high molecular weight compounds (HMWC). Additionally and importantly, this chemistry does not consider the atmospheric abundance of liquid water in clouds, fogs and aerosols. For example, model predictions suggest that water is 2-3 times more abundant than all other aerosol species including organic matter, globally (Liao and Seinfeld, 2005).

In this presentation I present evidence that multiphase SOA formation involving gas followed by aqueous reactions in clouds, fogs and wet aerosols (SOA_{aq}) helps to explain these observations. I discuss chemistry leading to SOA_{aq} formation and how this chemistry is different in clouds/fogs versus in aerosols. I present information about the gas-particle partitioning of aqueous SOA products, and briefly review progress toward modeling $SOA_{aq.}$ Finally, I identify some important unresolved questions.

Gas phase oxidation of organic emissions frequently leads to the formation of smaller, more oxidized, water soluble compounds. After partitioning into water, these compounds can react further, e.g., with hydroxyl radical. The low volatility products of the aqueous reactions then remain in the particle phase, even after water evaporation, forming SOA_{aq} (Blando and Turpin, 2000).

We conducted aqueous photooxidation experiments by generating OH radicals (~10^{-12} M) in: filtered rainwater, aqueous solutions containing water-soluble gases scrubbed from ambient air, and single-compound solutions (30-3000 μM). Samples were analyzed by electrospray ionization mass spectroscopy (ESI-MS), ion chromatography (IC), IC-ESI-MS, Fourier transform ion cyclotron resonance mass spectroscopy (FT-ICR MS), and for total organic carbon. We have also taken solution from these reactions to generate and evaporate droplets using a Vibrating Orifice Aerosol Generator (VOAG). By comparing results with standards of known volatility, we determined the vapor pressure of the resulting aerosol.

Our experiments conducted with cloudwater surrogates suggest that SOA_{aq} precursors are predominantly aldehydes, organic peroxides and/or alcohols; products are predominantly organic acids. Our experiments and those conducted by others suggest that SOA_{aq} precursors include glyoxal, methylglyoxal, glycolaldehyde, acetic acid, and acetone. At cloud relevant concentrations, oxalate, glycolate and pyruvate are prominent products and the presence of sulfate and nitrate have little impact on the chemistry. OH radical chemistry in the much more concentrated solutions found in wet aerosols leads to the formation of high molecular weight compounds through organic radical-radical reactions (Lim et al., 2010; Tan et al., 2012). Non-radical chemistry can also play an important role in wet aerosols. We measured an effective liquid vapor pressure of ~10^{-7} atm for glycolaldehyde SOA (pH ~ 4) in droplet evaporation experiments. It should be noted that the volatility of SOA_{aq} will depend on whether organic acid products are present as acids or salts.

Several groups are now adding SOA_{aq} to chemical transport models. The approaches that are being taken and the insights these provide will be discussed, as will several yet unresolved questions that still hamper efforts at accurate SOA_{aq} prediction.

Introduction

Carbon, primarily a byproduct of incomplete combustion of fossil fuel and biomass burning constitute only a few % of the total PM mass, but disproportionately affect the global climate by absorbing the incoming sunlight and directly warm the atmosphere. BC coated with sulfate is even more effective than externally mixed BC and SO4 particles. Recent studies have indicated that substantial radiative forcing in the Arctic is due to the indirect impact of BC on the albedo of snow and ice surfaces. We are determining the concentrations of BC, EC, MSA, SO_4, and selected trace elements in weekly samples collected at Kevo, Finland from 1964-2010 to assess the impact of aerosols on (1) radiative forcing, (2) source regions that have contributed to the burden of BC/EC and SO4 in the Arctic region, and (3) how the regional emissions impacting Arctic have changed with time.

Methods

Samples were collected over 7 day periods beginning in October 1964 through the present in Kevo [Yli-Yuomi et al., 2003a,b], Finland in an automated system to measure airborne radioactivity. The filters from 1964-1978 have been analyzed for trace metals by neutron activation (INAA) and inductively coupled plasma mass spectrometry (ICP-MS), major ions and methane sulfonate (MSA) by ion chromatography, black carbon, and elemental carbon [Yli-Tuomi 2003a,b]. Filters after 1978 have been analyzed for total and soluble trace elements by inductively coupled plasma mass spectrometry (ICP-MS), and major ions and methane sulfonate (MSA) by ion chromatography. Black carbon, and elemental carbon were analyzed using the approach developed by Li et al. [2002]. The light absorption of each new filter was measured with a Magee OT21 transmissometer. EC was measured using a Sunset Analyzer and the NIOSH protocol [Birch and Cary, 1996].

Results and Conclusions

Figure 1 shows the annual average BC values for 1965 to 2000. The concentrations of BC aerosols during 1965 were 430 ng m^{-3}. From 1966 thru 1987 it varied from ~250 to 430 ng m^{-3}. Beginning in 1989, concentrations showed a systematic decrease to about 150 ng m^{-3}. From 1989 to 2002, the concentrations have remained between 150 and 230 ng m^{-3}. The data from 2003 to 2010 is not yet available. These data show that there was a substantial decrease in BC concentrations around the time of the collapse of the Soviet Union and the change in political systems in eastern Europe.

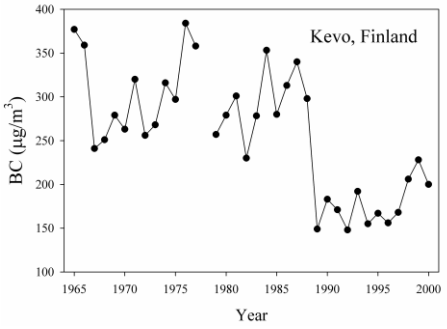

Figure 1. Time series of annual average concentrations of BC at Kevo, Finland

. The solubility of certain elements can provide information about the origin of the aerosol and formation processes. Trend analysis will be performed on individual species. The complete data set will be analyzed by Positive Matrix Factorization (PMF). The receptor modeling results will be connected with back trajectory data in a Potential Source Contribution Function (PSCF) analysis to determine possible source areas. Future work includes complete chemical analysis of the weekly filters through 2010 for trace elements and soluble trace elements by ICP-MS, major ions and methane sulfonate (MSA) by ion chromatography, and black carbon by light-absorption and thermo-optical techniques. This complete dataset will be able to provide insight into the long term trend of Arctic aerosol chemical species and the possible implications of global climate change in the Arctic.

Introduction

Atmospheric aerosol particles play an important role in climate and air quality. Except for the Aerosol Characterization Experiment 2, optical, microphysical and chemical aerosol properties were not measured simultaneously and hence aerosol characterization is incomplete in Portugal. Thus in summer 2011 an intensive field campaign was performed at Évora, Portugal.

Data and Instrumentation

The Evora Geophysics Center is operating several instruments quasi continuously since several years in order to determine aerosol particle optical and microphysical properties. A nephelometer provides the particle scattering coefficient at three wavelengths; a MAAP provides the particle absorption coefficient at one wavelength. A TEOM is used to measure the particle mass concentration. A sun photometer included into the AERONET network is measuring the aerosol optical depth and a multi-wavelength Raman lidar was operated twice a day providing the vertical profile of atmospheric aerosols.

Particles were collected on TEM grids by a cascade impactor with nominal particle diameter cut-offs at 1.8, 0.7 and 0.45, and 0.1 µm, approximately, and subsequently analysed by VP-SEM+EDS to obtain morphological and chemical compositional data Furthermore, aerosol particles were collected on 3 different types of filters (quartz fiber, PTFE, glass fiber) over 24 hours. The filter change was done about noon. Each filter was weighted with an analytical balance before and after the sampling period, providing the particle mass concentration over 24 hours. The glass fibre filters were analysed by X-ray diffraction to provide the main minerals of the sample.

Results

The main summer campaign was conducted between 9 and 28 August. In comparison to previous years, the 2011 August was cooler, and clouds were more frequent than in average. On about half of the days, typical "background" conditions could be observed: an aerosol with a comparatively constant composition, consisting of sea sea-salt, ammonium sulfates, aluminosilicates, and calcite and with a low anthropogenic fingerprint. Two outbreaks of desert dust could be observed as well. Figure 1 shows mean hourly aerosol types identified from nephelometer and corresponding to the filter sampling period.

Figure 2 shows particle mass concentrations determined from the 3 different filter types and from the TEOM. Additionally, the aerosol optical depth determined by the sun photometer is shown. A general good correlation between all measurements is obvious. During desert dust outbreaks, the particle concentration increased by about a factor of 5 in mass concentration and in optical depths as well.

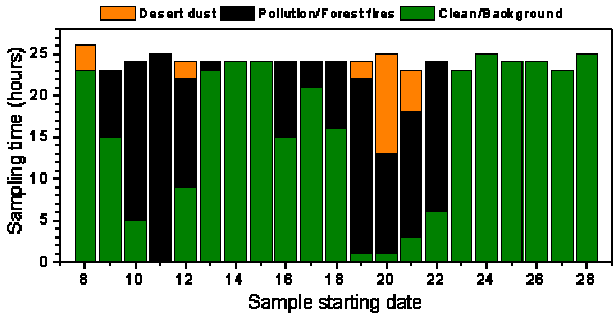

Figure 1. Aerosol types for the sampling period of the filter measurements in August.

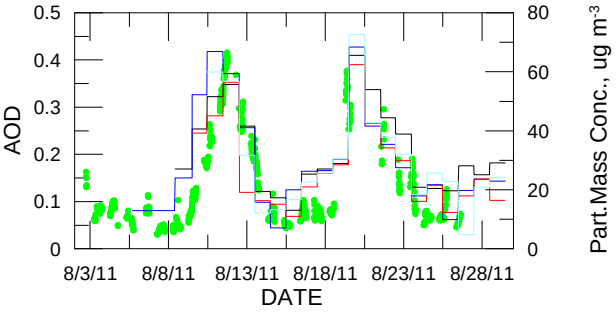

Figure 2. Particle mass concentration (black – TEOM; blue – glassfibre; cyan – PTFE; red – quartz) and aerosol optical depth (green dots) during the summer campaign

Aerosol physical and chemical properties were measured in two sites in Amazonia since January 2008. The clean site is at Central Amazonia and is located in a pristine Amazonian forest site. A second sampling site is located in Porto Velho, Rondonia, an area strongly affected by biomass burning emissions. Long term measurements, from February 2008 are being carried out in these two sites, as part of the EUCAARI (European Integrated Project on Aerosol Cloud Climate and Air Quality interactions) and AEROCLIMA (Direct and indirect effects of aerosols on climate in Amazonia and Pantanal) projects. The dataset obtained encompass the first long term aerosol measurements ever performed in Amazonia, elucidating the differences between the biogenic aerosol population naturally released by the forest metabolism and the anthropogenic aerosols.

In the pristine central Amazonia, measurements were taken at the Cuieiras forest site, tower TT34, with coordinates 2°35'40"S and 60°12'33"W, above the canopy (45m), under dry conditions (RH<40%). A MAAP 5012 absorption photometer in series with a nephelometer (TSI 3563) was used to measure aerosol absorption and scattering, respectively. Scattering coefficients were corrected for truncation errors. Observations were adjusted to 1000 mbar and 0°C. Aerosol size distributions were measure using a Lund DMPS system, as well as a TSI SMPS system. Aerosol composition, and several trace gases that helps to characterize aerosol sources were also measured.

In Rondonia, a sampling station was installed close to the city of Porto Velho, in the "Parque Natural de Porto Velho" at coordinates (8,69° S; 63,87° O). This region have with important land use change and biomass burning emissions. A MAAP 5012 absorption photometer and an Ecotech Aurora 3000 nephelometer are used to measure aerosol absorption and scattering. A TSI SMPS measure the aerosol size distribution continuously. Diffusion dryers are used to keep the relative humidity below 40%.

In the pristine Amazonian atmosphere, aerosol scattering coefficients ranged between 1 and 200 Mm^{-1} at 450 nm, while absorption ranged between 1 and 20 Mm^{-1} at 637 nm. A strong seasonal behavior was observed, with greater aerosol loadings during the dry season (Jul-Nov) as compared to the wet season (Dec-Jun). Although the forest site is locally well preserved, it receives the influence of regional biomass burning emissions during the dry season.

During the wet season in Manaus, aerosol scattering (450 nm) and absorption (637 nm) coefficients averaged, respectively, 14 ± 22 and 0.9 ± 0.8 Mm^{-1}. Both optical coefficients were greatly increased during the dry season, averaging 58 ± 58 Mm^{-1} and 4.1 ± 3.8 Mm^{-1}, correspondingly. Angstrom exponents for scattering were lower during the wet season (1.6 ± 0.4) in comparison to the dry season (1.9 ± 0.2), which is consistent with the shift from biomass burning aerosols, predominant in the fine mode, to biogenic and dust aerosols, predominant in the coarse mode. Single scattering albedo, calculated at 637 nm, did not show a significant seasonal variation, averaging 0.86 ± 0.06 and 0.86 ± 0.04, respectively for wet and dry season, even with that large variation in aerosol sources and magnitude of scattering and absorption coefficients.

In Porto Velho, even in the wet season it was possible to observe a strong impact from anthropogenic sources. Biomass burning emissions in the dry season. $PM_{2.5}$ aerosol concentrations of about 300 ug/m² were measured in August and September for most of the years. AOT values at 550 nm above 3 are frequently observed in Porto Velho with AERONET CIMEL sunphotometers. Black Carbon were measured at 20 ug/m³ in the dry season, showing strong aerosol absorption. Very high aerosol light scattering coefficients above 300 Mm^{-1} were measured.

Remote sensing techniques using a combination of MODIS and CERES sensors were used to measured large scale aerosol radiative forcing. The effect of land use change was calculated and is a significant factor for the aerosol radiative forcing due to change in surface albedo.

This work presents a general description of the aerosol optical properties in Amazonia, both during the Amazonian wet season, when the aerosol population is dominated by particles of biogenic origin, and during the dry season, when there is a strong influence of biomass burning emissions. It is important to describe accurately the optical behavior of these particles in order to assess the impact of anthropogenic changes on the regional climate.

Presenting author email: paul.zieger@psi.ch

Atmospheric aerosol particles change in size due to water uptake which is determined by their chemical composition and the ambient relative humidity (RH). As a result also their optical properties - especially the aerosol light scattering - strongly depend on RH. Therefore, long-term measurements of aerosol physical and optical properties are generally recommended at dry conditions in order to keep measurements comparable (e.g. RH < 30 - 40% as recommended by (WMO 2003)). However, for the comparison of such ground-based measurements with other optical aerosol measurements, or for the use in climate models, accurate knowledge of the RH effect is very important.

The key parameter to describe the influence of RH on the aerosol light scattering is the scattering enhancement factor $f(\lambda,RH)$, which is defined as the scattering coefficient $\sigma_{sca}(\lambda,RH)$ at a certain RH divided by the dry scattering coefficient $\sigma_{sca}(\lambda,RH=dry)$:

$$f(\lambda, RH) = \frac{\sigma_{sca}(\lambda, RH)}{\sigma_{sca}(\lambda, RH = dry)},$$

where λ denotes the wavelength. The scattering enhancement can be directly measured e.g. with a humidified nephelometer.

Here, we will present results of a one-month field campaign at the regional continental site Melpitz, Germany performed in February/March 2009. A newly developed humidified nephelometer (WetNeph, Fierz-Schmidhauser et al. 2010) was operated together with a dry nephelometer, an Aerosol Mass Spectrometer (AMS), a Multi-Angle Absorption Photometer (MAAP), a Hygroscopic Tandem Differential Mobility Analyzer (H-TDMA) and other continuous aerosol instruments.

The scattering enhancement at Melpitz was found to be highly variable, e.g. $f(\lambda$=550nm,RH=85%) varied between 1.4 and 3.5 and depended on the air mass origin. The chemical composition was the main factor to determine f(RH), as can be seen in Fig. 1, where $f(\lambda$=550nm,RH=85%) is shown versus the inorganic mass fraction (inorganic mass fraction = (NO_3+SO_4) / $(NO_3+SO_4+Org+BC)$; with BC: black carbon) retrieved from AMS and MAAP measurements. The inorganic mass fraction and the scattering enhancement are clearly positively correlated. The aerosol size distribution played a minor role on f(RH) for that specific time period. A closure study showed that a good estimate on the aerosol chemical composition or on the aerosol hygroscopicity is of importance if f(RH) needs to be predicted from other auxiliary measurements.

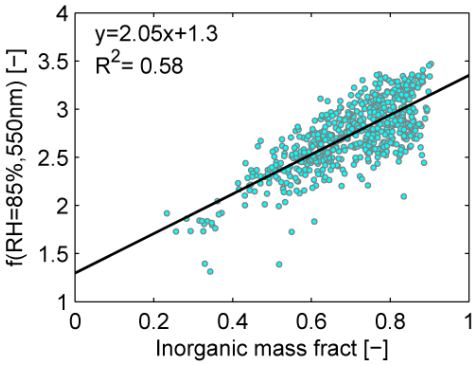

Figure 1: Scattering enhancement f(RH) (at 85% RH and λ=550nm) versus the inorganic mass fraction at Melpitz, Germany. The solid black line represents a weighted linear least squares regression.

Black carbon aerosols (BC), as a strong absorber of solar radiation, significantly constrain the radiative forcing of climate system and contribute to climate change by heating the lower atmosphere (Ramanathan and Carmichael 2008). The time scale of BC removal from the atmosphere is a crucial factor for most climate and process model input. The removal rate determines both vertical and horizontal distributions of BC, as well as its dispersion on local and regional scale. The main mechanism of BC removal is wet deposition through nucleation scavenging so becoming incorporated into cloud droplets or directly scavenged via impaction onto cloud and rain droplets. Given its initial hydrophobic properties, for nucleation scavenging to take place BC needs to acquire a more hydrophilic composition. The time scale for BC hydrophobic/hydrophilic conversion is a crucial factor to determine how efficiently BC can be removed by wet deposition. Conversion to a more hydrophilic state occurs by a variety of processes such as: condensation of hygroscopic materials from the gas phase onto BC particles; repartitioning of soluble material from other aerosol; and coagulation of BC with hygroscopic aerosol. A simplified term BC coating is invoked by most models to quantitatively determine the amount of non-BC materials that have been associated with BC particles.

The single particle soot photometer (SP2) has been used extensively in recent studies to quantitatively determine BC coating state at various locations and under different atmospheric conditions. However, the link between the BC coatings and the hygroscopic properties of BC in the atmosphere has not been explored. To explicitly answer the question of how coatings influence the hygroscopic properties of BC is crucial to further investigate how efficiently BC will act as cloud condensation nuclei and hence be removed by wet deposition.

This study was conducted at the NCAS-operated Weybourne Atmospheric Observatory (06/11-07/11). Depending on the metrological conditions, this receives the air masses from various source regions, including central England, continental Europe and the North Sea. The HTDMA-SP2 (hygroscopicity tandem differential mobility analyser) system (McMeeking et al., 2011) was used to measure the hygroscopic properties of BC and associated coating state in real time. The HTDMA selects aerosol of a specific dry size then measures the size distribution after exposing the particles to a specified elevated relative humidity, hereby deriving hygroscopic growth factors (gf). The SP2 was measuring downstream of HTDMA so sampled particles of known growth factor, thus allowing the determination of BC particle loadings, size and coating state as a function of gf. In addition, the new Soot Particle AMS (SP-AMS) measured the chemical composition of the coatings on the BC, which is also linked to BC hygroscopic properties. This study provides information on BC hydrophilic properties by direct measurement and relates the coating chemical composition of the coating to these properties.

About 15-60% of BC particles are measured to be hydrophilic during the experiment. Increased BC coating thickness was observed to increase the water uptake ability of BC, however, the actual hydrophilic fraction of BC also depended on the chemical composition of coatings. The gf of BC was observed to be enhanced when significantly coated with nitrate however less so if with the coating that was dominated by organic matter. Given that nitrate is the major constituent of secondary aerosol in polluted air masses over European, the presence of nitrate coating on BC will considerably reduce the lifetime of BC and its radiative forcing effect.

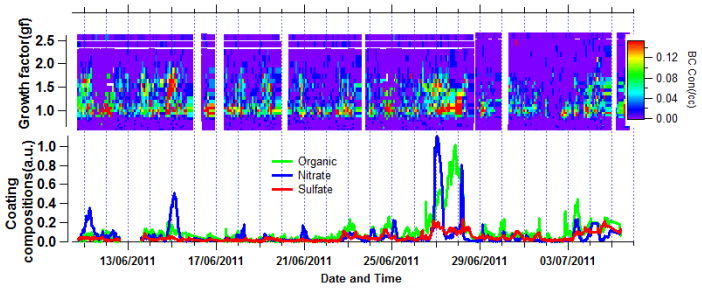

Figure 1. BC hygroscopic properties associated with coating content and compositions.

The aim of this study is to predict the size-selected composition of the nucleated nanoparticles and their ability to act as a cloud condensation nuclei. Particles were produced in CLOUD (Cosmic Leaving Outdoor Droplets) experiment, whose aim is to study possible link between galactic cosmic rays and cloud formation.

In the CLOUD experiment the atmospheric conditions were simulated in a chamber in which aerosols were formed. One can find detailed description of the CLOUD experiment elsewhere (Kirkby et al., 2011). To study the chemical composition of the formed particles and the particle-water vapour interactions we used data from hygroscopic and organic ethanol tandem differential analyzers (H- and OETDMA) (Joutsensaari et al., 2001), cloud condensation nuclei counter (CCN-c) (Droplet Measurement Technologies, Roberts and Nenes, 2005) and Aerodyne high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) (DeCarlo et al., (2006)). The smallest measured size was 15 nm for H- and OETDMA, 30 nm for CCN-c 30 nm and 50 nm for HR-ToF-AMS. For results interpretation also the gas phase chemistry studied by Proton Transfer Reaction Time-of-Flight Mass Spectrometer (PTR-TOF) and the ions composition (up to 2 nm) measured by Atmospheric Pressure Interface Time-of-Flight Mass Spectrometer (APi-TOF, Junninen et al., 2010) was used. Figure 1 illustrates the experimental system to analyze the nucleated nanoparticle properties during their growth.

From HTDMA and CCN-c measurements, we derived the hygroscopicity parameters (κ_{hgf} and κ_{ccn}, respectively) based on theory by Petters and Kreidenweis (2007). Same theory was also modified for calculating ethanol affinities (κ_{egf}):

$$\kappa_{egf} = (EGF^3 - 1) \cdot \left[\frac{1}{S} \cdot exp\left(\frac{4\sigma_e M_e}{RT\rho_e D_0 EGF}\right) - 1\right]$$

where EGF is measured ethanol growth factor, S is the saturation ratio, σ_e is the ethanol surface tension, M_e is the molecular weight of the ethanol, R is the gas constant, T is the temperature, ρ_e is the density of the ethanol and D_0 is the selected dry particles size in DMA. From HR-ToF-AMS we can derive the oxidation level of the particles and connect that to their hygroscopic properties (Massoli et al. (2010), Raatikainen et al. (2010)).

The analysis presented here will give valuable insight in the composition of the size-selected (from 15 nm) nucleated particles during their growth and further in their ability to act as cloud condensation nuclei in the atmosphere.

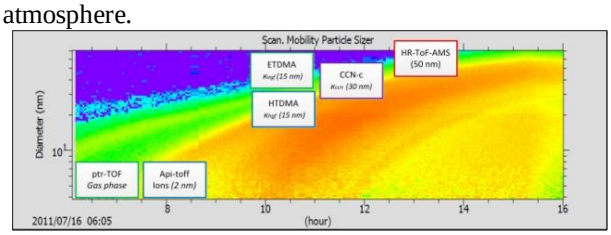

Figure 1. The experimental system to analyze the nucleated nanoparticles properties during their growth.

Hygroscopicity and cloud forming properties of Arctic aerosol during one year

S. Silvergren[1], U. Wideqvist[2] , J. Ström[2], and B. Svenningsson[1]

[1]Division of Nuclear Physics, Lund University, Lund, 22100, Sweden
[2]Department of Applied Environmental Science, Stockholm University, Stockholm, 10691, Sweden
Keywords: Arctic, CCN, hygroscopicity, aerosol chemistry.
Presenting author email: sanna.silvergren@nuclear.lu.se

The Arctic aerosol has a strong seasonal variation in terms of number concentration. During the Arctic haze from February to May, aerosol numbers increase significantly. When the sunlight returns and the precipitation start, a period of cleaner air begins which lasts until fall. Long-term aerosol measurements of hygroscopicity and cloud forming properties are scarce in the Arctic region. Previous campaign studies suggest that local production of organic rich aerosol particles occur during the summer (Leck *et al*, 2002) and model calculations have indicated that these could be important for cloud droplet formation (Lohmann and Leck, 2005). A relationship between the number of CCN and aerosol sulphate content have been shown by Bigg and Leck (2001). In addition, ice nuclei concentrations influence the CCN concentration (Lance *et al*, 2011).

We are now presenting the chemical composition, hygroscopicity, CCN activity of aerosols collected at the Zeppelin station during one year.

From September -07 to August -08 twelve filters were collected with a high-volume sampler (PM10 cut-off) at the Zeppelin station, located at 474 m above sea level on Svalbard's west coast, a site that has been assessed as virtually free from local, anthropogenic particle emissions. The chemical composition was assessed from additional small filters with OC/EC analysis and ion chromatography (IC). The results are shown in figure 1. The water-soluble fraction was extracted and analyzed with respect to the ability to interact with sub- and supersaturated water vapor. For this we used a Hygroscopic Tandem Differential Mobility Analyser (H-TDMA) coupled with one or two Cloud Condensation Nuclei Counters (CCNC).

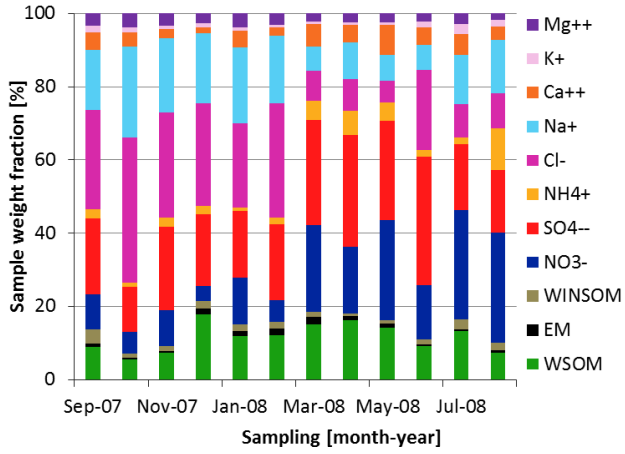

Figure 1. Chemical composition of Arctic aerosol.

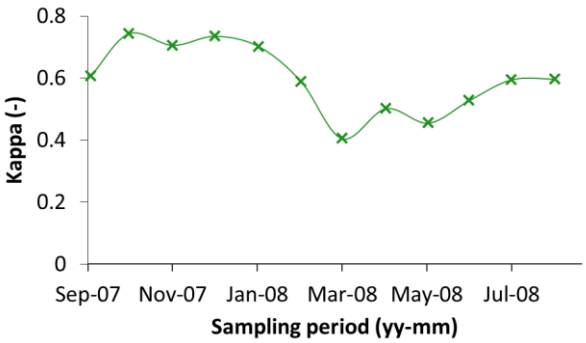

Figure 2. Annual CCN properties (preliminary results).

The kappa values derived from averaged CCNC measurements in figure 2 show that the cloud forming properties vary during the year. The fall aerosol particles are clearly more efficient CCN than the spring aerosol. Both are periods dominated by accumulation mode particles in number concentrations. The summer months have size distribution shifted to Aitken mode and these particles are slightly more favourable as CCN than spring aerosol of same size.

To investigate whether the statement that sulphate and/or organics are important for the CCN population is consistent with our results we plotted the relative amount of aerosol constituents against the kappa values. Sulphate, nitrate and ammonium had a weak negative correlation while sodium and chloride rich aerosol resulted in better CCN properties. It is not surprising that sodium chloride is efficient as CCN and is important to note that it is found mainly in coarse particles. However, in contradiction to previous findings no correlation between organic content and CCN efficiency was seen and more unexpectedly magnesium showed a slight positive correlation to the kappa value.

In addition to these results, the kappa values derived from growth factors at 90% relative humidity and a closure between chemical composition and hygroscopicity and CCNC will be presented.

Presenting author email: kirstenlieke@gmx.de

Transport by ship plays an important role in global logistics. Current international policy initiatives by the International Maritime Organization (IMO) are taken to reduce emissions from ship propulsion systems (NO and SO, primarily). However, particulate emissions (e.g. soot) from ships are yet not regulated by legislations. To date, there is still a lack of knowledge regarding the global and local effects of the particulate matter emitted from ships at sea. Particles may influence the climate through their direct effects (scattering and absorption of long and shortwave radiation) and indirectly through formation of clouds.

Many studies have been carried out estimating the mass and particle number from ship emissions (e.g. Petzold et al. 2008), many of them in test rig studies (e.g. Kasper et al. 2007). It is shown that particulate emissions vary with engine load and chemical composition of fuels. Only a few studies have been carried out to characterize the chemical composition and cloud-nucleating ability of the particulate matter (e.g. Corbett et al. 1997). In most cases, the cloud-nucleating ability of emission particles is estimated from number size distribution.

We applied measurements to characterize particulate emissions from a MAN B&W Low Speed engine on test bed. A unique data set was obtained through the use of a scanning mobility particle sizing system (SMPS), combined with a cloud condensation nucleus (CCN) counter and a thermodenuder - all behind a dilution system. In addition, impactor samples were taken on nickel grids with carbon foil for use in an electron microscope (EM) to characterize the mineral phase and mixing state of the particles. The engine was operated at a series of different load conditions and an exhaust gas recirculation (EGR) system was applied. Measurements were carried out before and after the EGR system respectively.

The measurements show significant changes in number size distribution and CCN activity with varying conditions. Results of transmission electron microscopy revealed salt condensates of nanometer size attached to soot particles. High resolution structural analysis of single particles shows that three different phases (graphitic soot, crystalline salt and amorphous condensed organic matter) may be present in the same particle volume. A closure between CCN activation curves, EM samples, and SMPS size distribution will be presented and used to identify climate active parts in single particles.

Session WG04S1O. Combustion and industrial aerosols

Results and experience of long-term study of reduction of fine particle emissions from wood combustion boiler by a compact electrostatic precipitator

A. Bologa, H.-R. Paur and K. Woletz

Institute for Technical Chemistry, Karlsruhe Institute of Technology
Hermann-von-Helmholtz-Platz 1, Eggenstein-Leopoldshafen, 76344, Germany
Keywords: biomass combustion, fine particles, emission control, electrostatic precipitator.
Presenting author email: andrei.bologa@kit.edu

In the Europe the combustion of wood is widely used for domestic heating. The power generation is mostly done by means of combustion of wood-logs, chips or pellets in small scale combustion appliances, e.g. stove and boilers.

Wood combustion it is responsible for emissions of fine particles which are associated with various diseases. Usually particles are composed of ash, elemental carbon and organic matter and particle chemical composition, particle size distribution, number and mass concentration vary greatly depending on the design of the boiler, fuel quality, mixing of air and fuel, combustion temperature, etc.

Last time various filter systems were developed for reduction of fine particle emissions from small scale biomass combustion. These devices include cyclones, wet scrubbers, condensers, bag filters, cartridge filters, electrostatic precipitators (ESPs'), etc. The electrostatic precipitators are the most attractive devices as they ensure high mass collection efficiency and are operated at low power consumption and low pressure drop in comparison with other gas cleaning equipment. The design of the ESPs' range from conventional to space charge ESPs', from dry to wet units, from precipitators integrated into the combustion appliances up to the ESPs' installed downstream the combustion units, inside of the gas duct and/or chimney and at the exit of the chimney.

By biomass combustion in the boilers with integrated hear exchangers, the electrostatic precipitators are operated at gas temperatures of 100-200°C and for wood-log stoves up to 300-400°C.

The purpose of the current work is to present the results of the study of reduction of fine particle emissions from a 100 kW wood-combustion boiler by use of the CAROLA electrostatic precipitators.

The CAROLA electrostatic precipitators are developed in the Karlsruhe Institute of Technology in the Institute of Technical Chemistry. In the ESPs' the gas cleaning technology is based on the particle charging in a corona ionizer and charged particles precipitation in the grounded, external electric field free collector. The DC negative corona discharge is used for particle charging in the precipitators (Bologa *et al*, 2010).

For effective reduction of fine particle emissions from the exhaust gas, the compact CAROLA-precipitators are designed for boilers with capacity of 10 kW, 25 kW and 50 kW. For the long-term tests, several electrostatic precipitators were manufactured and installed in parallel downstream the 100 kW wood-chips combustion boiler. The purpose was to study the long-term operation stability of the ESPs', power consumption and the mass and fractional collection efficiency of the precipitators.

The particle mass concentration in the gas flow upstream and downstream of the ESPs' was measured by gravimetric method according to the German norm VDI 2066. For the measurements of particle number concentrations in the gas flow, the Scanning Mobility Particle Sizer (SMPS, Fa. Grimm) was applied.

The stability of the operation of the precipitator was ensured by the protection of the high voltage insulator with a screen electrode from the direct particle loaded gas flow. The ESPs' were operated without any additional air input for the high voltage insulators protection from loading with fine particles (Bologa *et al*, 2011).

The CAROLA-precipitators were operated with relatively small electrode gaps in the ionizer at maximum operation voltage of 20 kV and corona current of 1,5 mA. Thus the designed precipitators were characterized by the low power consumption.

The designed CAROLA-electrostatic precipitators are the space-charge ESPs' in which particles are precipitated on the surface of the grounded brush electrodes installed in the collector stage of the unit (Bologa *et al*, 2012). A single brush electrode is currently used in the ESP modules up to 25 kW boiler and double brush electrodes are used in the ESPs' for the boilers with capacity of 50 kW. In the designed modules, the automatic cleaning of the collector stage is realised by the periodical rotation of the brush electrode(s).

Among the control of fine particle emissions, in the current work it is planned to discuss the results of the measurements of the gaseous emissions from the wood combustion boiler and the possibilities for their reduction.

Significant amounts of transition metals such as Zn can be enriched in fine particle fraction in biomass combustion. A hypothesis exists that these metals may have an important role in the toxicity of particulate matter (PM) (Fernandez et al. 2001). However, the influence of the metals on toxicity of PM is not clear. In this study the fuel chemical composition was altered in order to enrich Zn fraction in PM. The aim of this study was to find out Zn behavior in biomass combustion and its role on toxicity of PM_1 (particle aerodynamic diameter <1 µm).

The fuel pellet was doped with Zn so that the concentrations were estimated to be 200, 500 and 2500 mg Zn/kg fuel. Also the reference pellet, which Zn concentration was not altered, was used. In addition, one experiment where the combustion conditions were intentionally degraded was made with 200 mg Zn/kg pellet. The combustion appliance was a pellet boiler (25 kW). Gaseous emissions were measured with FTIR (Gasmet technologies) from the stack. PM_1 samples for toxicological and chemical analyses were collected with Dekati Gravimetric Impactor (Dekati) and PM_1 samples for OC/EC analyses with filter holders (Gelman Sciences 2220) from diluted flue gas. Particle emissions were also measured with on-line measurement instruments: ELPI (Dekati), SMPS (TSI) and TEOM (Thermo Scientific).

The analyzed fuel Zn concentrations are presented in Table 1. With increasing fuel Zn content the size of the fine particles was found to grow and the particle number concentration to decrease. PM_1 emissions were found to increase as the fuel Zn content increased. CO and NO_x were found to decrease as the Zn concentration in the fuel increased.

Table 1. CO, NO_x and PM_1 emissions and GMD results with different Zn concentrations in the fuel

mg/MJ	11 mg/kg (reference)	170 mg/kg poor	170 mg/kg	480 mg/kg	2300 mg/kg
CO	74	340	48	52	41
NO_x	43	30	26	30	19
PM_1	12	42	20	24	57
Zn in PM_1	0.11	2.6	3.2	8.3	48
K in PM_1	2.2	2.6	2.6	2.0	1.7
GMD (nm)	62	129	87	89	145

The studied samples from Zn doped pellet and reference pellet combustion induced a dose-dependent decrease in cell viability (MTT assay). All samples had statistically significant decrease with all doses compared to the control (Fig. 1). Even the reference sample clearly caused cytotoxic effects. However, with the samples where Zn was added the toxicity was more severe.

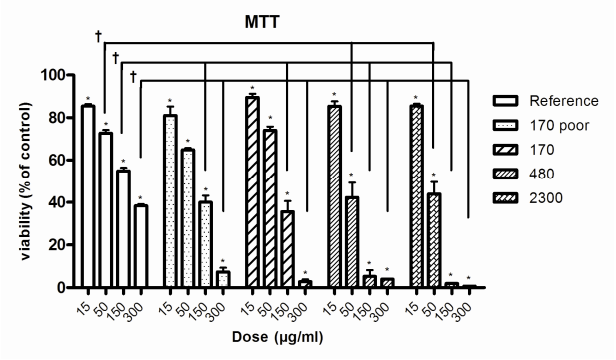

Fig. 1. Viability of RAW264.7 macrophages after exposure to four doses (15, 50, 150 and 300 mg ml^{-1}) of cell medium suspended particles emitted from a pellet boiler (the mean SEM). Asterisks (*) indicate a statistically significant difference from control cells as presented 100 % ($p < 0.05$, Dunnett's test), and crosses (†) denote statistically significant difference between the corresponding doses of the particles from the reference pellet and Zn doped pellet combustion ($p < 0.05$, Tukey's test). n=6 in total.

No major differences between the smallest doses were detected when the Zn doped samples were compared to the reference sample. However, with the 50 µg/ml dose the samples 480 and 2300 had statistically significant difference compared to the reference sample. With the 150 and 300 µg/ml dose all Zn doped samples had statistically different effect to cell viability when compared to the reference sample.

Results indicate that Zn can be one factor of the PM_1 induced health effects in biomass combustion. However, detected cytotoxic effects cannot be entirely explained by the PM_1 Zn content.

Comparison of particle concentrations measured direct from hot flue gas and diluted sample gas from wood combustion

J. Tissari[1], H. Lamberg[1], O. Sippula[1], J. Jokiniemi[1,2]

[1]Department of Environmental Science, Univ. of Eastern Finland, P.O. Box 1627, FI-70211 Kuopio, Finland
[2]VTT Technical Research Centre of Finland, P.O. Box 1000, FI-02044 VTT, Espoo, Finland
Keywords: Aerosol sampling, Dilution, Wood combustion, Fine particles
Presenting author email: jarkko.tissari@uef.fi

Residential wood combustion (RWC) for heat production has been found to be a major source of e.g. fine particle mass emissions, but also polyaromatic hydrocarbons and several gaseous pollutants throughout Europe. The Air Quality Directive (2008/50/EC) sets stringent requirements on maximum levels of particle matter in the ambient air and thus, also stringent emission limits for RWC appliances have been recently set in different countries. However, there are significant problems in executing of emission reduction actions, because in RWC the obtained emission factor and chemical composition of the particle mass is strongly dependent on the measurement technique used. The most important question is, whether the sampler collects organic material or not. In many standard measurements, the particulate mass emission is measured directly from hot flue gas which gives too low emission factor because organic vapours partially penetrate the filter in a gaseous form. Because different measurement methods are used within Europe and national emission limit values are strongly connected to the measurement method, comparison of different methods and finding of relevant methods to determine particle matter emissions from RWC appliances is needed.

In this study, two different measurement methods were compared in two types of masonry heaters. In the conventional masonry heaters (CMH) there was no air staging (led to high organic emissions) while in the modern masonry heaters (MMH) the air supply was divided to primary air and secondary air (low organic emissions).

The PM (dust) samples were collected directly from the hot flue gas according to the EN 13284-1 standard. The fiberglass filters were heated before and after the sampling at temperature of 160 °C, stabilized for 4 h in desiccator and were weighed using a balance of 1 mg sensitivity. For fine particle measurements, a partial sample flow from the stack was led to the two step dilution system (Tissari et al., 2007) with porous tube diluter (PRD) and ejector diluter (ED). The PM_1 samples were collected on filters from diluted gas using a pre-impactor and the filter holders. The PM_1 samples for gravimetric and elemental analyses (IC, ICP-MS) were collected on Teflon membrane filters and for organic (OC) and elemental carbon (EC) analysis on quartz fiber filters. Also particle number emissions, number size distributions and mass size distributions were measured. The gaseous compounds were measured continuously with an analyzing rack for CO, CO_2, NO_x and O_2 and the organic gaseous substances (OGC) with a flame ionization detector.

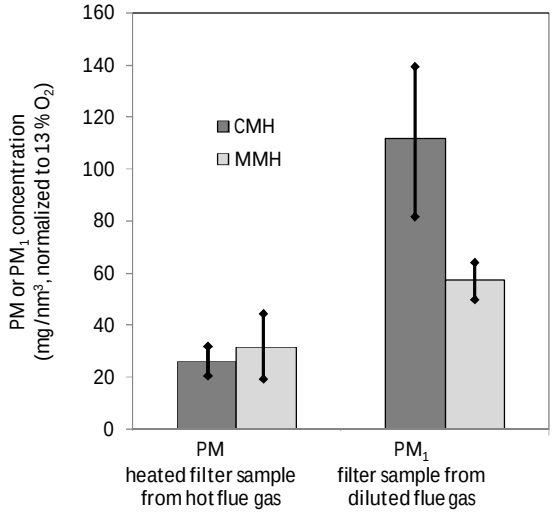

Fig.1. Comparison of PM and PM_1 measured from hot and diluted flue gas.

Table 1. OC, EC and fine ash concentrations in CMH (n=2) and MMH (n=5) appliances (mg/m^3, norm. to 13 % O_2 ± standard deviation) measured from diluted gas.

	OC	EC	Fine ash
CMH	60±20	50±30	3±2
MMH	20±7	33±8	3.4±1.1

PM_1 concentration (diluted and weighed sample) was 1.1 to 4.4 –fold as compared to total PM concentration collected from hot flue gas (Fig. 1) and it was not connected to the combustion quality (Table 1). The PM had also relatively large variation which can be due to several reasons. First, there were losses in the PM sampling, because rinsing of the sampling probe was not performed and the filters were heated after the sampling. Second, random existing of coarse particles in the flue gas is depending more on appliance structure and flow rates in the firebox than combustion conditions. Thus, the results indicate that particle emission measured from diluted flue gas is better connected to combustion efficiency i.e. highest PM_1 emissions with highest CO, OGC, EC and OC levels.

Continuous flow reactor for a defined measurement of the SOA formation potential of wood burning emissions

A. Keller, H. Burtscher
Institute for Aerosol and Sensor Technology, University of Applied Sciences Northwestern-Switzerland,
5210 Windisch, Switzerland
Keywords: SOA (Second. Organic Aerosols), Wood Combustion, Emissions, Measurement (characterization).
Presenting author email: alejandro.keller@fhnw.ch

Wood burning emissions, specially emissions from small combustion installation (SCI), contribute largely to the environmental particulate matter pollution. Current legislation considers only the control of primary particulate matter emissions and carbon monoxide. However, wood burning also produces organic gaseous carbon (OGC), that undergoes photooxidation and aging in the atmosphere and forms particles referred to as secondary organic aerosol (SOA, Grieshop et al., 2009; Heringa et al., 2011). Ambient measurements also show the importance of the organic fraction, which can reach values over 80% and become by far the single largest contributor to ambient anthropogenic particulate matter pollution (Szidat et al., 2007). For these reasons, it is desirable to monitor and limit the emissions of OGC and, ideally, base this control on its SOA production potential. There is however no standard tool for that.

We present a compact photo-oxidation continuous flow reactor as a conditioning system for real time monitoring of the SOA production potential of SCI. The SOA produced in our reactor can be measured using standard aerosol monitoring devices. We have tested our method using the gas phase emissions from different residential wood burning installations. The SOA production of our reactor expressed as an emission factor, in terms of SOA mass per emitted CO_2, closely matches the values found in the literature for smog chamber experiments. A short residence time of the order seconds allows us to give a time resolved picture of the emissions (see, e.g., figure 1).

The question of dimensioning the system in terms of requirements for light intensity, residence time and dilution is not trivial. If the system is not well dimensioned, a low OGC concentrations could result in a reduced SOA production rate whereas high OGC concentrations may not be completely transformed inside the reactor. Both cases will result in an underestimation of the SOA production potential.

We will present experiments using different wood burning devices, settings for dilution and residence time, and various UV wavelengths. Our results suggest that it is not enough to measure OGC or CO to establish the potential SOA formation. However, a photo-oxidation continuous flow reactor could be incorporated in type approval testing and emission control measurements as a way of including SOA in the legislation for emission control of SCI.

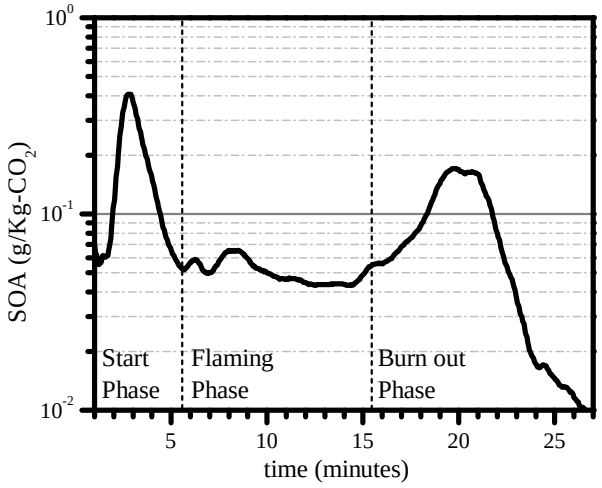

Figure 1: Time resolved SOA emission factor for a cold start from a log-wood stove as measured after a 3 second exposure to UVC followed by 3 seconds exposure to UVA.

This research was supported by the Swiss Federal Office for Energy (SFOE), the Swiss Federal Office for the Environment (FOEN) and the IMBALANCE project of the Competence Center Environment and Sustainability (CCES) from the ETH Zurich.

Brown carbon (BrC) originating from biomass combustion is very relevant in terms of health and climate. Light absorbing carbonaceous aerosols in general and black carbon (BC) in particular are all products of incomplete combustion. Optical methods are used for their detection and increased absorption in the short wavelength region (relative to black aerosols) is interpreted as presence of BrC.

We used an aerosol generator (CAST propane flame burner) as a source of aerosols, together with on-line measurements (Aethalometer Model AE31; TSI nephelometer 3563) and off-line measurements, performed on quartz fiber filters. The CAST burner was used as a model for combustion of carbonaceous fuels with varying ratio between the carbon in fuel and oxygen, available for combustion (C/O ratio). The study used a two component model to identify BrC and BC contributions to absorption, the Aethalometer model. The different wavelength dependence of the BC or BrC absorption coefficient (b_abs,i), proportional to $\lambda^{-\alpha(i)}$ (where λ is the wavelength and $\alpha(i)$ is the absorption Angstrom exponent of $i=BC, BrC$) was used to discriminate between BrC and BC (Sandradewi et al., 2008):

$$b_{abs}(\lambda) = b_{abs,\,BrC}(\lambda) + b_{abs,\,BC}(\lambda) \qquad \lambda = 470\ nm,\ 880\ nm \quad (1,2)$$

$$\frac{b\_abs,BrC(470)}{b\_abs,BrC\ (880)} = \left(\frac{470}{880}\right)^{-\alpha(BrC)} \quad (3)$$

$$\frac{b\_abs,BC(470)}{b\_abs,BC\ (880)} = \left(\frac{470}{880}\right)^{-\alpha(BC)} \quad (4)$$

We assumed the Angstrom exponent of pure BC α_{BC}=1, while α_{BrC} = 4.56 was determined from the experiment data, assuming that in the experiment with C/O=0.6, only BrC was generated (see Figs. 1 and 2). Values for $b_{abs,BrC}(470)$, $b_{abs,BrC}(880)$, $b_{abs,BC}(470)$, and $b_{abs,BC}(880)$ were computed with equations 1-4, using experimental data.

High α-values, up to six, were observed in the conditions with C/O ratio 0.60, in measurements with C/O ratio 0.21 we observe α value with values between 1.2 and 1.8. Contributions of BC and BrC for different values of C/O ratio were determined, two extreme examples C/O=0.21 and 0.6 are shown on Fig. 2. We see that for combustion conditions with high C/O, absorption from BrC dominates and can even surpass the BC absorption at low C/O conditions.

Biomass combustion in simple stoves, open fireplaces and forest fires also takes place at unfavorable C/O values. In our model we show that the absorption of BrC in such combustion processes needs to be taken into account when modeling climate effects of biomass combustion.

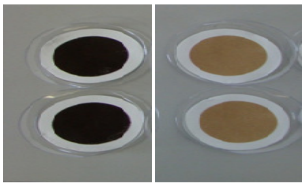

Fig. 1: Filters after sampling the exhaust air of C/O ratio 0.21 (left) and C/O ratio 0.60 (right).

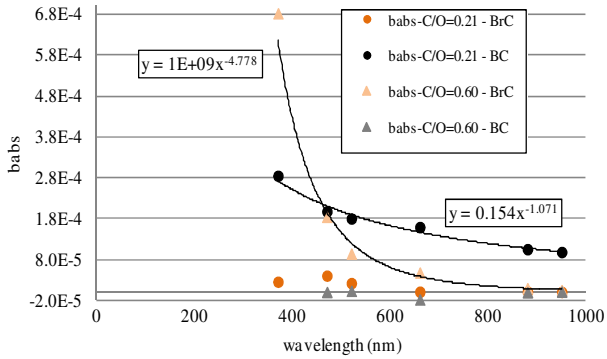

Fig. 2: Scatter plot of $b_{abs,BrC}$ and $b_{abs,BC}$ (1/m) at C/O ratio = 0.21, and of $b_{abs,BrC}$ and $b_{abs,BC}$ at C/O ratio = 0.6.

A big number of studies have showed the risk for the health and the environment of the fine and ultrafine particles issued from industrial sources. But this effect is not only due to the size of particles but also to their chemical composition by to the presence of specific toxic elements, as heavy metals. The metals are emitted both in elemental and compound (organic and inorganic) forms from many industrial process, that include among others the foundries.

These metallurgical processes represent one of source of the particles, and information regarding these emissions, including particle size distribution and metal partitioning between different particle sizes are likely important parameters to take into account in order to establish strategies to control the emissions.

In this study, the emissions of four sectors of Spanish metallurgy were investigated, zinc, copper, aluminium and steel and as part of it is included the distribution of metals by particle size in the emissions from fusion process. A total of 31 individual measurement results were obtained.

Table 1. Installations analyzed in this study.

Metallurgy		Nº of Installations
Primary º	Aluminium	3
	Copper	1
	Zinc	1
Secondary	Aluminium	13
	Copper	4
	Steel	7

Sampling and measurement was carried out in accordance with US EPA 201A and VDI 2066/5 procedures using three types of cascade impactors: Mark III and DEKATI 30LPM or KS207 Kalman System GMBH. The samples of collection substrates were chemically analyzed according to method EPA IO-3.1 as previous step to the determination by ICP-OES and/or ICP-MS and FAAS

Mass of particle and heavy metals, which apply a minimum threshold for releases to the atmosphere according to European Pollutant Release and Transfer Register (E- PRTR) were determined. Four ranges of particle aerodynamic diameter were analyzed, dp (in microns): dp>10, 10>dp>2.5; 2.5>dp>1; dp<1 and consequently PM10, PM2.5 and PM 1 could be studied.

The relationship between the mass of particles of a certain size (PM1, PM2.5, PM10) to the mass Total Particulate Matter (TPM), as well as the relationship between the mass of each metal found in a range of size and its total mass, are compared.

As an example, the results corresponding to PM1 size range are showed below. *(Specific values are avoided due to confidentiality agreements)*.

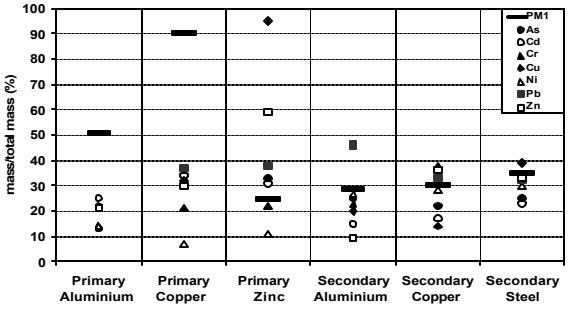

Figure 1. Ratio PM1/TPM and mass ratio of metal in PM1 to metal in TPM, versus foundry type.

In this size interval, the relation PM1/TPM varies in a wide range and you can see an enrichment or impoverishment of metals in this particle size depending on type of foundry. So in most of smelters, metals do not enrich PM1 particles, except for the primary zinc and secondary cooper foundries.

Knowledge of the distribution of heavy metals by size would allow perform a selective separation of particles containing metals of particular interest, either for its high toxicity or for being catalyst in the formation of other pollutants. This implies progress in the design of advanced systems for the control of emissions, based on the one hand in the multifunctionality of the equipments and on the other one the adaptation of emissions to separation and filtration conditions.

Coagulation of Combustion-Formed Nanoparticles in Medium Temperature Regime

M. Sirignano, and A. D'Anna
Department of Chemical Engineering, University of Naples, Naples, Italy
Keywords: nanoparticles, coagulation.
Presenting author email: marianosirignano@yahoo.it

Coagulation of combustion formed nanoparticles is a key issue in combustion and aerosol science (Smoluchowski, 1916, Bockhorn *et al*, 2007). It is widely known that this process controls the size distribution of the particles emitted from combustion sources and their evolution in the atmosphere.

Many insights have been gained on particle coagulation from in-situ optical measurements and on-line differential mobility analysis of the particles formed in combustion at high temperatures. Experiments have shown that nanoparticles with sizes lower than 10nm have a very low coagulation rate at flame temperatures with respect to that estimated by the gas-kinetic theory, allowing them to long live in the exhaust of combustion systems and be emitted and diluted in the atmosphere before coagulation occurs.

Experimental data have driven modelling attempts to determine the coagulation efficiency mostly based on the long-range interactions between colliding particles, their size and composition (Hamaker, 1937, D'Alessio *et al.,* 2005).

The temperature regimes of combustion plumes, i.e. conditions in which particle coagulate before being diluted and emitted in the atmosphere, are significantly different from flame temperatures as well as ambient temperature and particle coagulation in such conditions has never been measured. The aim of this study is to experimentally study the process of particle coagulation in temperature conditions (intermediate) typical of the plume of combustion devices. To this end a tubular reactor with a residence time of 1.65s, which can be operated at different temperatures up to 650K, is used. Particles, generated by premixed ethylene/air flames with equivalence ratios across the soot threshold limit, are fed to the tubular reactor allowing them to coagulate. The wide range of equivalence ratios used allows us to produce particles with very different size distributions, concentrations and chemical and morphological characteristics.

The evolution of the size distribution functions of the particles for effect of the change of the reactor temperature is measured by a differential mobility analyser with high sensitivity in the 2-100nm size range.

Particles exhibit different coagulation efficiency for the different operating temperatures. At room temperature, 2nm particles coagulate forming particles as large as 10-20nm, whereas at higher temperatures, particles size distribution does not change with respect to that measured at the entrance of the reactor. This turns in very ineffective coagulation. Larger particles (sizes larger than 10nm, do not exhibit high sensitivity to temperature, maintaining very effective coagulation efficiencies in the entire temperature range investigated.

Numerical simulations have been performed and a size dependent coagulation efficiency retrieved. The results confirm the also at low and intermediate temperature regimes, the use of a size dependent coagulation efficiency expression is mandatory to match the evolution of the particles during coagulation.

Additional information has been obtained on homogeneous and heterogeneous condensation of large polycyclic aromatic hydrocarbons by adding them in the tubular reactor in order to simulate exhausts conditions more similar to real systems. These latter results open the sight on a formation pathway that can be fundamental in certain flame conditions and in the post combustion zone of real combustion systems.

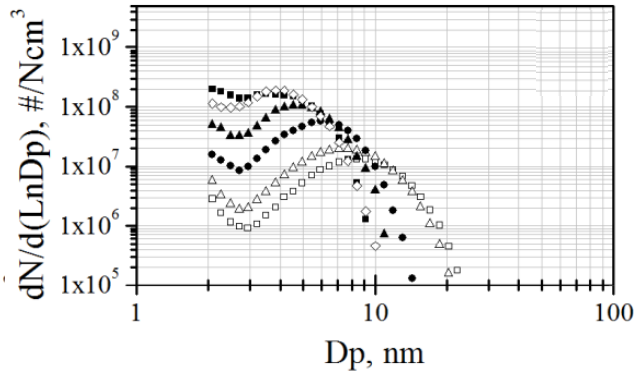

Figure: Evolution of the size distribution of particles generated in flames for fixed residence time (t=1.65s) and different temperatures in the reactor: inlet conditions (300K, t=0s (■), and 300K(□), 400K(△), 500K(●), 600K(▲), 650K(◇), t=1.65s.

Nucleation and growth of welding fumes on the vicinity of the welder: Implications on health effects assessment and protection strategy

Marroquin ML[1], C. Gutierrez-Canas[1], Egizabal[2], Aragon G. [1], Mugica I. [1], Casas N. [1], Flor B. [1] and Larrion M. [1]

Keywords: Welding fumes, nanostructure, nucleation, health effects.
Presenting author email: cristina.gutierrezcanas@ehu.es

Exposure to welding fume has been associated with both pulmonary and systemic health endpoints (Antonini, 2003). This has strong implications on booth design and protective equipment/materials. Regulations in industrialized countries specify a limit for total welding fume, e.g. 5 mg/m3 (TWA). Not very often, limits are identified for particular metals. The carcinogenic activity of welding fumes has usually been related exclusively to chemical features, in particular to the amounts of Ni and Cr in the bulk sample (McNelly *et al*, 2004). However, this approach does not take into account other important features, such as the structural distributions of metals or the surface characteristics (Moroni *et al*, 2009).

For both spatial and temporal variability are significant, a consensus about sampling strategies is crucial, probably depending on the intended results. (Lee *et al* 2007) report size distributions at different locations (Horizontal welding), concluding on differences of up to 3 orders of magnitude in the size range of 100-200 nm.

Earlier works study the temporal and spatial variability within experimental booths (Zimmer *et al*, 2001) and physicochemical characterization of fumes (Moroni *et al*, 2009). As stated in (Zimmer *et al*, 2001) "The arc welding aerosol is similar to a combustion aerosol and will be significantly altered with respect to where it is sampled". Therefore, the main aims of this work are: a more deeper understanding of the influence of welding process on aerosol characteristics and the study of the evolution of undisturbed.

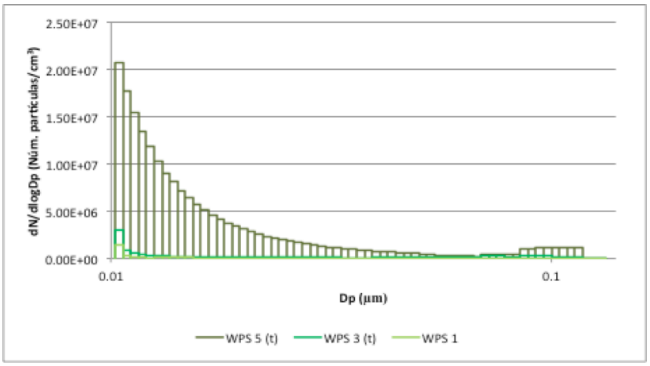

Figure 1. Mobility diameter distribution (as measured by scanning –WPS, MSP Corp) of the undisturbed plume, measured at 1,3 and 5 meters far from the welder.

Sampling and analytical methods have been described elsewhere (Gutierrez-Canas *et al*, 2011). To evaluate the gas to particle conversion rates, three SMPS systems (Figure 1) operate at fixed positions (1, 3 and 5 m far from the welder). Here are presented results for stainless steel welding (SS x5 Cr Ni 18 10) and two different welding processes: MIG (Metal Inert Gas) and SMAW (Shield Metal Arc Welding). Cascade impactors were used to collect size-seggregate samples. A MOUDI (MSP Corp) was used to collect the samples for toxi- and cito- analysis, whereas a HFI (MSP Corp) was used to collect samples for further elemental (ICP/MS) and mineralogical (XRD) analysis. TEM grids were located directly on a NAS (TSI Inc.) at different positions.

Welding procedure has been established as a critical factor for aerosol physics and chemistry. Figure 2 shows an example: whereas SMAW aerosol consists of spinel-like oxides formed during cooling and agglomerates of magnetite-like particles, MIG aerosol is structured by multiphase aggregates of globular to plate-like crystals characterized by variable amounts of different metals and slag-forming elements.

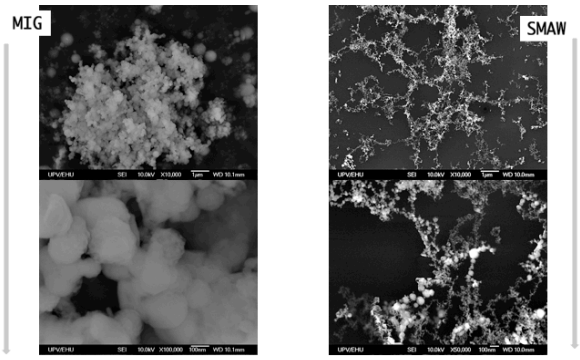

Figure 2. SEM images of stainless steel fume. (Left) Using a flux (Right) Using a inert gas shielding.

Chemical (speciation of toxics) and toxicological data will be discussed as size-seggregated ones.

WG05S2O. Carbonaceous aerosol and wood burning contribution to PMx

Levels of carbonaceous aerosols in remote, rural, urban and industrial sites of Spain

Querol X.[1], Alastuey A.[1], Viana M.[1], Moreno T.[1], Reche C.[1], Minguillón M.C.[1], Ripoll A.[1], Pandolfi M.[1], Amato F.[1], Pérez N.[1], Pey J.[1], Cusack M.[1], Vázquez R.[1], de la Rosa J.[2], Sánchez de la Campa A.[2], Rodriguez S.[3], Pío C.[4], Alados-Arboledas L.[5], Titos G.[5], Atíñano B.[6], Salvador P.[6], García Dos Santos S.[7], Fernández Patier R.[7]

[4.] Aveiro University, Portugal. [5.] University of Granada, Spain. [6.] CIEMAT, Madrid, Spain. [7] Instituto de Salud Carlos III, Madrid, Spain.

The objectives of this study is interpreting the time and spatial variability of ambient air levels of particulate non mineral carbon (nmC), organic and elemental carbon (OC and EC) and BC in rural/remote, industrial, urban and traffic environments across Spain. To this end data obtained with similar methods in 72 monitoring sites across Spain in the period 1999-2011 is compiled and interpreted. Major focus on: a) Mean concentration ranges for nmC, OC, EC, BC reached in the above environments; b) Inter-annual and seasonal trends; c) OC/EC ratios; d) BC/EC ratios; e) possible origins of OC and EC. We obtained data on nmC from 72 monitoring stations across the Iberian Peninsula (IP), the Balearic and Canary Archipelagoes and the Spanish Northern African territories. For OC and EC we obtained data from 32 sites. The determinations were carried out in PM10, PM2.5 and PM1 samples. Below are summarized the sites from which we obtained Cnm, **OC/EC and BC** levels (**the two latter in bold and bold underlined letters,** respectively):

- 2 remote sites at NE Iberian Peninsula (**Monstec**) and the canary Islands (**Izaña**)
- 9 rural/regional background sites in the IP, including **Montseny, Monagrega**, Bemantes, El Perdón in the northern part of the IP Cortijo Endrinales, **San Jorge** in the central IP and Matalascañas, Valverde and Campillo in SW IP.
- 8 industrial-rural or industrial-suburban sites including **Ponferrada**, Plaza Castillo-Almeria and Poblado-Córdoba (power generation) and Torrelavega (chemical industry) in N IP, **Monzón** (metal and agro-industry) in NE IP, **Arenosillo** (metallurgy, petrochemical plants and fertilizers) and Punta Umbria (metallurgy and fertilizers) in SW IP and **Santa Cruz** (shipping and petrochemical emissions) in the Canary Islands.
- 19 industrial sites including Tarragona, Puertollano (both with large chemical and petrochemical estates), **Huelva**, **La Linea**, Puente Mayorga, Los Barrios and Aguadulce (with petrochemical and metallurgical estates), **L'Alcora, Onda,** Vila-real**, Borriana** and Almazora (influenced by ceramic and glass manufacture emissions form a large industrial estate), **Bailén** (manufacture of breaks), Llodio, **Bajo Cadagua** and **Zabalgarbi** (metallurgy), **Avilés** (coke production), Torredonjimena and **Montcada** (cement production).
- 7 suburban sites in the IP and the Balearic islands, including Palma, Chapineria, Burgos, Badajoz, Santa Ana-Cartagena, El Vacar-Córdoba, Nerva-Huelva. These are stations located in the outskirts of cities or villages.
- 18 urban background sites including, **Granada, Melilla,** Las Palmas de Gran Canarias, **Albacete**, **Santander**, Alcobendas, **Madrid**, **Barcelona, Sabadell**, Girona, Moguer, Cadiz, Córdoba, Sevilla, Jaén, 2 sites in **Bilbao** and **Zaragoza.**
- 9 road traffic sites in **Sabadell**, Girona, Barcelona, **Madrid**, Granada, Almería, **Barreda-Torrelavega**, **Bilbao** and Cartagena.

In all cases with the exception of the urban background from Madrid measurements were carried out by filter sampling of PMx with high or low volume samplers followed by sample treatment and laboratory analyses.

The presentation summarizes major finding on the interpretation of the time and spatial variability of levels of nmC, EC and OC.

Long term monitoring of black carbon at eight measurement sites in Switzerland

H. Herich[1], C. Hueglin[1], A. Fischer[1] and B. Buchmann[1]

[1]Empa, Swiss Federal Laboratories for Materials Science and Technology, Duebendorf, Switzerland

Keywords: Black Carbon, Aerosol Light Absorption, Source Apportionment

Presenting author email: hanna.herich@empa.ch

Beside their effects on radiative forcing, soot aerosols have been found to cause health effects as they are carcinogenic. Diesel engines and incomplete biomass burning are the major emission sources of soot particles. Especially during winter, the wood burning (WB) emissions from residential heating have been found to contribute significantly to the soot concentrations (Herich et al. 2011; Piazzalunga et al. 2011).

In this study we present continuous long-term measurements of black carbon (BC) at eight measurement stations in Switzerland from 2007 - 2011. All measurements were performed as part of the Swiss national air pollution monitor network (NABEL) and were either conducted by multi-angle absorption photometers (MAAP) or seven wavelength aethalometers. In addition, twenty-four hour high volume filter samples were collected at all stations in parallel and on a regular basis. The filters were analyzed for elemental carbon (EC) by thermo-optical analysis (TOT with EUSAAR 2 temperature protocol) and for light absorption (at 370 nm and 880 nm) by a SootScan Transmissometer (OT21, Magee Scientific Corporation).

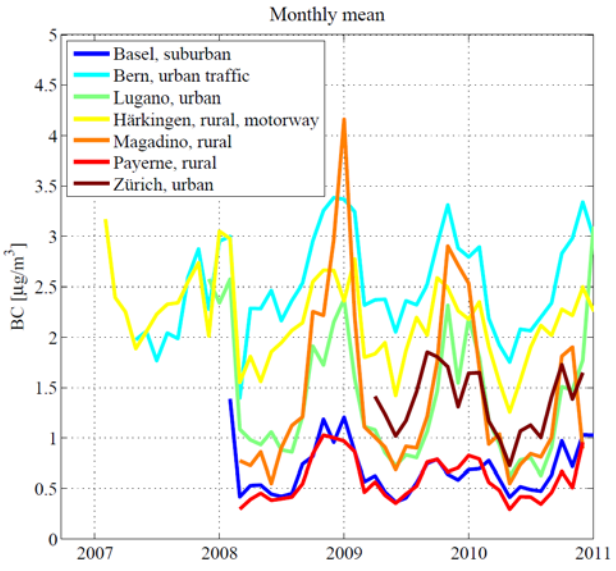

Figure 1. Monthly mean concentrations of BC at different measurement sites in Switzerland.

The site specific aerosol light absorption cross sections were calculated from the relationship between the measured optical absorption coefficient and EC as determined by TOT/EUSAAR 2. Consequently, the presented BC concentrations are consistent with EC. In addition, the aethalometer model (e.g. Sandradewi et al. 2008, Herich et al. 2011) is used for determination of the contribution of fossil fuel and WB emissions to total BC. Mean BC concentrations were highly dependent on the type of location, highest soot loadings were found at urban and traffic related sites, see Figure 1. The annual average concentration levels of BC ranged from 0.6 µg/m^3 (rural station) to 2.6 µg/m^3 (urban kerbside). At all stations the soot concentrations indicated a strong seasonal dependence with highest concentrations in winter compared to the other seasons. The contribution of WB emissions to total BC is negligible during summer but can contribute to more than 30% in winter at rural stations.

This study represents part of the research project IMBALANCE funded by the Competence Center Environment and Sustainability of the ETH Domain (CCES). Support from the Swiss Federal Office for the Environment (FOEN) is gratefully acknowledged.

Cartography and long term trends (1998-2011) of polycyclic aromatic hydrocarbons (PAHs) in France

A. Albinet[1], M. Beauchamp[1], G. Harel[1], L. Malherbe[1] and E. Leoz[1]

[1] French National Institute for Industrial Environment and Risks (INERIS), Verneuil en Halatte, 60550, France
Keywords: PAH, Measurements, Ambient air pollution, Aerosol chemistry, Air quality.
Presenting author email: alexandre.albinet@ineris.fr

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental contaminants widely studied due to their known toxicity. In the atmosphere, they are released in both, gaseous and particulate phases, as by-products from the incomplete combustion of organic matter and fossil fuel. In Europe, these compounds are regulated and their ambient air monitoring is required since 2004 by the introduction of the European directive 2004/107/CE (European Official Journal, 2005) with an application delay for the end of February 2007. A target value for benzo[a]pyrene in PM_{10} (B[a]P – as a marker for the suite of PAH compounds) has been set to 1 ng/m^3 on annual average for every single monitoring station.

As to date, no national cartography has ever been reported for any country and the study of long temporal trends of PAHs is poorly documented in the literature (e.g. Becker *et al.*, 2006; Meijer *et al.*, 2008; Menichini *et al.*, 1999; Schauer *et al.*, 2003). Additionally, to our knowledge, only one recent study reported results about the long term evolution of the contribution of B[a]P to the ambient air PAH mixture (Menichini *et al.*, 1999) while B[a]P was chosen as marker for the suite of PAH compounds.

The objective of this study was first, to realize a French cartography of atmospheric PAHs and to study their spatial and temporal variations concentration and profile (B[a]P/Σ_7PAHs and Σ_7PAHs/PM_{10}) at a national scale. Second, temporal trends were investigated on selected monitoring sites (monitoring periods > 5 years) in relation to emission time trends, location and seasonal effect.

In France, the monitoring of PAHs started in 1998 and a quasi-total coverage of the French national territory is now effective with about 90 sites instrumented for the monitoring of PAHs performed according to the European reference method of measurement EN15549. Concentration data were provided by each local air quality network (AASQA) and then computer processed by INERIS in order to build national cartographies and statistical analyses.

Overall, results obtained showed that, at a national scale, B[a]P annual mean concentration levels are lower than the target value of 1 ng/m^3 (Figure 1). Only industrial sites and some monitoring sites (mainly urban typology) located in specific regions, characterised by their important industrial activity, their relief and/or their geographical location (Nord-Pas-de-Calais (North), Lorraine (North-East) and Rhône-Alpes (East)), showed higher annual mean concentrations. High concentrations levels of PAH observed on suburban sites highlighted the importance of the monitoring of this site typology. The contribution of B[a]P to the mixture of the 7 regulated PAHs (European Official Journal, 2005) seemed stable in annual mean but highly variable between warm and cold seasons in relation to the photochemical activity and PAH source number (e.g. residential heating as additional source of PAHs in winter season) as for PAH concentration levels.

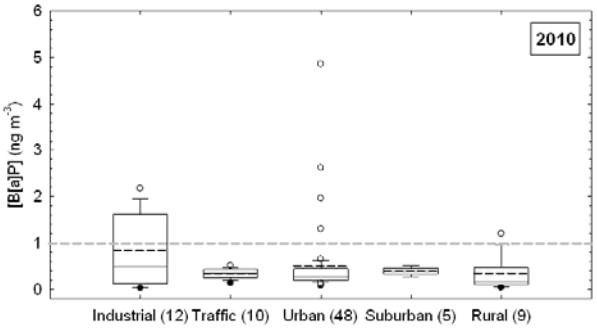

Figure 1. Box plot of B[a]P concentration levels according to the sampling site typology for 2010 in France (number of sites).

A statistical time-series model was used in order to decompose and analyse long term trends of PAHs (equation 1) (Becker *et al.*, 2006).

$$Y_t = T_t + S_t + e_t \qquad \text{(equation 1)}$$

where Y_t is the observed time series, T_t is a longer term trend, S_t is a seasonal component (period of 1 year) and e_t is an irregular or "noise" component. A statistical analysis (seasonal Mann Kendall) was then applied in order to evaluate the existence of a significant trend.

Results obtained showed a statistically significant decrease in PAH concentration levels (- 1 ng m^{-3} in 10 years) for all the selected sites. Moreover, results showed that the choice of B[a]P as representative of PAH chronicle contamination is questionable. Differences of temporal evolution of the contribution of B[a]P to the mixture of PAHs was clearly observed between monitoring sites of different regions. In Ile de France (Paris), the ratio B[a]P/Σ_7PAH increased significantly while the trends were largely decreasing (-50 % in 10 years) in Rhônes-Alpes region (Lyon/Grenoble).

Finally, all the results obtained highlighted the influence of local and regional influencing parameters such as the climatology, the nature of PAH sources and the topography.

This work was supported by the French Ministry of Environment (MEDDTL) and by the French central laboratory of air quality monitoring (LCSQA).

Keywords: PM10, OC, EC, levoglucosan, wood burning.
Presenting author email: willy.maenhaut@ugent.be

From February 2010 to February 2011 PM10 aerosol samples were simultaneously taken every 4th day at 7 monitoring sites in Flanders, Belgium. Two of the sites (i.e., Borgerhout and Gent) were urban background sites; one (i.e., Mechelen) a suburban background site, and the other four (i.e., Hamme, Lier, Retie, and Houtem) rural background sites, whereby Hamme and Lier were expected to be particularly impacted by biomass burning. The samplings were done for 24 h and 47-mm diameter Pallflex® Tissuquartz™ 2500 QAT-UP filters were used. After sampling the PM10 mass concentration was determined by weighing; organic and elemental carbon (OC and EC) were measured by thermal-optical transmission analysis using the NIOSH protocol (Birch and Cary, 1996) and the wood burning tracers levoglucosan, mannosan, and galactosan were determined by means of gas chromatography / mass spectrometry (Pashynska *et al.*, 2002).

The ratios of levoglucosan to mannosan (L/M) and of levoglucosan to the sum of mannosan and galactosan (L/M+G) have been proposed to assess the origin of the wood burning tracers (Fine *et al.*, 2004; Schmidl *et al.*, 2008; Fabbri *et al.*, 2009). The L/(M+G) ratio enables one to discriminate between biomass burning and lignite burning; L/(M+G) values for various source tests for biomass burning range from 0.4 to 18, whereas high ratios of about 50 are indicative of lignite burning (Fabbri *et al.*, 2009). The L/M ratio can be used to assess the relative importance of hardwood and softwood burning. Fine particles emitted from fireplace combustion of woods grown in the midwestern and western United States have L/M ratios in the 13-24 and 3.9-6.7 ranges, for hardwoods and softwoods, respectively (Fine *et al.*, 2004). Schmidl *et al.* (2008) found for fine particle emissions from wood stove combustion of common woods growing in mid-European Alpine regions L/M ratios of around 14-15 for hardwoods, while softwoods gave low ratios, 3.6-3.9. The annual average L/M ratios for our 7 sampling sites ranged from 6.2 to 7.1 and there was little variation with season; for winter and summer campaigns at Gent in 1998 and 2000-2001 (Zdráhal *et al.*, 2002; Pashynska *et al.*, 2002) the campaign average L/M ratios were in the range 4.1-7.2. This suggests that softwood burning was clearly more important than hardwood burning in Flanders in 2010-2011 and that this was also the case at Gent in 1998 and 2000-2001. Incidentally, the annual average L/(M+G) ratios at our 7 sites were in the range 4.5-4.9, while the winter and summer campaign average L/(M+G) ratios for Gent in 1998 and 2000-2001 were 3.4-5.6; these ratios are all within the range of 0.4-18 given above for various source tests for biomass burning.

From our L/M ratios we derived the relative contributions of softwood and hardwood burning, thereby using the same approach as used by Schmidl *et al.* (2008). It was found that softwood burning accounted, on average, for about 70%, and there was little variation in this percentage with site or with season. The levoglucosan data were used to assess the contribution of wood burning to the OC and to the PM10 mass, again following the approach of Schmidl *et al.* (2008). These contributions varied substantially with season (with largest percentages in winter, followed by fall) and there were also substantial differences between the sites, with largest percentages for the rural site of Hamme, where there are apparently large local sources of wood burning. The seasonal medians of the contribution from wood burning to the OC in Hamme were 19%, 5%, 48%, and 62% for spring, summer, fall, and winter, respectively. The percentages of the contribution from wood burning to the OC for 4 of the 7 sites (i.e., Gent, Borgerhout, Lier, and Retie) were very highly correlated with each other (all $r>0.9$), indicating that the impact from wood burning at these 4 sites was a regional phenomenon.

The yearly median percentage of the contribution from wood burning to the PM10 mass ranged from 2.1 to 4.3% for 6 of the 7 sites, but was as large as 8.3% at Hamme. These percentages are somewhat larger than the yearly median percentages of the contribution from EC to the PM10 mass; the latter ranged from 1.6 to 3.3% for 6 of the 7 sites, and was 4.8% at Borgerhout.

Contribution of wood burning to the exceedance of PM_{10} limit values in residential areas of the Rhine-Ruhr conurbation (Germany)

U. Pfeffer, L. Breuer and D. Gladtke

North Rhine-Westphalia State Agency for Nature, Environment and Consumer Protection
Wallneyer Str. 6, 45133 Essen, Germany
Presenting author email: ulrich.pfeffer@lanuv.nrw.de
Keywords: PM_{10}, wood combustion, levoglucosan, emission reduction, air quality

European limit values for PM_{10} are still exceeded at many monitoring stations across Europe. 2011 was a year with long lasting episodes with unfavourable meteorological conditions in Germany. These episodes with high pressure, low wind speed and low inversion layers led to outstanding PM concentrations especially during winter/spring and in November 2011.

In order to reduce the PM burden in cities and agglomerations it is essential to have sound knowledge about relevant sources of particles and their contribution to PM levels in the breathing zone.

During the last years wood burning in private homes (open fire places, wood and pellet stoves) became more and more popular. This may be reasonable in respect to climate change (CO_2-neutral), but problematic for air pollution control.

Biomass smoke can be a very important constituent of organic particles in the mid and west European background (e. g. Puxbaum et al., 2007).

Recently, it was demonstrated that also in the large city of Milan wood burning may contribute 6.0 - 16.5 % to the PM_{10} concentration (Piazzalunga et al., 2011).

In densely populated areas of the Rhine-Ruhr conurbation (Germany) extensive measurements of PM_{10} were performed using high volume samplers with quartz filters and low volume samplers with glass fibre filters. In these dust samples concentrations of levoglucosan as a tracer for wood burning were determined. By comparing day (without) and night concentrations (with wood burning) at various sites an empirical factor relating levoglucosan to PM mass originating from biomass burning was evaluated and used for determining PM_{10} shares caused by wood burning. First results show that during unfavourable weather conditions (inversion episodes) like in November 2011 up to 25 % of the measured PM_{10} concentration may be caused by biomass burning in residential areas in the Rhine-Ruhr agglomeration. Even if the contribution of wood burning to annual averages is small (approximately only 1.5 to 2.5 µg/m³), the influence on the number of daily averages exceeding 50 µg/m³ can be very significant, because high wood burning activities logically coincide with low ambient temperatures where PM levels are already elevated due to bad dispersion conditions.

Figure 1 shows PM_{10} concentrations (number of days in exceedance of 50 µg/m³) and its share caused by biomass combustion measured at various sites in North Rhine-Westphalia (NRW) in November 2011 (stations mostly in densely populated cities).

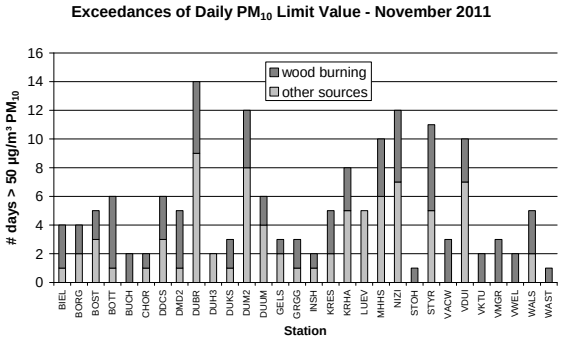

Figure 1. Contribution of wood burning to PM_{10} concentrations in NRW

It can be clearly seen that the number of days with PM_{10} values above 50 µg/m³ could be significantly reduced without wood burning.

Consequently, any measures lowering PM emissions from wood burning in domestic heating installations have a significant potential for the reduction of days exceeding the limit value of 50 µg/m³. In a first step old installations should be replaced or refitted by stoves with modern filter techniques which are already on the market.

A UK-wide assessment of black carbon and PM from wood burning

Gary W. Fuller[1], David C Green[1] and David Butterfield[2]

[1] MRC HPA Centre for Environment and Health, King's College London, London, SE1 9NH, UK

Introduction

Member states of the European Union are committed to obtain 20% of their energy requirements from renewable sources, including biomass, by 2020 as part of a raft of proposals to reduce CO_2 emissions. In response the UK has announced financial incentives for homes and businesses to switch from fossil fuel to renewables in a strategy to 'de-carbonise' the generation of heat in the UK. Concern has been raised over the possible urban air pollution impacts arising from widespread installation and use of biomass heating. There is a risk that an increase in biomass burning may undermine the achievement of PM_{10} EU Limit Values and the EU exposure reduction target for $PM_{2.5}$. Although PM from biomass burning is a recognised problem in Scandinavian and Alpine countries, according to the UK Digest of Energy Statistics, wood heating in the UK is thought to be too small to quantify. It was therefore felt prudent to confirm this by establishing a baseline for the PM concentration from biomass across the UK.

Methods

Aethalometer measurements (370 & 880 nm, Magee Scientific) were analysed for 2009 and 2010 from background locations in 18 urban areas. Spot loading corrections (Virkkula et al, 2007) were undertaken and black carbon (BC) concentrations were apportioned between fossil fuel and wood burning assuming an Ångstrom absorption coefficient of 2.0 for wood burning and 1.0 for road traffic emissions on the basis of measurements next to a busy central London Road. PM concentrations from wood burning were estimated using coefficients derived by Sandrawei et al, 2008 and Favez et al, 2010 adjusted for the specific wavelengths used.

Results and discussion

Estimates of wood smoke PM were compared to campaign measurements (2 x 6 weeks) of levoglucosan (a wood smoke tracer) in London and gave correlation coefficients (r^2) of 0.76 and 0.77 confirming the ability of the aethalometer to detect PM from this source.

Mean BC concentrations were between 1.6 and 2.0 µg m^{-3} in urban areas in England, Scotland and Wales. Here BC was dominated by fossil fuel sources with wood burning comprising between 6 and 25%. A lower BC concentration of 0.5 µg m^{-3} was found in rural southern England, with 35% from wood burning.

Diurnal analysis of PM form wood burning (Figure 1) shows peak concentrations in each evening indicative of domestic heating. Weekend concentrations exceed weekdays by ratios of up to 1.3 indicating considerable discretionary or decorative wood burning. A lag between rural and urban concentrations shows PM from wood burning diffusing from cities into the surrounding countryside. Overall wintertime wood burning accounted for 5 to 10% of total PM_{10} in mainland urban areas and around 5% in rural southern England.

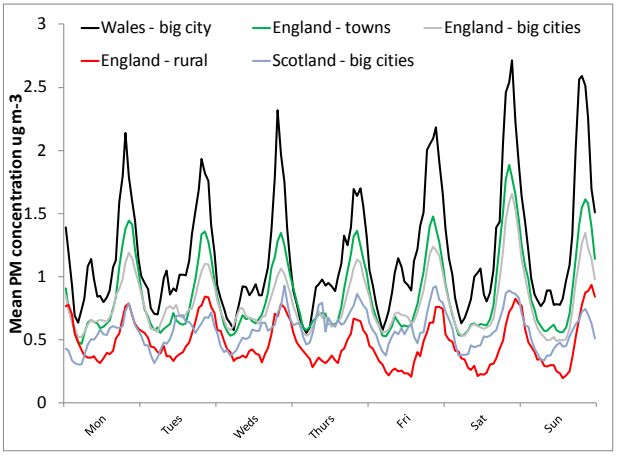

Figure 1 Mean PM from wood burning averaged by hour of day and day of week in England, Scotland and Wales.

Small towns in Northern Ireland are not on the UK natural gas grid. Here fuel use surveys and PAH concentrations suggest that coal burning is prevalent. Coal smoke has an Ångstrom absorption coefficient of around 1.4 (Yang et al, 2009) which would interfere with the aethalometer assessment of PM from wood burning and separate quantification of coal and wood burning is not possible. However, the mean evening Ångstrom coefficient of 1.7 during wintertime suggests a combination of coal and wood burning may be taking place in these areas.

Insight into the primary and secondary organic fraction of the organic aerosols in and around Barcelona

B.L. van Drooge, M. Alier, R. Tauler, J.O. Grimalt

Institute of Environmental Diagnostics and Water Research (IDÆA-CSIC), Jordi Girona 18, 08034 Barcelona, Catalonia, Spain
Keywords: Dicarboxylic acids, PAH, Hopanes, Levoglucosan
E-mail contact: barend.vandrooge@idaea.csic.es

Monitoring and chemical analysis of atmospheric fine particulate matter (PM1) is important due to its health impact and influence on climate change (Forster et al. 2007, Pérez et al. 2009). The air quality in the urban area of Barcelona is dominated by traffic related emissions. Moreover, the area is characterized by high levels of particulate matter and reactive chemical species due to emissions, the weak synoptic conditions and high solar radiation (Millán et al. 1997, Pérez et al. 2010). Ambient air filter samples were collected during intensive sampling campaigns during 2009 and 2010 (DAURE and SAPUSS) on urban background site (UB), road sites (RS) and a rural background at 780 m (RB). The samples were analyzed for organic tracer compounds, e.g. polycyclic aromatic hydrocarbons, hopanes, levoglucosan and nicotine, as well as secondary organic aerosols tracer compounds, e.g. dicarboxylic acids, for source characterization and identification of the organic patterns of primary and secondary aerosols. The obtained are compared with "on-line" data, such as those generated with Aerosol-Mass-Spectrometer. The results are discussed in terms of their relation to emission sources and influence of meteorological conditions in order to get an insight on the source contributions to the complex organic aerosol [5].

PM1 filter samples were collected with 12 or 24 hour resolution in background and road site in Barcelona (41º22"N; 2º11"E) and in a rural site in the Monseny natural park, using a Hivol-sampler. Polycyclic aromatic hydrocarbons, hopanes, levoglucosan, nicotine, and dicarboxylic acids were analyzed using GC-MS with TMS derivation of the polar compounds beforehand. Complementary data on meteorological conditions, and air-mass trajectories for the sampled days were recorded. Moreover, statistical tools, such as PCA (Principal Component Analysis) and MCR-ALS (Multivariate Curve Resolution - Alternating Least Squares), were used to analyze the variance in the database.

In the urban area, PCA analysis showed strong correlations between organic compounds separating them in three component groups: those related to primary emissions and those related to secondary aerosols and biomass burning. MCR-ALS analysis also resolved three components (Figure 1). The first component was related to regional air mass circulation and consequently accumulation of secondary aerosols, as well as an influence of regional biomass burning. The second component was related to anthropogenic activities (traffic and tobacco smoke) that was more intense in RS. A third component could be related to food cooking activities, or SOA formation other than described in the first component. The organic tracer compounds, representing the three identified components correlated very well with the organic aerosol analyses of the HR-AMS. From these analyses it was estimated that in UB about 50% of OA is secondary, and probably mainly biogenic, while this was about 40% in RS. Primary sources, mainly traffic, contributed to about 30% to the OA in UB and about 50% in RS.

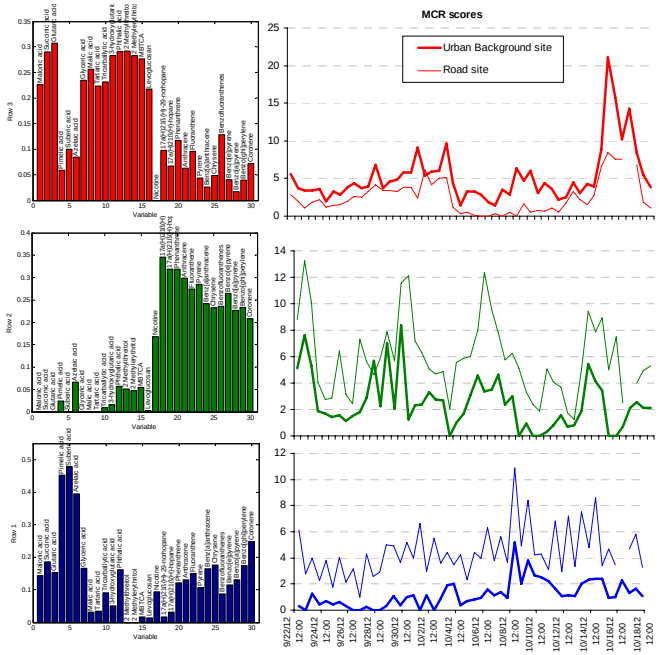

Figure 1. Organic tracer compounds per component (left) and the scores during the sampling days in UB and RS (right).

Session WG09S2O. Aerosol Modelling: Emission inventories, transport and transformation

A 40-year retrospective high-resolution European radon flux inventory including climatological variability

I. López-Coto[1], J.L. Mas[2] and J.P. Bolivar[1]

[1]Dept. of Applied Physics, University of Huelva, Huelva, 21071, Spain
[2]Dept. of Applied Physics I, University of Seville, Seville, 41012, Spain
Keywords: Emissions, Fluxes, Modelling, Trace gases.
Presenting author email: israel.lopez@dfa.uhu.es

The natural radioactive noble gas radon, ^{222}Rn, is mainly terrestrial in origin and is dispersed in the air by atmospheric transport and mixing. Radon is a noble gas (no deposition, washout or chemical reactions), and the only loss mechanism is radioactive decay so the residence time of radon in the atmosphere is well-known.

The radioactive decay of radon and its progeny can lead to ionization of air molecules and consequently influence aerosol size distribution . Besides, simulating radon transport is currently one of the best tools for evaluating transport schemes in regional-to-global climate /atmospheric models. Yet the usefulness of this tool is limited by the quality of the radon emission rate in soil-to-atmosphere inventories.

In this work, a 40-year retrospective high-resolution European radon flux inventory has been calculated. Average values of the radon exhalation rate, probability distributions and seasonal fluctuations have been obtained. To achieve this, a numerical model of radon transport in finite, heterogeneous and porous media has been developed that has enabled us to calculate the exhalation rate of European soils by using geological, geochemical and climatological parameters with a horizontal resolution of 0.5 ' (~ 1 km).

Model and input databases

The theoretical model is based on the fundamental equation of radon transport in porous media, taking into account the dependency of the transport coefficient on temperature and humidity. It also includes a simple model that evaluates the effect of snow cover.

The Europe-wide scope of the model proposed requires knowledge of the different physical, chemical and thermodynamic parameters of soils with good spatial resolution. Thus, the activity concentration of ^{226}Ra was determined from total uranium concentration which was obtained from the FOREGS geochemical database. The geophysical properties were derived from the Harmonized World Soil Database (HWSD) of the FAO. Data on the temperature, soil moisture and thickness of snow cover have been obtained from the ECMWF's global ERA-40 re-analysis.

Results

In general, the results show wide variations depending on location and season of the year, with a spatial standard deviation close to the annual average value (30 Bq m^{-2} h^{-1}) In turn, the seasonal deviation is about 25% of the annual average value. Systematically lower latitudes exhibit the largest deviations, with greater amplitude in seasonal fluctuations.

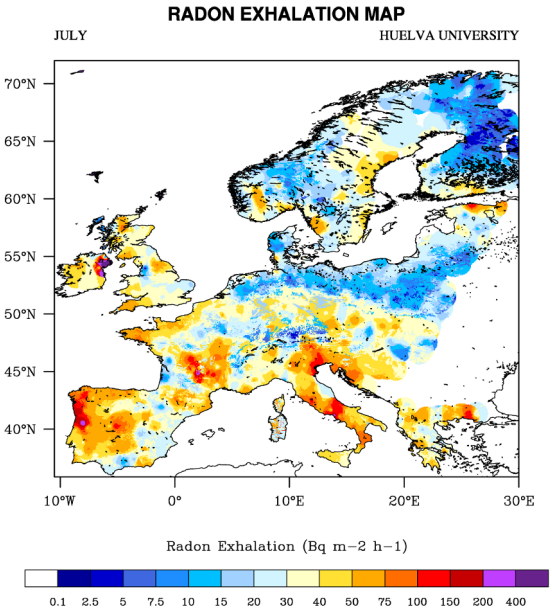

Figure 1. Radon exhalation rate of European soils for July of the composite year (40 years).

Conclusions

A numerical model of radon transport in finite, heterogeneous and porous media has been developed to calculate the exhalation rate of European soils by using geological, geochemical and climatological parameters with a horizontal resolution of 0.5 ' (~ 1 km).

A climatology of radon exhalation has been produced and the average values obtained, along with the probability distributions, seasonal anomalies and a European high resolution radon exhalation monthly average. The results were compared with experimental measurements of radon flux in the literature, and showed good general agreement.

The calculated inventory can be easily integrated into atmospheric transport models and also serve as a high-resolution baseline for policy decisions regarding the determination of areas of high risk of exposure to radon.

Modelling Contribution of Biogenic VOCs to New Particle Formation in the Jülich Plant Atmosphere Chamber

L. Liao[1], M. Boy[1], D. Mogensen[1,2], T. F. Mentel[4], E. Kleist[3], A. K.-Scharr[4], R. Tillman[4], H. Vuollekoski[1], M. Kulmala[1] and M. D. Maso[1,4]

Presenting author email: li.liao@helsinki.fi

Biogenic VOCs are substantially emitted from vegetation to atmosphere, and their emissions have been estimated to be of the order of 1150 Tg per year globally (Guenther et al., 1995). Isoprenoids and terpenoids, including e.g. isoprene (C5H8), monoterpenes (C10H16), and sesquiterpenes (C15H24) are the most abundant BVOCs, accounting for over 50% of BVOC emissions (Guenther et al., 1995). The oxidation of terpenes by OH, O_3, and NO_3 in air generating less volatile compounds may lead to the formation and growth of secondary organic aerosol, and thus presents a link to the vegetation, aerosol, and climate interaction system (Kulmala et al, 2004). Studies including field observations, laboratory experiments and modelling have improved our understanding on the connection between BVOCs and new particle formation mechanism in some extent (see e.g. Tunved et al., 2006; Mentel et al., 2009). Nevertheless, the exact formation process still remains uncertain, especially from the perspective of BVOC contributions.

The purpose of this work is using the MALTE aerosol dynamics and air chemistry box model to investigate aerosol formation from reactions of direct tree emitted VOCs in the presence of ozone, UV light and artificial solar light in an atmospheric simulation chamber. The measured chamber data, including both gas and aerosol phase measurements are used to evaluate the model. This model employs up to date air chemical reactions, especially the VOC chemistry, which may potentially allow us to estimate the contribution of BVOCs to secondary aerosol formation, and further to quantify the influence of terpenes to the formation rate of new particles.

Experiments were conducted in the plant chamber facility at Forschungszentrum Jülich, Germany (Jülich Plant Aerosol Atmosphere Chamber, JPAC). The facility consists of three Borosilicate glass chambers (164 L, 1150 L, and 1450 L) with Teflon floors. Either one of the two smaller chambers were served as plant chamber followed by the large chamber as reaction chamber (1450 L). The detail regarding to the chamber facility has been written elsewhere (Mentel et al., 2009). During the experiments, gas phase sulphuric acid was measured by CIMS. VOC mixing ratios were measured by two GC-MS systems and PTR-MS. An Airmodus Particle size magnifier coupled with a TSI CPC and a PH-CPC were used to count the total particle number concentrations with a detection limit close to the expected size of formation of fresh nanoCN. A SMPS measured the particle size distribution. Several other parameters including ozone, CO_2, NO, Temperature, RH, and flow rates were also measured.

MALTE is a modular model to predict new aerosol formation in the lower troposphere, developed by Boy, et al. (2006). In this study, we use modules that include aerosol dynamics, air chemistry, and organic chemistry of VOCs as a MALTE box model for the chamber simulation. Considering that each individual terpene compound may react quite differently, the generalized parameterizations of terpene chemistry in models are less used, and most biogenic VOCs will be accounted for individually when modelling the atmospheric new aerosol formation. We first evaluate the modelled results with measurements, and further we investigate the influence of different order of magnitude of terpene mixing ratios, especially isoprene and monoterpenes to the most important parameter of new particles formation, i.e. the formation rate (J_1). Also, the influence of varying organic source rates on the sulphuric acid concentration available for particle formation is discussed.

Development of emission inventories of recreational boats

Victoria Agranovski

Air Quality Sciences, Department of Environment and Resource Management, Brisbane, 4001, Australia
Keywords: Air pollution modelling, emission inventory, off-road transport, recreational watercrafts
Presenting author email: victoria.agranovski@derm.qld.gov.au

Accurate modeling of air quality can improve understanding of human exposure to ambient pollutants. Characterization of marine traffic emissions is particularly important for modelling air quality and atmospheric processes associated with air pollution in coastal regions. Investigation of individual pollutant sources and source apportionment is especially imperative for developing, monitoring and reviewing environmental policies, regulations and plans to make sure they meet specific requirements. This study was focused on the emissions from recreational vessel traffic as part of developing emission inventory for off-road mobile sources in the State of Queensland, Australia.

Recreational vessels emission inventories were developed for the two regions, Gladstone and the South East Queensland. The inventories were developed from bottom-up surveys of registered boat owners coupled with the local activity data gathered from the State's database on registered marine vessels, for 2006-2011 years. The advantage of using these two complimentary approaches is improved accuracy and reliability of the input data for modelling off-road emissions from this source category. In addition, this approach has enabled development of simplified technique for estimating emission projection based on average per vessel emission rates. This is especially beneficial for estimating air quality in the areas for which the input activity data is limited.

In 2011, there were more than 7,400 and 141,300 recreational vessels registered in Gladstone and SEQ (corresponds to 3 and 53% of State figure), respectively. The five-year trend analysis of relevant activity data revealed that recreational fleet in Queensland consists of vessels with a range of engine size (Fig.1) and fuel type.

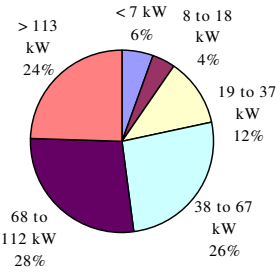

Figure 1. Distribution of vessels by engine power.

The fleet includes trailerable, small vessels (typically less than 8 m) that are launched at ocean or river boat ramps as well as larger, moored vessels, typically above 8 m which are not easily towed. The former includes sailing boats and larger cabin cruisers with auxiliary engines. The vast majority of vessels are however smaller than 8m (95%) and use outboard petrol engines (~88%). Emissions were estimated by applying appropriate emission factors listed in the Australian guidelines for developing emission inventories for recreational boats (Environment, 1999) to fuel usage. Fuel usage in the study regions were estimated from domestic surveys. To enable accurate estimates to be developed the vessels were categorised primarily on their engine/fuel type (Table 1).

Table 1. Annual emissions from recreational boats

Base year	2006	2009	2010	2011
Vessels, #	119,196	136,368	139,926	141,378

The Role of Compensating Errors in Reaction-Transport Models of Atmospheric Aerosol

P.A. Makar [1], R. Nissen[2], A. Teakles[2], J. Zhang[1], Q. Zheng[1], M.D. Moran[1], H.Yau[2]

Three dimensional aerosol models have the goal of simulating atmospheric aerosol formation and removal processes, but the accuracy with which they accomplish this aim will depend on the manner in which the processes are parameterized. Simplifications are often made to the science, and a seemingly arbitrary choice of methodologies can have a significant effect on model accuracy. The choices made to simulate one part of the equations describing aerosol creation and removal may have a profound effect on other parts of the system. This creates the potential for compensating errors in the results of the overall simulation.

In this study, A Unified Regional Air-quality Modelling System, AURAMS, v1.4.2, and the Community Multiscale Air-Quality Model, CMAQ, v4.6, were compared for a domain covering coastal north-western North America. The models were harmonized, with the same emissions inventory, horizontal grid, horizontal resolution (12km), and meteorological input information, for three one-month periods. The focus of the work described here will be the summer 2005 simulation, similar results having been noted for winter 2005 and summer 2004.

The models' performance differed greatly, in contrast with earlier comparisons, and the models were subsequently compared at the process parameterization level. The choice of process simplification and/or parameterization was found to have a profound effect on model results. In the case of AURAMS, revising the operator splitting methodology was shown to reduce positive biases in sea-salt aerosol predictions by a factor of three. For CMAQ, the use of a relatively high minimum cut-off in vertical diffusivity was largely responsible for improved night-time PM performance, but at the expense of reduced accuracy for ozone.

Once these parameterizations were improved and/or the simplifications were removed, it became clear that these choices were compensating for errors associated with the emissions and/or mixing of anthropogenic primary particulate matter. Model emissions were created from US EPA and Environment Canada data using the Sparse Matrix Operating Kernel Emissions (SMOKE) emissions processing system. The inputs for this system include information to allow the spatial and temporal allocation of annual political jurisdiction-based emissions into hourly gridded values, as well as into model-specific chemical species.

Time series showing the diurnal variation in primary PM emissions were reconstructed from SMOKE's library of temporal profiles and the emissions inventory. Some of the main sources of primary PM were found to be emitted at times inconsistent with the emitting activity, and Canadian spatial allocation fields were sometimes mis-assigned or contained errors. Corrections for these problems, updates to the Canadian emissions of ocean-going vessels, and parallel updates to the mobile emissions for the Canadian side of the grid, were incorporated into a second round of emissions generation and model simulations.

A marked improvement in some (though not all) of the $PM_{2.5}$ statistics for the models was noted, as were significant local improvements, though errors in primary PM speciation were still seen in urban regions.

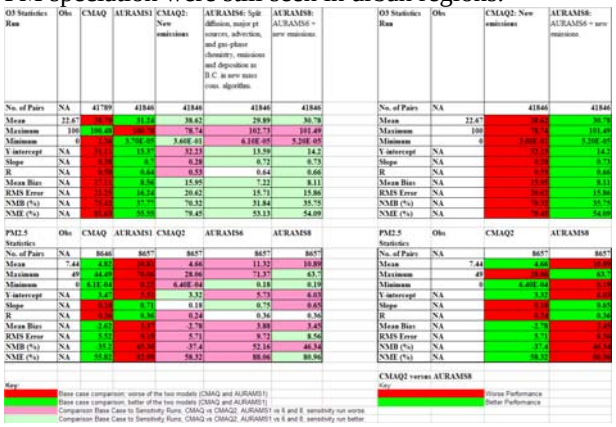

Table 1: Comparative statistics between CMAQ and AURAMS, for O_3 and $PM_{2.5}$, for five different model simulations.

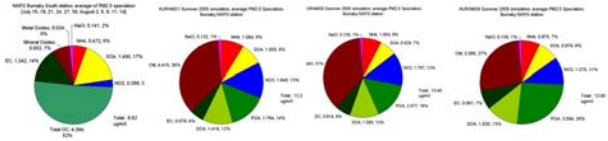

Figure 1: Comparison of particle speciation for Burnaby South Station (left: Observations, right: three AURAMS simulations).

A second examination of the primary PM emissions for downtown Vancouver was launched. A few key sources were found to contribute most of the urban primary PM, with temporal and spatial allocations that were once again inconsistent with expectations for those emitting activities. The effects of improving additional set of allocation factors will be discussed.

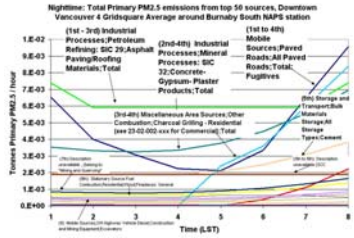

Figure 2: Time series showing major contributors to early morning primary $PM_{2.5}$ emissions in downtown Vancouver, using the first revision of the emissions database.

Application of Process Analysis in the CAMx model for evaluating physical and chemical processes affecting PM in Switzerland

G. Ciarelli, S. Aksoyoglu, J. Keller, D.C. Oderbolz, A.S.H. Prévôt

Laboratory of Atmospheric Chemistry (LAC), Paul Scherrer Institute, Villigen, CH-5232, Switzerland
Keywords: Modelling (regional), Aerosol modelling, Meteorology, Source apportionment.
Presenting author email: giancarlo.ciarelli@psi.ch

In this study, results from the Process Analysis (PA) tool provided with the Comprehensive Air Quality Model with extensions (CAMx) are presented for Switzerland. Process Analysis allows for in-depth analysis of photochemical model performance by revealing the contributions from individual physical and chemical processes operating within the model. This kind of investigation can be useful to improve model performance as well as to develop for control strategies. The process rates are integrated across each model output time interval (hourly). This information provides a complete description of temporal changes in species concentration due to different processes as well as their magnitude.

The air quality model system consists of the meteorological model Weather Research and Forecasting (WRF) version 3.2.1 and the Eulerian photochemical model CAMx version 5.30 (ENVIRON, 2010). A modular script called CAMxRunner was used to perform the simulations (Oderbolz et al., 2012). The model domain had a horizontal resolution of 0.25° x 0.125° and 14σ layer (lowest layer depth: 20m) covering Europe. Details about some of the model inputs are given in Aksoyoglu et al. (2011). We studied two periods in January and June 2006, in order to define the seasonal variation of the physical and chemical processes affecting the PM2.5 concentrations.

We investigated the contribution of the major physical (e.g. boundary advection tracking the inbound or outbound transport of the species) and chemical processes (e.g. production through gas-phase and aqueous chemistry) as well as direct emissions and removal, to the concentrations of particulate nitrate, sulfate, ammonium, primary and secondary organic aerosol in space and time. The focus was on the most populated area around Zurich in the Swiss Plateau.

Variations of processes rate in the vertical layers were also investigated. In particular, the diffusion term was used as a "tracer" in order to identify the layer height to use for the analysis (i.e. from the surface layer to the approximate height of the mixed layer).

Results are used to identify the main processes affecting the PM concentrations in the studied area. They also give us the information about whether particles are locally produced and/or transported from other regions. As an example, changes in sulfate concentration due to various processes are shown in Figure 1 for the first four days in June 2006. In this case advection from west and north directions are dominating over the local production for sulfate during the studied period in that region.

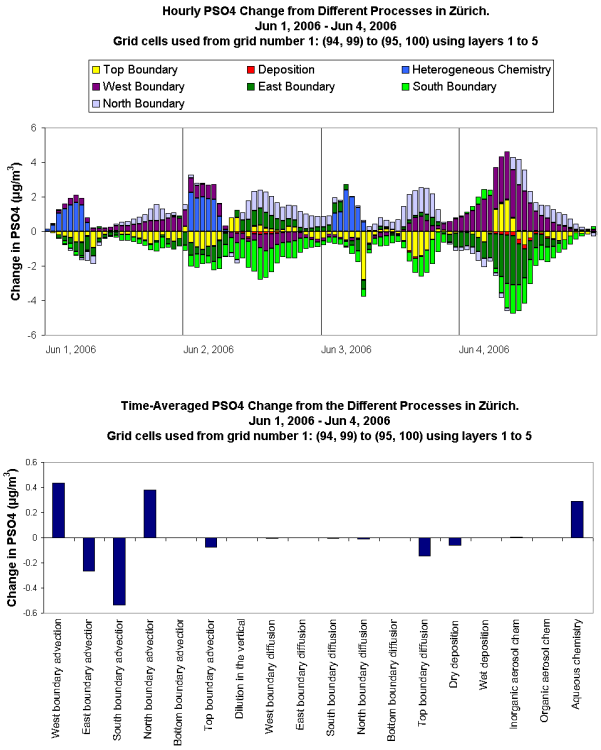

Figure 1. Example of hourly (top panel) and time-averaged (lower panel) change in sulfate due to different processes in Zürich (1-4 June 2006)

Modeling aerosol chemical properties: impact on cloud and precipitation formation

C. Barbet, L. Deguillaume and N. Chaumerliac
LaMP/CNRS, Clermont University, Blaise Pascal University, 24 Av. des Landais, 63177, Aubière, France

As observed at the Puy-de-Dôme monitoring site, which is located at an altitude of 1450m in the center of France, when the number concentration of aerosols is around 450 #.cm^{-3} it is estimated that the air mass is maritime whereas when the number concentration is nearly 2500 #.cm^{-3} it is a continental air mass. Then, if the atmosphere is poor in aerosol particles, the vapor condensation on aerosols leads to the formation of clouds droplets which reach easily the critical size to precipitate. So, it is necessary to study aerosols distributions native to different air masses in order to understand clouds droplets distributions. Detailed investigations of the properties of atmospheric aerosol particles were performed in autumn (September 2008), winter (March 2009) and summer (June 2010) using a Time-of-Flight Aerosol Mass Spectrometer (Freney et al., 2011).

These three cases, well documented for various seasons and for contrasted pollution levels native from various air masses are simulated with WRF-chem, using RADM2 (Stockwell et al., 1990) chemical mechanism associated with MADE/SORGAM aerosols (Ackermann et al., 1998). The proportion of various chemical components (ammonium, nitrate, sulfate, sodium, chloride, organic matter…) in aerosol chemical composition are quantified and compared to the observations. Sensitivity studies are conducted to assess the relative importance of anthropogenic vs biogenic emissions in SOA formation and their impact on cloud and precipitation formation.

Effect of precursor emissions on $PM_{2.5}$ concentrations over Europe

E. Tagaris, R.E.P. Sotiropoulou, N. Gounaris and S. Andronopoulos

Environmental Research Laboratory, NCSR Demokritos, Aghia Paraskevi Attikis, 15310 Athens, Greece
Keywords: particulate matter, emissions, modeling, Europe
Presenting author email: tagaris@ipta.demokritos.gr

Atmospheric pollution is a focus of attention because of its important role in many areas including human health (e.g., Seinfeld and Pandis, 2006; Peng et al., 2005). For this reason simulating air and particle concentrations as accurate as possible is fundamental in air quality planning and strategies for attainment of air quality standards. Although simulated meteorology could be compared with observation data spread throughout the domain suggesting the related uncertainties it is very difficult to accurately characterize emissions. Emission inventories are subject to significant uncertainties given that they are based on data sets of limited spatiotemporal coverage and always contain assumptions on interpolation and extrapolation of a limited set of sample data. The objective of this study is to modify appropriately precursor emissions improving air and particle concentrations predictions over Europe.

Meteorological fields are derived using the Penn State/NCAR Mesoscale Model (MM5) (Grell et al., 1994).

Emissions are processed by the Sparse Matrix Operator Kernel Emissions (SMOKE v2.6) Modeling System (http://www.smoke-model.org). The TNO gridded anthropogenic emissions inventory for the year 2006 over Europe in a 0.1 × 0.1 degrees resolution (ftp://neptunus.tno.nl) is used. The Biogenic Emission Inventory System, version 3 (BEIS3) is used for processing biogenic source emissions (http://www.epa.gov/asmdnerl/biogen.html) using the USGS gridded land use data in 1 Km resolution (http://edc2.usgs.gov/glcc/glcc.php).

The Community Multiscale Air Quality (CMAQ v 4.7) Modeling System with the Carbon Bond mechanism (CB05) (http://www.camx.com/publ/pdfs/CB05_Final_Report_120805.pdf) is used for the regional air quality modeling (177 × 217 grid cells of 35 km × 35 km, with 14 vertical layers) (Byun et al., 2006).

Emission scaling factors are applied for each country on NO_X, SO_2 and $PM_{2.5}$ emissions due to the significant number of monitoring data throughout the domain for these pollutants based on the country average ratio between observed and predicted concentrations.

Model performance is evaluated using the air quality information system maintained by the European Environment Agency (http://www.eea.europa.eu); a systematic bias for both air (i.e., NO_2, SO_2) and particle (i.e., $PM_{2.5}$) pollutants has been found. Application of scaling factors improves $PM_{2.5}$ and air pollutant model performance although the model still underpredicts $PM_{2.5}$ concentrations; this is related to the uncertain representation of secondary organic aerosol formation (Chen et al., 2005; Kroll et al., 2006).

Elevated $PM_{2.5}$ concentrations up to 40 ug/m^3 during winter are simulated over Europe (Figure 1). NO_3 is dominant during winter in Western Europe and in a few Eastern countries due to the high NO_2 concentrations. OC from biomass burning is a significant contributor in $PM_{2.5}$ components in Eastern Europe. During summer NO_3 is dominant only in regions with elevated NH_3 emissions such as the Netherlands and Northern Italy. For the rest of the domain SO_4 and OC are significant $PM_{2.5}$ components with SO_4 being dominant in the South and OC in the East.

Atmospheric aerosol particles meet a growing interest in today's environmental concerns because of their potential impacts on the global radiative budget and human health. In this context, combustion aerosols are extensively studied as they originate from industrial and transport activities for a large part. They usually are in the form of more or less compact aggregates made of primary particles. The evaluation of their effects on the environment requires the knowledge of their microphysical properties.

One way to determine these properties is based on a Transmission Electron Microscopy (TEM) analysis. 2D characteristics of the aggregates' projection (Fig. 1 left) are measured on the micrographs and extrapolated to 3D using 2D-3D transposition relationships (Baron and Willeke, 2001). These mathematical relationships were established from studies of numerically generated aggregates of pre-defined fractal dimension and composed of monodisperse primary particles. They are nowadays widely used (Neer and Köylü, 2006). However, very few works have focused on the validity of these relationships when applied to real soot aggregates. Indeed, it is difficult to establish 2D and 3D characteristics of soot aggregates using a single experimental approach.

We investigate aircraft soot aggregates sampled at the exit of a turbofan engine by combining TEM and Electron Tomography (ET) analyses. Micrographs are processed using the "ImageJ" software (http://imagej.nih.gov/ij/). Statistical values for the population of aggregates are issued: primary particles mean diameter, aggregates mean gyration diameter.

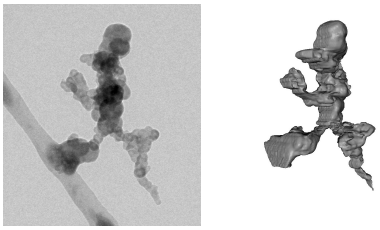

Figure 1. TEM micrograph of an aircraft soot aggregate (left) and the 3D visualization of its tomogram (right).

The 3D tomogram of this aggregate is built by ET using the plug-in "TomoJ" (Messaoudi *et al.*, 2007). We developed a plug-in *SootExpert* able to determine the 3D characteristics of an aggregate on its tomogram (volume, gyration diameter and fractal dimension). In a first step, we validate our plug-in on a numerically generated aggregate (Fig. 2), its volume and gyration diameter are known. The values determined by *SootExpert* are very close to the characteristics of this aggregate (Table 1), assessing the reliability of our plug-in.

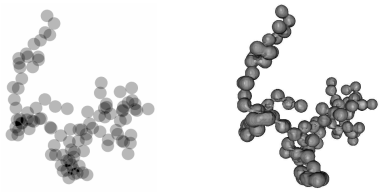

Figure 2. Projection of a numerical aggregate (left) and the 3D visualization of its tomogram (right).

	Known 3D characteristics	*SootExpert* 3D characteristics
Gyration diameter (nm)	310	298
Volume (nm^3)	$1\,456\times10^3$	$1\,616\times10^3$

Table 1. Comparison between the known and the determined 3D characteristics of a numerical aggregate.

In a second step, the ET analysis is applied to aircraft soot aggregates (Fig. 1 right). Van Poppel *et al.* (2005) and Adachi *et al.* (2007) have used ET to characterize atmospheric aerosols, with no special interest to the links between 2D and 3D characterizations. We study, for a single aggregate, the correlation between the 3D characteristics determined on its tomogram and the statistics resulting from the TEM analysis of the series of its projections. We can thus indicate the validity of the transposition relationships for aircraft soot aggregates. Then we compare this aggregate's 3D characteristics determined by *SootExpert* with the statistical values determined on the population, to investigate if a single aggregate is representative of its population.

Novel Features of (Re-)Crystallization and Particle Population Dynamics In Compressed Gas-Expanded Liquid

D. E. Rosner

Department of Chemical and Environmental Engineering, Yale University, New Haven CT, 06520-8286, USA
Keywords: Aerosol fundamentals, Multiphase processes, Coagulation, Supersaturation.
Presenting author email: daniel.rosner@yale.edu

With the ultimate objective of developing rational yet tractable continuous process models, attention is called here to novel features of a class of environments in which compressed gas (e.g., CO_2(g)) is employed as an "anti-solvent" to cause particle precipitation from conventional organic solvents. Under the acronyms: PCA (*precipitation with compressed antisolvent*), SASP (*supercritical anti solvent precipitation*), or GASP (*gas anti solvent precipitation*), this approach is currently being explored for continuously producing valuable ultrafine powders; e.g., to increase the bio-availability of sparingly soluble pharmaceutically active ingredient. We demonstrate the need for systematic modifications in the rate-laws governing organic crystal nucleation (N), growth (G) and coagulation (C) in these remarkable environments (neither liquid-like nor ideal gas-like). Consideration of such "transcritical" conditions not only provides the motivation for instructive new fundamental research, but uncovers opportunities for attractive process improvements.

In this overview of our recent research, we focus on some predicted consequences of:

1. "Intermediate" molecular volume fraction (neither liquid-like nor ideal gas!)
2. "Compressibility"---i.e. rapid "dilation" (see Rosner and Arias-Zugasti, 2011a) of solute-containing liquid solvent droplets
3. Temperature "Contrast"---i.e. exploiting large local temperature gradients to modify rates of particle coagulation (see Rosner and Arias-Zugasti, 2011b) and/or capture (Rosner and Arias-Zugasti, 2007)

We have also developed quadrature-based moment methods to include such N/G/C phenomena in suitably generalized yet tractable population-balance methods (see Rosner et al. 2003) compatible with state-of-the-art CFD simulation techniques.

Many of the techniques we have developed and recently applied to predict the performance of high-pressure continuous spray combustors (see, e.g., Rosner et al. 2011, Rosner and Arias-Zugasti, 2011c, Labowsky et al. 2011), or the evolution of restructuring nano-particles in counterflow diffusion flames (Rosner and Pyykonen 2002, Rosner 2005), are in fact relevant to these equally challenging (albeit milder temperature!) PCA-environments. Indeed, we must ultimately account for the interaction of at least two populations (Rosner 2009); i.e., the solute-charged solvent spray population with the precipitated population of submicron organic crystals---including its continuous efficient capture.

New insight into organic driven particle formation and growth during the CLOUD experiment

F. Riccobono[1], E. Weingartner[1], U. Baltensperger[1] and the CLOUD collaboration

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland
Keywords: ion-induced nucleation, organics, growth, CLOUD
Presenting author email: francesco.riccobono@psi.ch

Formation of atmospheric aerosol has been observed in a wide range of atmospheric conditions in many different locations and altitudes all over the globe (Kulmala *et al.*, 2004). Nucleation and subsequent condensational growth alters the atmospheric aerosol size distribution and ultimately affects the climate. Despite extensive research, fundamental questions remain about the role played by organic compounds on the nucleation and growth mechanisms. The latest CLOUD experiment at CERN aimed to investigate how organic compounds and their interplay with cosmic radiation affect the formation and growth of new particles.

Several experiments have been performed in the CLOUD aerosol chamber at CERN in the presence of pinanediol, a first oxidation product of α-pinene. The CERN Proton Synchrotron provided an adjustable and precisely measurable beam of artificial cosmic rays, spanning the atmospheric ionization range from the upper troposphere to ground level (Kirkby *et al.*, 2011).

Integrated measurements by several instruments, such as an Atmospheric Pressure interface Mass Spectrometer (APi-TOF), Condensation Particle Counters (CPC) with different counting efficiency curves, a Scanning Mobility Particle Sizer (SMPS) together with a newly tailored diffusion technique (LDT, Laminar Diffusion Tube), provided a comprehensive picture of the processes governing the evolution of the particle size distribution inside the CLOUD chamber.

The effects of pinanediol on nucleation rates and growth rates are presented as nucleation and growth rate enhancement factors with respect to ternary nucleation of sulfuric acid, water and ammonia. Nucleation and growth rates enhancement factors as function of organic compounds and ion concentration will be discussed.

Special focus will be given to the size dependency of the growth rate enhancement factors obtained with the LDT. This instrument uses the 1.2 meter long sampling line of the CLOUD chamber as a diffusion tube, in which the particles are lost to the walls by diffusion as a function of the sample flowrate and of the particle diameter. Downstream of the LDT the particle concentration is determined with a Condensation Particle Counter.

The observed growth rates determine which fraction of the freshly nucleated particles can grow to CCN sizes and which fraction is lost by coagulation with larger pre-existing aerosol particles. Figure 1 depicts the steep increase of particle's lifetime as the diameter of the nucleated particle grows. The combination of low saturation vapor pressures of sulfuric acid and oxidized organic compounds increases the survival probability of nucleated particles. The role of sulfuric acid and organic compounds in speeding up the growth rates (i.e. increasing the survival probability) will be presented as a function of particle size.

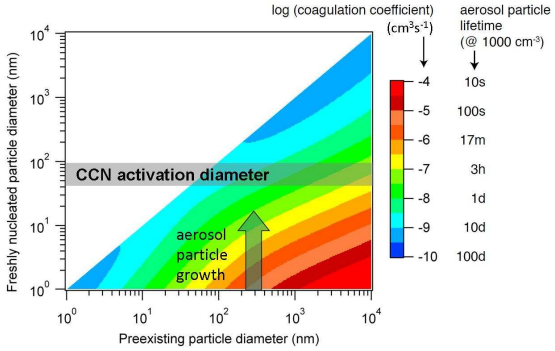

Figure 1. Grow or die: depending on the pre-existing surface area (number and size of pre-existing particles) the lifetime of freshly nucleated particles varies by 6 orders of magnitude (from red to blue). Rapid growth increases the probability of a nucleated particle to avoid coagulation and form a new CCN.

Saturation Fluctuations and Rain Initiation

Charles Clement

15 Witan Way, Wantage, Oxon OX12 9EU, U.K.

Keywords: rain, condensation, turbulence, fluctuations

The initiation of raindrops in clouds is a longstanding problem which is still not well understood theoretically. It was recognised early that the usual coagulation processes between the numerous, but small (about 3 μm), cloud droplets are too slow to produce raindrops large enough to fall under gravity, and also to give the wide size distributions of droplets observed in clouds. In this paper we discuss how the more rapid condensation process can contribute to raindrop formation, including the recent suggestion (Wilkinson 2011) that the Ostwald ripening process plays a significant role.

Processes affecting the growth of activated droplets and subsequent redistribution of mass between them were summarised by Clement (2008), and include changes arising from interaction with radiation as well as the Ostwald ripening process which involves mass transfer from small droplets to large ones because of the greater equilibrium vapour pressure outside a curved surface. The difference in equilibrium saturation, S, of water for a droplet radius, R, from that for a plane surface is given by $R_\gamma(T) / R$, where $R_\gamma(T)$ is 1.2 nm at 0^0 C and 1.0 nm at 20^0 C. Thus the process is driven by changes of S of the order of 10^{-3} for 1 μm droplets, and 10^{-4} at 10 μm, and the theory describing it requires a uniform saturation surrounding a collection of droplets which is slowly reducing between these values as the mean droplet size increases between the two values of R.

Saturation fluctuations in the atmosphere were examined by Kulmala *et al* (1997) in connection with droplet growth, and the observations from aircraft discussed were found to lead to fluctuation values for S of 1-4 10^{-2}. Droplet growth and evaporation from such fluctuations will dominate over those from Ostwald ripening, and we now discuss whether they can lead to raindrop formation.

To simulate the effect of fluctuations on growth, Kulmala *et al* (1997) calculated growth of a droplet population containing a constant 0.01 ppb of nitric acid and included the Kelvin effect so that the initial droplets of size R_0 needed to be activated. The saturation was represented by a stochastic model changing with time with a Gaussian probability density of mean S_{av} and standard deviation σ_S. An exponential correlation function was used for changes with time:

$$< (S(t) - S_{av})(S(t + t') - S_{av})> = \sigma_S^2 \exp(-t'/\tau_c) \quad (1)$$

where τ_c is a correlation time.

Results were obtained for varying values of S_{av}, σ_S and τ_c which showed that wide size distributions could be produced, often with a separate unactivated peak, even for $S_{av} < 1$. We reproduce here some results obtained for the mean radius as a function of time for S_{av} =1 and correlation time τ_c = 100s except for 2.5 s when it was taken to be τ_c = 10 s. They clearly show that, with parameters not untypical of some atmospheric situations, droplet sizes of over 20 – 30 μm can be reached in timescales of 10-30 mins. At these sizes, the droplets start to fall with significant velocities (Stokes velocity of 0.15 ms^{-1} at 30 μm) with the ability to collide and coalesce with smaller droplets. Much more data on realistic fluctuations on different types of cloud are needed to apply this theory more widely.

The origin of saturation fluctuations, especially those in clouds, is still a difficult problem. The full equation for S (Clement 2008) has many components which have not yet been fully accounted for in calculations. Atmospheric calculations involving turbulence, such as those of Sidin *et al* (2009) concentrate on those arising from vertical motions. The possibility of other sources from diffusive processes and the interaction with radiation will be discussed.

Thermophoretic coating with molybdenum oxide nanoparticles

Lucija Boskovic[1] and Igor E. Agranovski[1]

[1]Griffith School of Engineering, Griffith University, Brisbane, 4111 QLD, Australia
Keywords: aerosol coating, thermophoresis, nanoparticles, oxides
Presenting author email: l.boskovic@griffith.edu.au

Dipping and spinning are the most extensively investigated sol-gel coating methods, however they suffer from the general requirements of axially or radially symmetric substrates, and the difficulty in achieving thick layers with a single coating Brinker and Scherer (1990). For these reasons, other coating methods such as electrophoresis, thermophoresis, sedimentation, and spraying have been investigated. The only viable deposition mechanisms for submicron particles are electrophoresis and thermophoresis. The electrophoretic coating is limited to conductive substrates that can serve as an electrode Dixen and Fissan (1999), on the other hand for thermophoresis no such limitation applies.

Many applications of hot wire and plate to plate thermophoretic precipitators (TP) were made in order to increase uniformity of the particle deposition. Messerer et al (2003) designed a plate to plate thermal precipitator with a flow channel length of 45cm to investigate the deposition of agglomerate soot aerosol particles under flow and temperature conditions relevant for heavy-duty diesel engine exhaust gas system. They have noticed the color change over the entry length at the inlet which indicates less soot deposition, and no visible treaces of particle deposition on the heated upper plate. Later, Gonzalez et al (2005) constructed a new TP for collection of nanometer-sized aerosol particles. Size of this precipitator was much smaller compared to Messerer et al (2003) design, with the length of 9.3 mm and precipitation area of 55.6 mm2. The deposition along the TP was shown to be homogenous on a millimeter scale for both NaCl and Fe particles collected on thin foil substrates and microscope grids, respectively at the aerosol flow rate of 50 sccm.

This paper investigates thermophoretic coating with molybdenum oxide nanoparticles, generated by a glowing wire generator, on different surfaces and at different flow rates.

Figures 1 (a), (b) and (c) show molybdenum oxide particles deposited on cold plate of the TP and on sixteen TEM grids distributed along the plate at three different flow rates 0.3, 1 and 1.5 l/min, respectively.

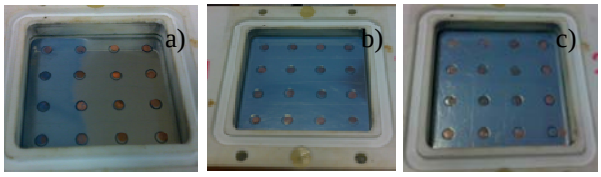

Figure 1. Molybdenum oxide nanoparticles deposited on the TP at flow rates a) 0.3 l/min, b)1 l/min and b) 1.5 l/min.

Figure 2 shows quantitative evidence of the particles collected by TP at three different flow rates (0.3, 1 and 1.5) l/min. The results are based on difference in mass of the TEM grids before and after particles deposition.

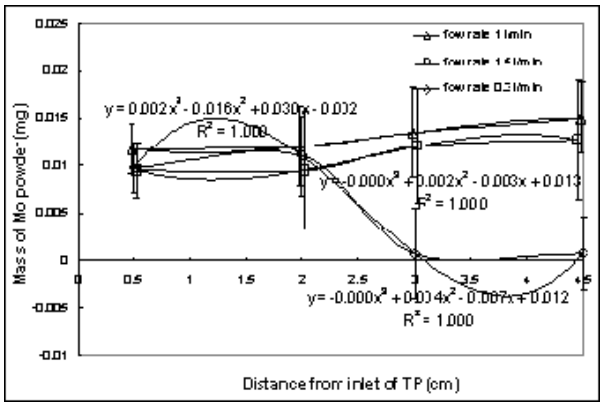

Figure 2. Quantitative evidence of the particles collected by TP at three different flow rates (0.3, 1 and 1.5) l/min

From the Figures it is clear that at 0.3 l/min flow rates vast majority of the particles settle closer to the entry of the precipitator with almost no particles collected close to the exit of the precipitator. With increase of the flow rate to 1 and 1.5 l/min results are showing that almost uniform collection of the particles is achieved along the whole area of the precipitator with slight increase in efficiency closer to the exit of the precipitator. The experimental curves were fitted with third order polynomial trendlines.

The uniformity of molybdenum oxide film generated on a glass slide at 1.5 l/min was investigated by Environmental SEM. The micrographs of the film confirmed that homogeneous densely packed network of molybdenum oxide particles is present along the precipitation area. Based on the results the thermophoretic precipitator described by Boskovic and Agranovski (2012) can be efficiently used for uniform coating with nanoparticles directly on various surfaces.

The growth or evaporation of droplets or crystals in a gas mixture is controlled by the balance of mass and heat transfer. The nature of the condensing vapor and above all its relative abundance in the atmosphere plays a major role in the mass transfer processes. We investigate the influence of molecular diffusion, thermal diffusion or Soret effect (mass transfer), and Dufour effect (heat transfer), with previous work done by Kulmala and Vesala (1991) as a starting point (hereafter KV91) and extending it to the case of high relative abundances of the condensing vapor.

Mars has a 95% CO_2 abundance in its atmosphere within which CO_2 ice clouds form. Those were first unambiguously observed by Montmessin *et al.* (2007). They present an unusual insight into cloud formation in the solar system because their formation involves the condensation of the major atmospheric component. Low atmospheric densities implies that the commonly-used continuum equations for mass transfer need to be modified by a correction factor (e.g. Fuchs and Sutugin, 1971) that accounts for the free molecular regime effects.

Soret effect and Dufour effect do not appear very important in cloud formation on Earth but might play a role on Mars in the formation of CO2 ice clouds. They are analogous terms in the sense that the former describes a mass flux rising from a temperature gradient and the latter a heat flux rising from a concentration gradient. The Dufour effect appears in the energy balance of the droplet or crystal:

$$D_{\mathrm{Duf}} I_{\mathrm{c}} - 4\pi r^2 K \frac{dT}{dr} = L_{\mathrm{sub}} I_{\mathrm{c}}$$

where I_c is the mass flow rate. From left to right appear the Dufour term (D_{duf}), the heat diffusion from Fourier's law, and the latent heat released by condensation (L_{sub}). Thus D_{duf} has to be compared to L_{sub}. Moreover we present the effect of thermal diffusion on the mass flow rate I_c as follows : $I_c = I_c^0/(1+Z_{th})$, where Ic^0 is the mass flow rate and Z_{th} a thermal diffusion-related term derived by assuming the simplest temperature profile above the droplet or crystal. Thus Z_{th} quantifies the effect of thermal diffusion on the mass flow rate. Importantly, in non-diluted conditions molecular diffusion has to account for the Stefan flow in Fick's law. Ic^0 accounts for it. Besides, in contrary to what KV91 did for water on Earth we could not simply used the classical mass flow rate of a condensing trace gas as 0^{th} order approximation to establish the thermal diffusion term. We had to rederive the equations and see how far the Stefan flow influences that coefficient. The result is that Z_{th} increases by 30% for the highest vapor concentration gradients between the crystal surface and the atmospheric background. Orders of magnitude of Z_{th} and D_{duf}/L_{sub} for typical Earth and Mars conditions are shown in Table 1.

Table 1. Z_{th} and L_{sub}/D_{duf} for tropospheric clouds and polar mesospheric clouds (PMC) on Earth, and CO_2 ice clouds on Mars

Planet - Cloud type	Z_{th}	$\frac{D_{\mathrm{Duf}}}{L_{\mathrm{sub}}}$
Earth - Tropo/H_2O_{liq}	10^{-2}	10^{-2}
Earth - PMC/H_2O_{ice}	10^{-5}	10^{-2}
Mars - Meso/$CO_{2,ice}$	≥ 10	$\leq 10^{-3}$

KV91 have studied the formation of a water droplet in Earth tropospheric conditions. Our results (Table 1) are valid in regards to KV91 conclusions in those specific conditions: Dufour effect dominates over thermal diffusion in tropospheric conditions. Indeed, using the values of Table 1 we observe that the energy balance puts the Dufour effect (through D_{duf}/L_{sub}) as a first-order correction term and the Soret effect (through D_{duf}/L_{sub} x Z_{th}) as a second-order correction term:

$$\frac{D_{\mathrm{Duf}}}{L_{\mathrm{sub}}} \frac{I_{\mathrm{c}}^0}{1+Z_{\mathrm{th}}} \simeq I_c^0 \left(\frac{D_{\mathrm{Duf}}}{L_{\mathrm{sub}}} - \frac{D_{\mathrm{Duf}}}{L_{\mathrm{sub}}} Z_{\mathrm{th}}\right)$$

We thus confirm in a different way the result of KV91.

A striking result is that thermal diffusion appears non negligible for CO_2 ice clouds on Mars ($Z_{th} \geq 10$) mainly because of high abundances of CO_2, while it is negligible for PMCs on Earth which form somewhat in similar atmospheric conditions but with very low abundances of water (< 250 ppm). These processes will be tested in a microphysical model presented in a companion abstract by Listowski et al.

Design of well-mixed aerosol chambers for stable aerosol generation

J.T.N. Knijnenburg, M.L. Eggersdorfer and S.E. Pratsinis

Department of Mechanical and Process Engineering, ETH Zurich, Zurich, CH-8092, Switzerland

Keywords: aerosol dynamics, Brownian coagulation, population balance, CSTR.
Presenting author email: jesper.knijnenburg@ptl.mavt.ethz.ch

Agglomeration or coagulation is a common phenomenon in well-mixed particulate processes like gas-phase aerosol reactors (Pratsinis *et al*, 1986) and liquid-fed crystallizers. In aerosol reactors, agglomeration or coagulation is the dominant mechanism for particle growth at high particle concentrations, especially during materials manufacture (e.g. titania, silica, etc). Well-mixed conditions in these particulate processes either by stirring or by intense fluid turbulence resemble those of continuous stirred tank reactors (CSTR) of classic reactor engineering.

The shape of the steady state size distribution in CSTR-like processes has been widely studied for a range of in- and outflow terms and coagulation kernels (e.g. Camacho, 2001). For Brownian coagulation in batch systems, the shape of the distribution becomes invariant after a given time, and one can speak of the so-called self-preservation. Independent of the initial distribution, the size distribution will always approach the same shape, as indicated by its constant geometric standard deviation (Landgrebe and Pratsinis, 1989). To our knowledge it has not been studied whether continuous, CSTR-like systems are also self-preserving at steady state.

Recently Fritzsche *et al* (2010) presented a CSTR-like aerosol generator to produce submicron aerosols. In their experiments, well-stirred conditions were fulfilled and Brownian coagulation in the transition regime was the dominant mechanism for particle growth. The steady state particle size distribution is independent of process parameters when scaled accordingly, and the size distribution follows a power law for intermediate particle sizes, in agreement with theory (Fritzsche *et al*, 2010; White, 1982). Long residence times were used to ensure that the produced aerosol size is coagulation-controlled.

Here, we present a numerical model for Brownian coagulation in a continuously fed well-stirred chamber. The goal is to provide a systematic understanding of how the size distribution in a CSTR can be controlled by process parameters. A population balance model is used to describe the temporal evolution of the particle size distribution:

$$\frac{\partial n(v)}{\partial t} = R(v) n_0(v) + \frac{1}{2}\int_0^v \beta(v-u,u)\, n(v-u,t)\, n(u,t)\, du - n(v,t)\int_0^\infty \beta(v,u)\, n(u,t)\, du - \frac{n(v)}{\tau_{res}} - \beta_{wall}(v)\, n(v)$$

Here $R(v)$ is the particle inflow rate per unit or chamber volume, τ_{res} is the residence time in the chamber, and $\beta_{wall}(v)$ is the wall loss coefficient (Crump and Seinfeld, 1981). The size distributions are characterized by various performance indices, derived from their moments. The model is applied to predict the coagulation-controlled size distribution from Fritzsche *et al* (2010). Validation was done by coagulation in the continuum regime (Figure 1).

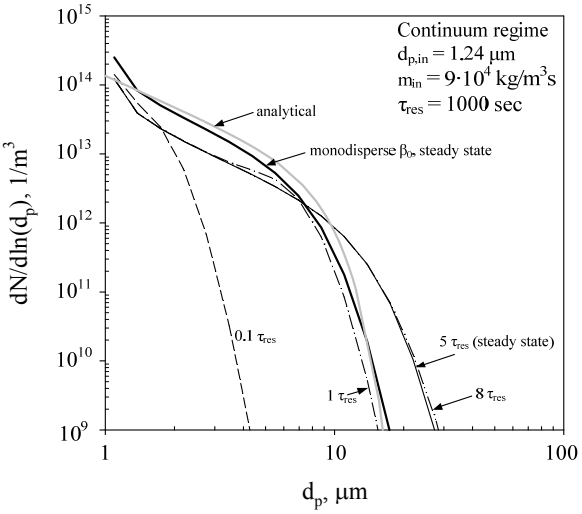

Figure 1. Evolution of particle size distribution over time by Brownian coagulation in the continuum regime. The monodisperse kernel β_0 gives good agreement with the analytical solution (Fritzsche *et al*, 2010; White, 1982).

The size distribution in CSTR-like processes does not evolve to an asymptotic self-preserving size distribution at steady state. The width of the size distribution is strongly dependent on the reactor residence time and the feed rate. Wall losses may have a strong influence on the size distribution but only for the large tail of the distribution for long residence times.

Abstract

The determination of cloud formation, water nucleation properties, supersaturation, and droplet growth is of paramount importance for meteorology and global climate models. Homogeneous nucleation and droplet growth rates measured in mixtures of synthetic air and water vapour are reported.

Experimental setup

The nucleation experiments are performed by means of the so-called pulse-expansion wave tube (see Figure 1). This is a special shock tube design in which the nucleation pulse is created at the end wall (left) of the high pressure section (HPS). It is separated by a diaphragm (D) from the low pressure section (LPS). The latter contains a local widening (W) of the cross-sectional area.

An expansion wave and a shock wave are formed after rapid opening of the diaphragm. The expansion wave creates a strong isentropic expansion in the measurement section at the end wall (left) of the tube. The second, weak expansion wave, which is created by the interaction of the shock wave with the beginning of the local widening (W), arrives at the measurement section somewhat later. The nucleation pulse is terminated by the arrival of a weak compression wave caused by the interaction of the shock wave with the end of the local widening (W). The nucleation and growth stages of the water droplet are consequently separated in time in this nucleation pulse method.

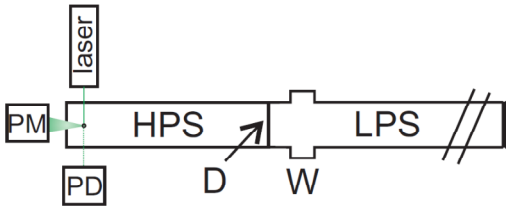

Figure 1. The pulse-expansion wave tube setup.

Droplet size and droplet number density can accurately be determined by a light extinction method (PD) and 90° Mie light scattering (PM).

The driving force for nucleation and condensation is the supersaturation, which therefore necessitates an accurate synthetic air/water vapour mixture preparation procedure. The latter is performed by means of a sophisticated mixture preparation device, in which gases are continuously premixed before injection in the high pressure section (Peeters *et al*, 2001). In this way, the synthetic air is the carrier gas charged with water vapour that will condense due to the sudden pressure decrease. The influence of the carrier gas on the condensation process and on the composition of the critical clusters is the subject of current research.

Critical cluster composition & classical nucleation theory corrections

Careful measurement of the dependence of the nucleation rate on supersaturation and total pressure allows us to determine the critical cluster composition in terms of air molecules and water molecules based on the nucleation theory for multi-component mixtures (Oxtoby and Kashchiev, 1994). The relatively high content of gas molecules in critical clusters is explained as adsorption of gas molecules on the surface of clusters.

At elevated pressures, appropriate corrections to the classical nucleation theory have to be applied. At high pressure, the solubility of vapor molecules in the gas phase in equilibrium with liquid is increased. This fact is quantified by the so-called enhancement factor, and leads to a decrease in the supersaturation for a given vapor molar fraction.

Another effect is the reduction of surface tension due to the adsorbed air gases. The effects of the gas on supersaturation and surface tension partially cancel. We analyze the gas effects by comparing the present results with the low-pressure nucleation data by Wölk and Strey (2001) with argon and Holten *et al.* (2005) with helium as carrier gas.

It is found that the carrier gas largely influences the composition of the critical clusters which is not predicted by the classical nucleation theory.

Session WG01S6O. Climate effects of aerosols

Model results of cirrus cloud modifications in a climate engineering framework.

Presenting author email: helene.muri@geo.uio.no

Cirrus clouds are an important element of the climate system and they can have a large impact on the Earth's radiation budget. Recent observations of mid-latitude cirrus clouds forming at temperatures below -40°C suggest that they are primarily formed by homogeneous freezing (Mitchell et al., 2011). These clouds hence tend to mainly consist of numerous small ice crystals. However, if efficient ice nuclei are present, heterogeneous freezing will be favoured, due to the suppression of the required supersaturation with respect to ice (Kärcher and Lohmann, 2003).

Mitchell and Finnegan (2009) proposed a climate engineering technique exploiting this competition between homogeneous and heterogeneous freezing, in order to cool the global climate. The term climate engineering, or geoengineering, can be defined as intentionally interfering with the climate system in order to temporarily offset or reduce the increase in surface temperatures by global warming.

The idea is to inject ice nuclei into cirrus forming regions, then a small number of ice crystals would form heterogeneously and grow rapidly by vapour diffusion. The large ice crystals would gain large fall speeds. Sanderson et al. (2008) found that the ice fall speed from cirrus clouds strongly affect climate sensitivity. The cirrus cloud coverage, life cycle, optical depth and upper tropospheric water vapour amounts are dependent on the ice fall speed. Seeding the cirrus with an effective ice nuclei could outcompete any pre-existing natural ice nuclei for the water vapour. Larger ice crystals could form, leading to a fall out of the cloud and hence cloud removal. This facilitates for more outgoing longwave radiation (OLR) being able to escape the climate system. Targeting the highest and coldest cirrus would be the most effective at increasing the OLR.

As the upper tropospheric water vapour is exported to the lower troposphere, the water vapour greenhouse effect is reduced. The combination of water vapour and cirrus cloud reduction should combine to give a cooling to counteract the surface warming due to high CO_2 concentrations.

The suggested seeding material is bismuth tri-iodide (BiI_3) (Mitchell and Finnegan, 2009). It is non-toxic, relatively cheap and can be produced in aerosol form by combustion of BiI_3 alcohol solution. It has an atmospheric residence time of 1-2 weeks.

The idea of climate engineering of cirrus clouds is a new one and until now not tested in GCMs. We present results of model experiments investigating the potential of the proposed climate engineering method using the CAM5 global climate model and WRF-CHEM cloud resolving model. This is done in the framework of the Barahona and Nenes (2009) ice nucleation scheme. The cirrus cloud parametrisation takes both homogeneous and heterogeneous freezing into account, including their interaction, when calculating ice crystal number and size distribution.

Compared to other suggested climate engineering methods, the one explored here has the advantage of addressing the longwave radiation directly, which is the part of the spectrum that is being perturbed by anthropogenic greenhouse gases. This avoids some of the caveats of other proposed climate engineering methods, e.g. stratospheric sulphur injections or seeding of marine stratus clouds. I.e. solar radiation management techniques where the reflected solar radiation to space is increased. It should however be noted, that none of these methods tackle the ocean acidification issue.

The influence of aerosols on the European heat-wave of 2003: a study with the regional model system COSMO-ART

The year 2003 was marked by a strong heat-wave in June, July, and August (JJA). During this period a synoptic blocking situation and unusual clear skies caused a drying-out of the soil. The combinations of these factors induced unusually high surface temperatures, up and above 40°C in Mid-Europe (Black et al. 2004). These high temperatures favoured the chemical formation of ozone as well as the biogenic emission of its precursors. This together with an extremely high photolytic activity, due to the very clear skies, led to high levels of ozone concentrations. At the same time, the high temperatures led to large numbers of wild-fires and strong emissions of biogenic aerosol precursor gases that contributed to unusual high concentration of aerosols in Europe, favoured by the blocking situation of air-masses. All these aspects qualify this situation as a particular test for air-quality models (Vautard et al., 2005).

We perform detailed calculations with the comprehensive model system COSMO-ART (Vogel et al., 2009). COSMO-ART is online coupled, which makes it possible to investigate feedbacks between particles and the state of the atmosphere in a homogeneous framework. The natural emissions of primary particles are parameterized as function of the ambient conditions. Primary soot and organic particle emissions are considered and secondary aerosols are formed from gaseous precursors that are treated by complex photochemistry in the model.

In this study the model system is applied for a continuous integration of 2 months from 15th June to 20th August 2003 over the COSMO-EU domain (see figure 1) at a resolution of approx. 14km with 40 vertical layers, and driven at the borders by ERA-Interim (Dee et al., 2011). Two simulations have been performed. In the first one no interaction of aerosols and the state of the atmosphere is considered, whereas in the second the simulated aerosols can interact with the state of the atmosphere via scattering and absorption of long and short-wave radiation, depending on the nature of the aerosols. The direct interactions of aerosols and clouds are not considered in the present study.

As an example of feedbacks that can be represented, we analyse the impact of a prognostic calculation of aerosols on the 2m temperature here. In figure 1 some systematic effects can be discerned. The 2 months average temperatures around the Mediterranean were reduced by approx. 1 K associated to high loads of aerosols and in particular Saharan mineral dust from North Africa in these regions.

In the Eastern part of the domain some regions show an increase of the 2m temperature. This effect could be related to the absorbing effect of black carbon on the long wave radiation and/or a systematic change in cloud cover over the regions.

The statistical significance of the observed changes is however in general not very high and longer runs are needed to confirm if the observed signals are systematic or particularly related to the considered time period.

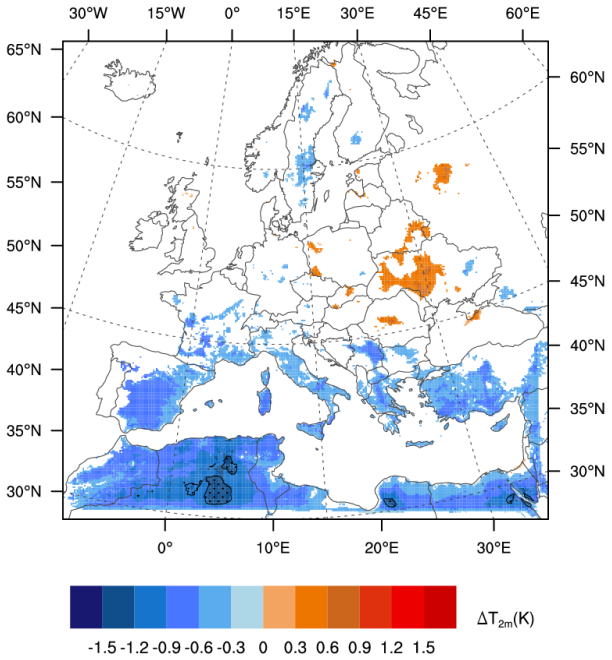

Figure 1. Absolute changes in average 2m-Temperature for the period from 15 June to 20 August 2003, from a run with COSMO-ART relative to a run with COSMO. White areas are where a t-test is not significant at the 66% level and stippled areas are where it is significant at least on the 90% level.

Aerosol indirect effect (AIE) is one of the greatest sources of uncertainty in the assessment of anthropogenic climate change. Much of this uncertainty arises from the relationship used to link aerosol with cloud droplet number concentration (CDNC). In addition, variability in the predicted meteorology and emission inventories used contribute to the differences in predicted AIE between GCM studies. Here the sensitivity of the first AIE to cloud droplet parameterizations, emission inventories and meteorological fields used is assessed.

The sensitivities are computed with the 3D NASA Global Modeling Initiative (GMI) chemical-transport model. GMI allows easy interchange of different model components while maintaining all others identical allowing a direct intercomparison of results obtained between alternate representations of aerosol, chemistry and transport processes. CDNC is computed using both empirical correlations (i.e., Boucher and Lohmann - BL (1995), Menon et al., - LB (2002)), and physically-based parameterizations (i.e., Abdul-Razzak and Ghan - AG (2000), and Fountoukis and Nenes - FN (2005)). Emissions from the University of Michigan (UoM) and the IPCC CMIP5 (CMIP) are used. Sensitivities are examined under two meteorological fields (i.e., NASA GEOS4 finite volume GCM (FVGCM) and NASA GEOS1-STRAT (GEOS)). Computed CDNC is used to calculate the effective radius (Re). The CLIRAD-SW solar radiative transfer model is used online to calculate the cloud optical depth (COD) and the shortwave fluxes from the surface to the top of the atmosphere (TOA). COD is calculated as a function of the effective radius. Evaluation of modeling results (i.e., Re, COD) is performed against satellite products from Moderate Resolution Imaging Spectroradiometer (MODIS) platform.

Depending on the meteorological field, the emission inventory and the droplet scheme used the annual mean CDNC ranges between 57 and 218 cm^{-3} (Figure 1) with larger differences seen over heavily polluted regions (e.g., Europe, China, NE USA), regions affected by long range transport of pollution (e.g., Atlantic Ocean) and regions affected by biomass burning (e.g., S. Africa, S. America). The droplet scheme used seems to be the most important parameter affecting CDNC followed by meteorology; the sensitivity of CDNC to emission inventories is small. The results for the shortwave cloud radiative forcing and the first AIE are quite similar across the modeling experiments reflecting the main differences seen in CDNC between simulations that use current and preindustrial emissions.

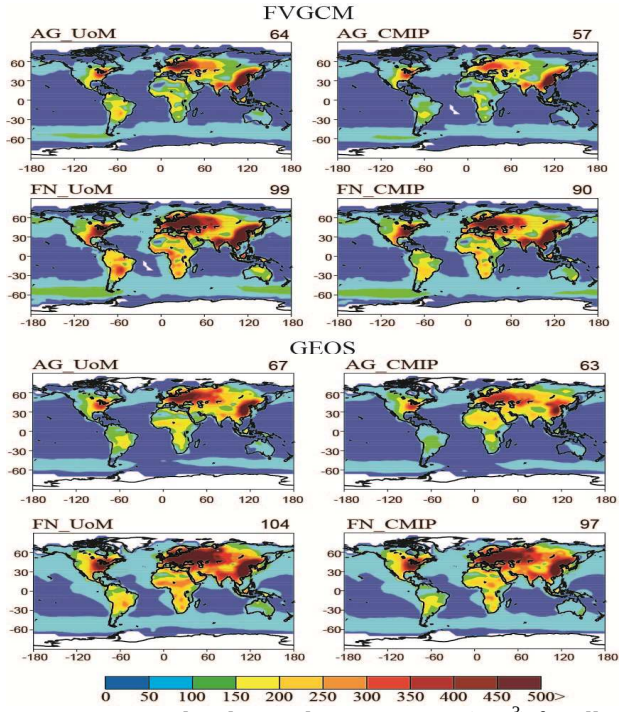

Figure 1. Simulated annual mean CDNC (cm^{-3}) for all emission inventories and meteorological fields used and the schemes of AG and FN. Global averages are shown in the upper right hand corner of each panel

Satellite images impressively demonstrate that aerosol layers originating from biomass burning, anthropogenic pollution or from deserts regions are regularly transported over long distances, even reaching other continents. Although the aerosol optical depth of individual layers can significantly contribute to the aerosol optical depth of the total atmospheric column [Weinzierl *et al.*, 2011], the global importance and the impact of these aerosol layers on atmosphere and climate is not yet known well enough.

Within the framework of the Contrail and Cirrus Experiment (CONCERT 2011), the DLR Falcon research aircraft conducted 11 research flights with a comprehensive aerosol in situ and trace gas instrumentation over Central Europe in September 2011. The aerosol in situ payload included a multi-channel CPC, several optical particle counters of type Grimm SKY-OPC 1.129, UHSAS-A, and FSSP-300. In addition, a multi-wavelength Particle Soot Absorption Photometer (PSAP) and a Single Particle Soot Photometer (SP2) was deployed, and the non-volatile particle size distribution was measured.

The main aim of CONCERT 2011 was a better understanding of contrails and natural cirrus clouds in the UTLS region, but in 9 of the 11 flights, also elevated aerosol layers were detected (see Fig. 1). 75% of the aerosol layers showed enhanced black carbon (BC) mass concentrations. Backward trajectory calculations indicate that the observed aerosol layers originated from boreal forest fires in Northern America, but also from anthropogenic pollution sources. In most of the cases the aerosol layers were found at altitudes between 2 and 5 km, but in two cases extended forest fire layers were present between 9 and 13 km altitude (Fig. 1, left panel). BC mass concentrations (size range: 70 nm - ~440 nm) in the elevated aerosol layers reached up to 0.3 µg m^{-3}. For comparison, BC mass concentrations ranged between 0.05 and 0.8 µg m^{-3} in the polluted boundary layer over Munich. From our SP2 data, we calculated the coating thickness of the BC particles in the elevated aerosol layers and found particles with a coating thickness of up to several hundred nanometers, whereas the BC particles in the boundary layers had only minor coatings. Such coatings can enhance the absorption of solar radiation [Schwarz *et al.*, 2008; Shiraiwa *et al.*, 2010], and therefore amplify the climate impact of those aerosol layers.

In our presentation, we will contrast the properties of the individual aerosol layers and show the impact of the aerosol source region and transport time on the observed microphysical and optical aerosol properties. We combine airborne in situ and ground-based lidar data to get information on the vertical and horizontal extent of the aerosol layers which is necessary to quantify the radiative effects of the individual aerosol layers. Expected heating rates and their impact on atmospheric stability will be discussed.

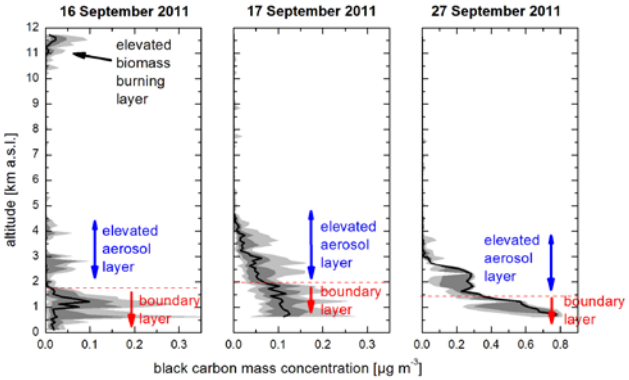

Fig. 1: Average vertical profiles of black carbon mass concentration for the research flights on 16, 17 and 27 September 2011. The black line denotes the median, and the light and dark grey shaded areas show the 10- and 90-, and 25- and 75-percentile values, respectively.

This work was funded by the Helmholtz Association (HGF) under grant number VH-NG-606 (Helmholtz Young Investigators Group AerCARE). The field experiment was organized and in part funded by the HGF grant VH-NG-309 (Helmholtz Young Investigators Group AEROTROP) and by the DLR project CATS.

The importance of wood burning as a source of absorbing aerosols in the European Arctic

K.E. Yttri[a], C. Lund Myhre[a], A. Stohl[a], C. Dye[a], D. Hirdman[a], J. Ström[b]

[b]Stockholm University, SE-106 91 Stockholm, Sweden

Keywords: Arctic, black carbon, sources, wood burning
Presenting author email: clm@nilu.no

Improved understanding of processes and sources of absorbing aerosols (here called black carbon, BC) in the Arctic is crucial in order to predict future climate development and implement effective mitigation steps. Due to the high surface albedo of snow and ice, even weakly absorbing aerosol layers can heat the Earth/atmosphere system in the Arctic. Furthermore, absorbing aerosols deposited on the surface can affect the snow and ice albedo and increase the amount of solar radiation absorbed, enforcing melting of snow and sea ice. It can be argued that the largest uncertainties when studying the aerosols impact on the Arctic climate are attributed to the highly absorbing BC, which is generated by incomplete combustion of fossil fuel and biomass.

Recent studies have argued that agricultural and boreal wild fires with their high emissions and proximity to the Arctic could be the most important source of Arctic BC in years of high wild fire activity (Stohl, 2006; Warneke et al., 2009). Additionally, countries bordering the Arctic are known to use substantial amounts of wood for residential heating; e.g. residential wood burning accounts for 70 % of the Norwegian $PM_{2.5}$ emissions of which elemental carbon (EC) constitutes 20 – 25 % (Yttri et al, 2009). BC emissions from these countries might be more important with respect to contributing to the Arctic BC concentration, compared to emission sources situated further south (Hirdman et al., 2009).

The current study presents the first one-year time series (13th of March 2008 to the 13th of March 2009) of the wood burning tracer levoglucosan in the Arctic, measured at the Zeppelin observatory (78º54' N, 11º53' E 478 m asl). 24 hours mean concentrations of levoglucosan were obtained from ambient aerosol filter samples subjected to High-Performance Liquid Chromatography coupled with Time-of-Flight Mass Spectrometry. The levoglucosan measurements have been used to study the influence of residential wood burning emissions and boreal forest fire emissions as a source of BC in the European Arctic. Supplementary measurements of EC (Thermal-Optical Analysis), light absorbing particles (Particle Soot/Absorption Photometer) and CO are used to interpret the results.

The results show that the mean concentration of levoglucosan observed at the Zeppelin observatory in winter is typically 2 - 3 orders of magnitude less than that reported for European urban areas in winter and 1 – 2 orders of magnitude less than that of the European rural background environment. Elevated concentrations in winter (mean ± SD; 1019 ± 1769 pg m^{-3}) compared to summer (mean ± SD; 108 ± 180 pg m^{-3}) were observed, resembling the seasonal variation seen for e.g. sulphate and BC caused by the Arctic haze phenomenon.

Calculations are made with the Lagrangian particle dispersion model FLEXPART to assess dominating source regions for levoglucosan. The European areas bordering the European Arctic were found to have a large influence on the observed levoglucosan concentrations at Zeppelin in winter, likely being a combination of the widespread use of wood burning for residential heating in Northern Europe and its proximity to the Arctic, governing atmospheric transport.

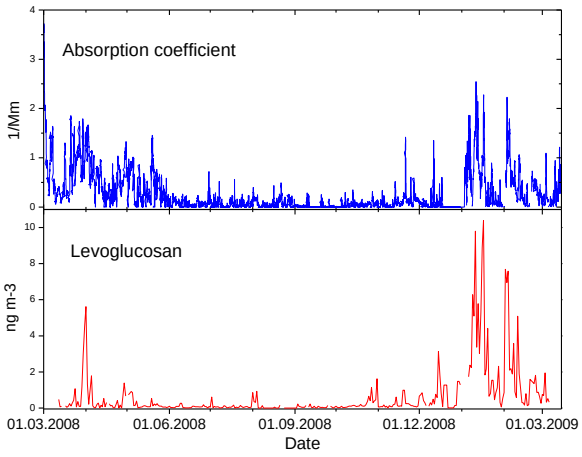

Figure 1: One year observations of levoglucosan and absorption coefficient at the Zeppelin Observatory

Presenting author email: jonas.svensson@fmi.fi

Investigations of Black Carbon (BC) have increased in recent years, as it has been proposed to significantly alter the climate, especially in the Arctic (e.g. Quinn et al. 2011). BC particles absorb solar heating (Flanner et al., 2007) and, if deposited in snow or ice it will lower the albedo and affect the radiative balance (Clarke and Noone, 1985). BC deposited on snow also contributes to earlier snowmelt (Flanner et al., 2007), which has the greatest effect in the spring when the highest amount of solar radiation is directed at the snowpack.

A comprehensive study of BC concentrations in snow in the Arctic was recently conducted by Doherty et al. (2010) and a variation from the different sampling sites was observed. The small scale (meter scale) variation, however, was not examined exhaustively and is in principle unstudied. The main objective of this study is to investigate the horizontal variation of BC on a high resolution scale (i.e. meter scale) in surface snow. The variation was further studied by comparing two sites with different character (clean vs. polluted). Due to the analysis method used, the thermal/optical method, elemental carbon (EC) is presented as a proxy of BC in this study.

Investigations were carried out in the vicinity of Stockholm, Sweden (representing the polluted site) and in Pallas, Arctic Finland (clean site). Individual surface snow (roughly the upper 5 cm) samples were collected in different grid-nets, with the most common grid-net consisting of a 20m by 20m square with samples taken every 5m within the square (see figure 1). Snow samples were melted and filtered through micro-quartz filters which were analyzed in a Thermal/Optical Carbon Aerosol Analyzer (OCEC) (Birch and Cary, 1996) for their apparent EC concentration.

A variability of EC in the sampled grid-nets was observed at both of the sites; however, the site with less pollution affecting it presented greater variation in comparison to the polluted site (figure 1 and 2). The higher variation at the Pallas site is probably explained by a higher degree of snow drift. Microphysics and snow metamorphism are also plausible factors which affect the variation of EC concentrations in the surface snow.

The results presented here on a meter scale will be compared with samples taken on a kilometer scale in Pallas. Additionally, a comparison between the Single Particle Soot Photometer (SP2) analysis method and the OCEC method for measuring BC in snow will be done.

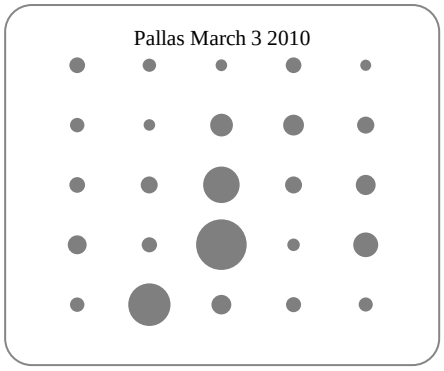

Figure 1. Grid-net from Pallas with a spatial scale of 5m between circles. The size of the filled circles reflects the corresponding sample's concentration size. The circle sizes are not proportional in size to the circles from Stockholm, as they are significantly higher.

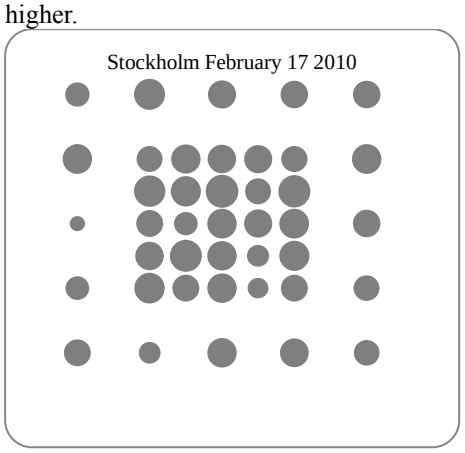

Figure 2. Grid-net from Stockholm with a spatial scale of 5m for the circles in the outmost square and 2.5m in the innermost part.

The need to reduce greenhouse gas emissions as well as regulated emissions drives the need to study alternatives for fossil fuels.

Hydrogenated vegetable oil (HVO) is the newest commercially available bio-based diesel fuel. It is composed of paraffinic hydrocarbons and includes essentially no aromatics or sulphur. HVO fuel is reported to lower regulated emissions (Aatola *et al.*, 2008). Compounds containing oxygen (i.e. oxygenates) can be blended to the fuel to further reduce the particle emissions. Oxygen content in biodiesel (i.e. FAME) has been reported to increase the oxygen content in the emitted soot as well as alter the oxidation behaviour of the emitted soot (Song *et al*., 2006). Increased oxygen content in particles could also have an effect on particle hygroscopicity.

In this study (Happonen *et al.*, 2012), we investigated how the addition of oxygenate (Di-n-pentyl ether, DNPE) to HVO fuel alters particulate emissions and particle hygroscopicity. Oxygen content in the DNPE-HVO blend was 2 wt-%. The effect on NO_x-emissions was also studied.

The measurements were performed on an engine dynamometer with single-cylinder test engine modified from a commercial six-cylinder off-road common rail diesel engine.

Particle size distributions were measured using a Scanning Mobility Particle Sizer (SMPS) and the total number concentration with a Condensation Particle Counter (CPC). Particulate mass (PM) was measured according to the ISO 8178-1:2006 standard. Particle hygroscopicity was studied using a hygroscopic tandem differential mobility analyzer (HTDMA). We also performed organic/elemental carbon (OC/EC) analysis on collected particle filter samples.

Particulate matter (PM) emission was reduced 26-32% with all measured loads while particle number reduced 10-17%. With 75% and 100% loads NO_x-emission was slightly higher with oxygenate blended fuel, unlike with 50% load where NO_x – emission was 2-3% lower.

Growth factors are all within error limits (one standard deviation), as shown in figure 2. However, the growth factors measured with HVO were measured at approximately 2%RH higher humidity than HVO-DNPE growth factors and still the growth factors with HVO-DNPE are slightly higher than with pure HVO. The differences would be clearer if measured at the same RH. Thus, fuel seems to slightly affect the hygroscopic properties of emitted particles.

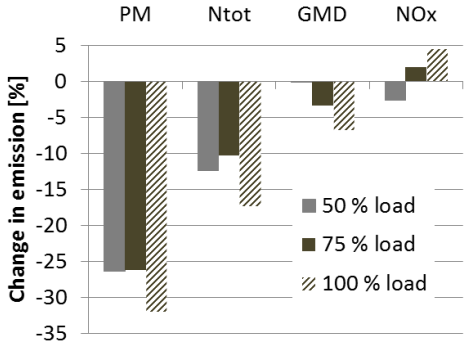

Figure 1. Relative changes in emissions caused by oxygenate blending with HVO fuel.

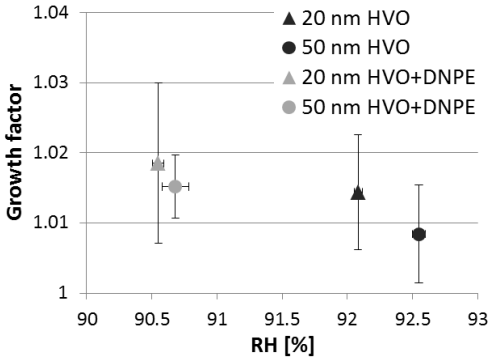

Figure 2. Growth factors of chosen particle sizes with and without oxygenate blending.

This study was funded by Tekes (Finnish Funding Agency for Technology and Innovation).

Particulate matter emissions from a winter operation of a modern on-road diesel engine powered by heated rapeseed oil

M. Vojtisek-Lom, M. Pechout, M. Mazač

Department of Vehicles and Engines, Technical University of Liberec, Liberec, Czech Republic
Keywords: combustion, diesel engine, rapeseed oil, vegetable oil, biofuels
Presenting author email: michal.vojtisek@tul.cz

Introduction

Diesel engines powered by liquid fuels move the world, but also release, directly in the streets, nanoparticles hazardous to human health. New fuels and engine technologies must therefore be evaluated carefully for their effect on particle emissions.

Neat vegetable oils, typically used for the production of biodiesel, are often used as motor fuels, despite their use falling short of being widespread due to adverse effects on engines. One of such adverse effects is the inferior combustion of vegetable oils at low engine speeds and loads resulting in increased emissions of particulate matter (PM), while PM generally decrease at moderate and higher rpm and loads (Czerwinski 2008, Vojtisek-Lom 2009). The increase in PM emissions was attributed primarily to higher viscosity of rapeseed oil compared to diesel fuel, causing worse atomization of the fuel, and worsened evaporation in the combustion chamber, leading to a less complete combustion; the decrease in PM to the differences in chemical structure of rapeseed oil, notably the absence of aromatics and about 10% by weight oxygen content.

To decrease PM emissions, majority of currently produced diesel engines use a Common-Rail (CR) injection system. In a CR system, multiple injections are performed, with the timing and quantities of fuel injected controlled and optimized for petroleum diesel fuel. While this approach greatly reduces PM emissions when operating on diesel fuel, a question arises as to its performance with vegetable oils for which it is not optimized. Higher PM were reported by Dorn (2007).

Experimental

In this study, a 4.5-liter, 130 kW, four cylinder, turbocharged Cummins ISBe4 medium truck/bus engine with a Bosch CR injection system was tested on an engine dynamometer during steady-state operation. The engine was operated without any exhaust gas aftertreatment system on diesel fuel, neat biodiesel (FAME) and heated RO. The exhaust was routed in an improvised full-flow dilution tunnel, part of which was located outside of the laboratory. PM mass emissions were measured by the gravimetric method. Particle size distributions in the range of 5-500 nm were measured by EEPS spectrometer (model 3090, TSI, St. Paul, MN, USA). The testing was performed during the winter at outside temperatures 265-270 K and engine intake air temperatures 285-290 K.

The dilution apparatus and its operating temperature were favorable for nucleation and condensation of particles. No efforts were taken to evaporate volatile matter from the particles by a thermodenuder or by diluting with heated air. Therefore, this experimental setup was considered to represent reasonable worst-case scenario of an engine operated during the winter.

Results and discussion

The particle number emissions for FAME were typically similar to tens of percent lower compared to diesel fuel in all size ranges. For RO, particle concentrations were between diesel and FAME above 20-30 nm, but markedly higher at lower diameters with a strong nanoparticle peak (see figure below for an example). These small particles are believed to be organic carbon which would be in gaseous form at higher temperatures. Total particle number emissions for RO were compared to diesel lower at full load but higher at all other regimes. The effect on total PM mass over ESC and WHSC cycles was not uniform and relatively small. With the exception of the nanoparticle peak which is subject to future discussions, no major adverse effects on PM emissions were observed during operation of a modern CR diesel engine on heated RO.

Keywords: diesel exhaust, nucleation mode, sulphuric acid.
Presenting author email: topi.ronkko@tut.fi

The sulphuric acid, formed from fuel and lubricant oil sulphur compounds, is suspected to be one of the most important compounds in diesel exhaust nucleation mode particle formation. However, in several studies the nucleation mode particle formation conditions and physical characteristics of the particles do not indicate sulphuric acid driven process. In these cases the nucleation mode is repeatedly shown to include nonvolatile compounds (e.g. Rönkkö et al. 2007) and carry an electric charge. In general, it seems that exhaust after-treatment methods can have critical role in particle formation. Thus, in this study the focus was in the effects of exhaust after-treatment on diesel exhaust gaseous sulphuric acid and on nucleation mode particle formation and characteristics.

Measurements were performed at an engine dynamometer with a Euro IV heavy duty diesel engine without exhaust after-treatment and with three different oxidative exhaust after-treatment solutions: with diesel oxidation catalyst (DOC), with the combination of DOC and particle oxidation catalyst (DOC+POC) and with the combination of DOC and diesel particle filter (DOC+DPF). Thus the tested exhaust after-treatment devices represented typical technologies in modern vehicles and, on the other hand, formed interesting entity from the viewpoint of particle formation.

All exhaust after-treatment devices were tested using fuel and lubricant oil with sulphur contents 6 and 1600 ppm, respectively. In addition, particular tests were performed also using fuel with 36 ppm sulphur. Measurements were conducted at four steady state driving modes (ESC 10-13). Exhaust sampling and dilution for particle measurements was conducted using porous tube diluter, ageing chamber and secondary dilution. Particle size distribution and number concentration measurements were made using Nano-SMPS, SMPS, CPC and ELPI, and a thermodenuder was used to study particle volatility characteristics. Gaseous sulphuric acid (GSA) concentration was measured by using a CIMS instrument.

Results indicate that the formation and characteristics of nucleation mode particles are strongly depended on exhaust after-treatment. Without exhaust after-treatment or with the DOC, the particle formation seems to be based on non-volatile core particle formation at high temperatures and on particle growth by volatile compounds during the exhaust dilution and cooling process. With the DOC also the sulphuric acid driven particle formation seems to be possible. With a DOC+POC the nucleation mode was not observed (Figure 1) with low sulphur fuel. Instead, when the DOC+DPF was used, the nucleation mode occurred at high load and particles were volatile which, together with increased GSA concentrations, indicate sulphur driven particle formation.

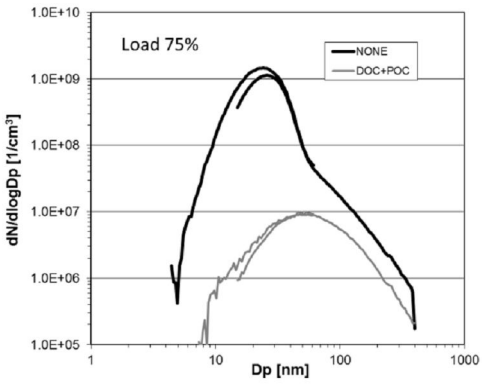

Figure 1. Particle size distributions of a heavy duty diesel engine without exhaust after-treatment (NONE) and with DOC+POC (Heikkilä et al. 2009).

The influence of oxygenated organic aerosols (OOA) and its volatile organic content on the oxidative potential of diesel particulate mater

Keywords: biofuels, reactive oxygen species, profluorescent nitroxide.
Presenting author email: s.stevanovic@qut.edu.au

Airborne particulate matter pollution is of concern for a number of reasons and has been widely recognised as an important risk factor to human health. A number of toxicological and epidemiological studies reported negative health effects on both respiratory and cardiovascular system. Despite the availability of a huge body of research, the underlying toxicological mechanisms by which particles induce adverse health effects are not yet entirely understood. The production of reactive oxygen species (ROS) has been shown to induce oxidative stress, which is proposed as a mechanism for many of the adverse health outcomes associated with exposure to particulate matter (PM). Therefore, it is crucial to introduce a technique that will allow rapid and routine screenings of the oxidative potential of PM.

In our previous studies we applied a new profluorescent nitroxide molecular probe (bis(phenylethynyl) anthracene-nitroxide; BPEAnit) [1], developed in an entirely novel, rapid and non-cell based assay, for assessing the oxidative potential of particles derived from various combustion processes (e.g. wood smoke and various diesel engines and fuels) [2,3].

One of the most important outcomes of our research thus far was that the oxidative potential per PM mass significantly varies for different combustion sources as well as different combustion conditions and feedstock used. However, possibly the most important finding from our studies was that there was a strong correlation between the organic fraction of particles and the oxidative potential measured by the PFN assay, which clearly highlights the importance of organic species in particle-induced toxicity [2,4] and reinforces the further investigations to explore this correlation.

To gain an insight into this relationship, additional measurements were conducted on an ethanol fumigated modern common rail diesel engine. In addition to running the engine with various levels of ethanol substitution several biofuels were used. Tests were designed to present emission differences due to changes in fuel and load settings.

A more detailed analysis of the organic content was performed to support the ROS measurements. This involved volatility measurement using a Volatility-Tandem Differential Mobility Analyser (V-TDMA) and particle composition using an Aerodyne Aerosol Mass Spectrometer (cToF-AMS). For detection of organic fraction we also used the ultrafine organic tandem differential mobility analyzer UFO-TDMA.

Volatility measurements indicating the overall organic coating on particles correlated with measured oxidative potential, but not as strong as in previous measurements. This indicated that ROS content is a function of organic particle composition but does not always exhibit a simple linear trend with volatility data. To investigate this relationship in more detail the data from the AMS were used. The fraction at the m/z of 44 (f44) was used as a tracer for the oxygenated organic aerosol (OOA) and 57 (f57) as the tracer for hydrocarbon like organic aerosol (HOA). The highest correlation was observed between the ROS concentration and the OOA.

Therefore the oxidative potential of the PM, measured through the ROS concentration, although proportional to the total volatile organic volume percentage shows a much higher correlation with the oxygenated organic fraction. This highlights the importance of the surface chemistry of particles for assessing the health impacts. It also sheds a light onto new aspects of particulate emissions that should be taken into account when establishing relevant metrics for health implications of various emissions.

Size-resolved particle emission factors for individual ships

Å.M. Jonsson[1], J. Westerlund[2] and M. Hallquist[2]

[1]IVL Swedish Environmental Research Institute Ltd, Box 5302, 400 15, Gothenburg, Sweden
[2]Atmospheric science, Department of Chemistry and Molecular Biology, University of Gothenburg, 412 96, Gothenburg, Sweden
Keywords: ship emissions, emission factor, coastal area, number size distribution
Presenting author email: asa.jonsson@ivl.se

More than 80 % of world trade is transported by ships and shipping is projected to increase further in the future (Buhaug et al., 2009). Emissions from shipping are today poorly regulated in legislation. Shipping has therefore become a more and more important source for urban air quality in coastal and harbour cities. Shipping also contributes globally to climate effects. E.g. globally the contribution of particles from shipping is almost as large as from road traffic, 1.7 compared to 2.1 Tgy^{-1} (Eyring et al., 2005). For emission inventories both laboratory and field measurements are needed to complement each other. Measurements for large fleets on individual ship basis for nanoparticles are today very scarce.

A method previously used for road side measurements where particle emissions were related to CO_2 as a trace of combustion e.g. (Hak et al., 2009) was in this study used for ship emissions. A sample was extracted from passing exhaust plumes on an island next to a large fairway and characterized with an EEPS (Engine Exhaust Particle Sizer, model 3090, TSI Inc.), a CPC (Condensation Particle Counter, 3775, TSI Inc.) and a non-dispersive infrared gas analyser (LI-840, LI-COR Inc.) for CO_2. A thermodenuder was used in front of the EEPS to measure the volatile to non-volatile ratio of selected plumes. Emission factors (EFs) was calculated with the following formula:

$$EF_{part} = \frac{\Delta part}{\Delta gas} \times EF_{gas}$$

where $\Delta part$ and Δgas are changes in particle number/mass and CO_2 during ship passages and EF_{gas} is the EF for CO_2.

In these measurements particle emissions from individual ships have been characterized, both regarding number, mass and size distribution (Part 1) but also for volatility (Part 2) (Jonsson et al., 2011). The measurements were conducted in the entrance to the port of Gothenburg which is an environmental control area (ECA) where the maximum fuel sulphur content was limited to 1 % by weight. In total 734 EFs (Fig. 1) were derived. 92 ship passages were also selected to determine the thermal characteristics of the particles emitted (Part 2). Compared to diesel buses without particle filter the EFs in this study were a factor of 10 higher for number and a factor of 2 higher for mass (Jonsson et al., manuscript in preparation, 2012).

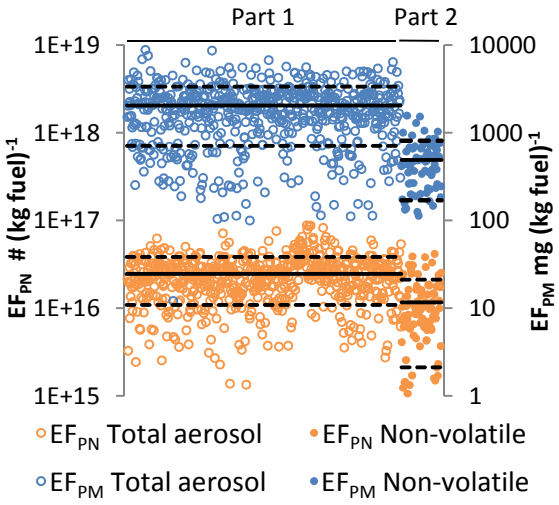

Figure 1. EF for 734 ship passages for number (EF_{PN}) and mass (EF_{PM}). The total aerosol was measured in Part 1 and the non-volatile fraction in Part 2. Solid lines represent averages and dashed lines represent 1 standard deviation.

Using a stationary measurement platform for ship emissions proved to be very successful both regarding reproducibility, cost and number of ships studied. Analysis of factors affecting the particle emissions e.g. ship speed and plume age are also considered (Westerlund et al., manuscript in preparation, 2012).

Towards an identification of aircraft soot among urban background: focus on nanoparticles emitted by CFM56 turbofan engines

D. Lottin[1], D. Ferry[2], J.-M. Gay[2] and D. Delhaye[1]

Today's scientific concerns incite to study both qualitatively and quantitatively the impact of combustion aerosols on the atmosphere because of the current questions of climate change and atmospheric pollution. For example, the combustion processes in aircraft turbofan engines produce particulate matter mainly composed of soot aggregates. These quasi-fractal, carbonaceous and submicron particles potentially act in the modification of the atmospheric radiative budget and in the degradation of the air quality in the airports vicinity (Lee *et al.*, 2009). This study focuses on the definition of size and morphological characteristics able to identify aircraft soot aggregates among urban aerosols.

Aircraft soot aggregates emitted by three different CFM56 turbofan engines (CFM International) are collected by impaction on Transmission Electron Microscopy (TEM) grids. The sampling is performed during engine cycles representative of combustion settings in airport areas. We analyze the TEM micrographs to determine the characteristic sizes of the aggregates, namely the primary particles diameters (d_p) and the aggregates gyration diameters (d_g) according to the usual methods of characterization (Baron and Willeke, 2001 and references therein). The geometric mean values calculated on the three populations of aircraft aggregates are compared to the characteristic sizes of diesel soot aggregates (Lapuerta *et al.*, 2012) and presented in Table 1. It appears that these aircraft soot aggregates are statistically smaller than diesel ones.

Characteristic sizes	$\langle d_p \rangle$	$\langle d_g \rangle$
Diesel	25 nm	110 nm
CFM56-5C	10 nm	70 nm
CFM56-5B	9 nm	40 nm
CFM56-7B	5 nm	60 nm

Table 1. Geometric mean primary particle diameter and gyration diameter for soot aggregates emitted by CFM56 and diesel engines (Lapuerta *et al.*, 2012)

The observation of TEM micrographs reveals that aircraft soot aggregates are generally more compact and less ramified than diesel ones (Figure 1). The determination of the statistical mass fractal dimension (Brasil *et al.*, 1999) does not highlight such morphological differences, since the values for CFM56 aggregates are very similar to values found in the literature for diesel aggregates (Lapuerta *et al.*, 2010 and references therein). Therefore, we use a complementary approach to describe the morphological characteristics of soot aggregates, based on a 2D analysis of the TEM micrographs. Firstly, we focus on the perimetric fractal dimension calculated on the aggregates as individuals using a covering-box method (Cleary *et al.*, 1990). Secondly, we describe the shape of the aggregates by using three shape descriptors, namely the roundness, the aspect ratio and the form factor (Chakrabarty *et al.*, 2006, Hentschel and Page, 2003). This approach seems efficient to distinguish soot aggregates according to their combustion source, i.e. diesel and aircraft ones.

However, further investigations will be undertaken to confirm the tendencies observed on size and morphology for soot aggregates emitted by technologically different aircraft engines. This could be used to complete the knowledge on the particulate matter emitted in the airport vicinity. To a further extent, this analysis has to be done for aggregates emitted by other urban, e.g. industrial or residential, combustion sources.

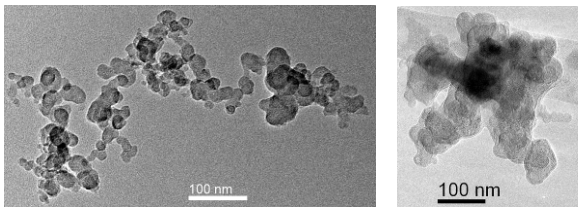

Figure 1. TEM pictures of diesel (left) and aircraft (right) soot aggregates.

During Project AAFEX-II (**A**lternative **A**viation **F**uel **E**missions e**X**periment), PM emissions measurements were conducted on a CFM56-2C1 gas turbine engine in March-April 2011 in Palmdale CA. The engine was mounted on a NASA DC-8 aircraft, which was parked on a pad, and emission samples were extracted at the engine exit plane (1m), in the near field (30m), and in the advected plume (145m). The engine was operated at several power levels, and burned several fuels: JP-8, a coal-based Fischer-Tropsch (FT) fuel, and a Tallow-based Hydroprocessed Esters and Fatty Acids (HEFA) fuel. In addition, a blend of JP8 and HEFA fuels and FT fuel doped with with a 1000 ppm sulfur compound, Tetrahydrothiophene (THT) were also studied. The objectives of the AAFEX-II campaign were to evaluate alternative fuel effects on engine performance and fuel-handling equipment, determine fuel effects on engine PM and gas phase emissions, study the role of sulfur on exhaust PM, investigate the impact of sample line chemistry and line losses on emission measurements, and to support the development of standardized exhaust sampling methodology.

The chemical composition of atmospheric aerosol is an important but difficult to measure aerosol characteristic. In the absence of direct quantitative chemical analytic methods, the measurement of an aerosol's hydration and volatility properties contributes significantly to our understanding of the chemical nature of the aerosol and how it will evolve in the atmosphere. During project AAFEX-II PM total number and size distribution measurements were made at the engine exit plane and at distances of 30 m and 145 m downstream in the exhaust plume. Additionally non-volatile PM number, size distribution, and hydration measurements were made at the 145 m position. Condensation particle counters and electrical mobility-based size spectrometers were used for number and size distribution measurements, a thermal denuder operating at 300 C was used for volatility characterization (Schmid et al 2002), and a tandem differential mobility analyzer with saturator was used for hydration measurement (Whitefield et al 1993).

Figure 1 shows an example of the 145 m PM soluble mass fraction (Smf) and volatile mass fraction (Vmf) as a function of particle diameter (x) when the engine is operating at 85% power and burning JP8 fuel. Both Smf and Vmf decrease with increasing particle size and have a correlation coefficient of 0.86.

Particles are found to be generated in the near field between 1 and 30 m. This particle generation decreases as power increases; it is small at high power except for the case of high sulfur fuel. Non-volatile

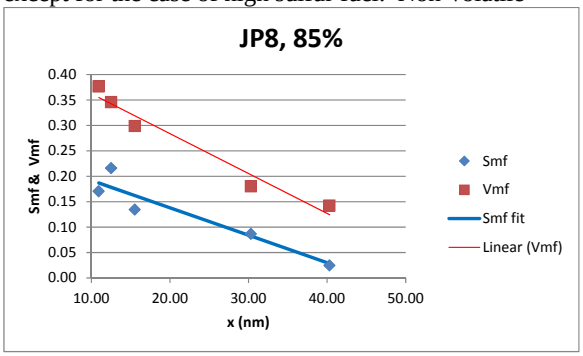

Fig. 1 Soluble mass fraction and volatile mass fraction vs. particle diameter

particles are generated between 1 and 145 m. This generation is observed to decrease with increasing engine power. JP8 and the HEFA-JP8 blends show the lowest proclivity for particle generation. At 145 m the volatile particle population is greater than the non-volatile by factors ranging from 10 to 300, with an average around 50. Particle mass is generated between 1 and 30 m; this generation decreases as power increases; it is small at high power except for the high sulfur fuel. PM non-volatile mass is generated between 1 and 145 m, perhaps due to scavenging. This effect decreases with increasing engine power, and it is small at high power for all fuel types. The volatile mass is greater than the non-volatile by factors ranging from 1 to 25, with an average around 7.

Session WG05S3O. PMx source apportionment

Comparison of receptor models using synthetic organic aerosol mass spectra

H. Hagino[1], and T. Morikawa[1]

[1] Energy and Environmental Research Division, Japan Automobile Research Institute, Tsukuba, Ibaraki, 305-0822, Japan

Keywords: Aerosol mass spectrometry, Source Apportionment, PMF, CMB
Presenting author email: hhagino@jari.or.jp

The atmospheric aerosols, especially fine particles, are known to have adverse health effects on human populations. Understanding the composition of fine particles is necessary to identify their sources and to predict their effect on various atmospheric processes. Although organic aerosols are major components of the fine particles in urban atmospheres, the composition, formation mechanisms, and seasonal variation of concentrations of organic aerosols (OA) are not well understood. To study the organic aerosol source apportionment, several receptor models have been developed, such as the Chemical Mass Balance (CMB) and Positive Matrix Factorization (PMF) models. These receptor models have frequently been applied to $PM_{2.5}$ measurement for air quality management. However, few studies have applied receptor modelling to datasets of aerosol mass spectrometer (AMS). The AMS data has been used to chemically characterise the sources and evolution of OA at many worldwide (Zhang *et al*., 2007).

The CMB (CMB8J ; Hayakari and Hanaishi (2001)) and PMF (PMF2 ver4.2 ; Paatero (2000)) were demonstrated to synthetic datasets that suppose ambient organic aerosol mass spectra from two sources. Two different organic aerosol mass spectra scenarios using different sources were considered. The scenario assumed that the similar time variations occurred between diesel exhaust particles as primary organic aerosol (POA) and *m*-xylene-derived secondary organic aerosol (SOA) (Figure 1).

The time trend of PMF and CMB agree well with a good correlation. However, PMF separate out factors corresponding to POA and SOA, then two sources that made relatively uniform contributions to the synthetic dataset. In addition, PMF resolved factor profiles also have similar profile abundances. The CMB represented that the source apportionment with the POA and SOA profile has a better fit to the synthetic dataset.

Each receptor model has its strengths and weaknesses. These weaknesses include CMB might misspecify sources and have collinearity problem (Lowenthal, *et al*. 1992); for PMF, it should interpreted as sources and aerosol components. In addition, PMF might fail to separate out some factors (sources) (Brinkman *et al*., 2006).

The CMB is an ideal approache when the profiles of the emissions for all relevant sources are known and do not change with time. The more dataset from laboratory and field studies need to be analysed to evaluate the receptor models.

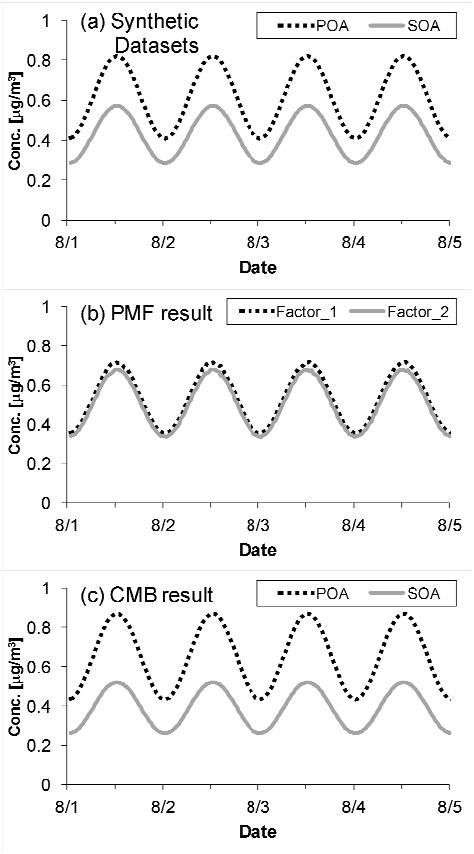

Figure 1. Time trends of synthetic dataset (a), PMF analytical result (b), and CMB analytical result (c).

Particulate carbonaceous matter (PCM) is found to constitute 10–40% of PM10 levels at rural and natural background sites in Europe Recent reviews have highlighted the complexity of the carbonaceous aerosol both in terms composition and formation mechanisms, but over the last few years a number of measurement results using tracer methods have become available which have started to shed light on the important sources of PCM in Europe (e.g. Gelencsér et al., 2007; Szidat et al., 2009).

Within the EUCAARI project, data on 14C, EC, OC and GC-MS analyses, and sometimes NMR and AMS, are available from a number of sites, including in Hungary, Finland, Germany, Italy (eg Gilardoni et al., 2011), and Sweden (Genberg et al., 2011). The link between tracers and their associated organic carbon amounts are of course very uncertain. Using method developed in Gelencsér et al. (2007) and Szidat et al. (2009) we define both a central best-estimate value for each factor and a plausible range of uncertainty. In order to tackle the multitude of possible combinations of these uncertain parameters, we have made use of an effective statistical approach known as Latinhypercube sampling (LHS). All valid combinations of parameters (i.e. excluding those producing negative contributions) are condensed in frequency distributions of possible solutions. This work focuses on the use of this method with EUCAARI and other observations to shed light on the sources of PCM in Europe. The LHS approach is used to calculate the relative contributions of the primary/secondary and anthropogenic/natural sources of the carbonaceous aerosol.

Finally, we will use model calculations using the EMEP MSC-W model (Simpson et al., 2012, Bergström et al., 2012), and variants of the so-called volatility basis set SOA schemes (eg Donahue et al., 2009) to illustrate how source-apportionment analysis can be used to discriminate between different SOA schemes, and to constrain model possibilities. An important finding of these studies is that large uncertainties exist in the emission inventories for residential wood-burning in Europe.

The EU-MED APICE project (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions; www.apice-project.eu) aims to quantify the impact of harbour and harbour related activities to PM concentration observed in 5 Mediterranean harbours: Barcelona (Spain), Marseille (France), Genoa (Italy), Venice (Italy) and Thessaloniki (Greece). For that purpose, long term monitoring campaigns are currently underway in these 5 harbours by each of the local scientific partner of the project. In order to intercompare source apportionment approaches used by each partner and to harmonize the methodologies between areas under study, a 6 weeks intercomparison campaign has been conducted in Marseille during winter 2011.

Marseille is the most important harbour of the Mediterranean Sea. It handles twice the traffic compared to Genoa, and nearly three times the traffic of Barcelona or Valencia. A huge petrochemical area, among other industrial plants (steel mill, coke plant...), is also located close to Marseille, the second most populated city in France with more than 1 million inhabitants. Industrial and shipping emissions of PM are generally among the least well known sources in the field of atmospheric research and largely merit in depth studies in this context. Furthermore, this intercomparison campaign is also the ideal framework to test our ability to apportion such specific sources among many others in a densely populated area.

Comprehensive chemical characterization of PM2.5 and PM10 have been performed by each partner on the same 24h basis during this 6 week-long campaign, including measurements of major ions, OC/EC, metals/elements and organic markers (hopanes, levoglucosan, PAHs, n-alkanes, fatty acids, resin acids, methoxy phenol,..). Independent results from each partner are now intercompared. High temporal resolution measurements were also achieved with high-resolution time-of-flight aerosol mass spectrometers (HR-ToF-AMS), aethalometer, multi-angle absorption photometer (MAAP), scanning mobility particle sizer (SMPS) and proton transfer reaction mass spectrometer (PTR-MS) for VOC measurements. Positive Matrix Factorization (PMF) and Chemical Mass Balance (CMB) were used to apportion sources. Preliminary example of source apportionment is presented with figure 1.

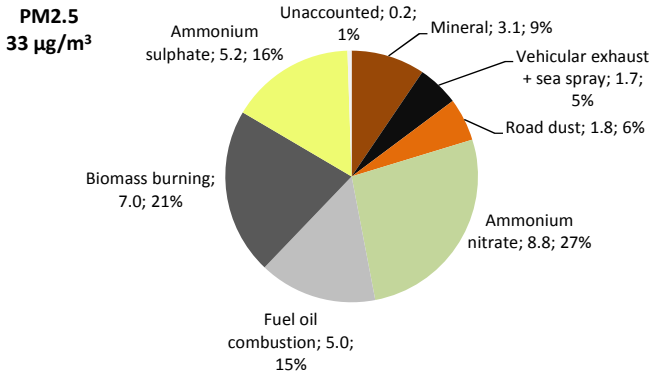

Figure 1. Example of source apportionment by PMF, using both organic markers and metals.

In this presentation, we will compare several source apportionment approaches:
- CMB with organics markers and elements/metals,
- PMF with elements/metals and major aerosol fractions (OC/EC, major ions),
- PMF with elements/metals, organic markers and major aerosol fractions (OC/EC, major ions) (figure 1),
- AMS/PMF.

Combination of CMB and PMF has also been performed (*i.e.* factors derived from PMF analysis have been injected as source profiles in CMB calculation). This combined approach is particularly interesting for sources such as mineral or road dust, for which no source profile exists (or presents too much variability between environments to be considered as scientifically sounded).

This work is supported by the MED programme under grant 2G-MED09-26.

Receptor models are commonly used to identify the sources of ambient particulate matter (PM) in Europe. However, the use of different tools and methodological approaches make it difficult to compare the results of different studies.

In order to promote harmonization in this field an intercomparison exercise involving 16 expert groups was organized and evaluated by the JRC within the framework of FAIRMODE.

The test DB consisted of 178 $PM_{2,5}$ speciated samples deriving from two real-world re-arranged DBs (Lee & Hopke, 2006 JGR; Jaeckels et al., 2007 EST). Concentrations and uncertainties of 46 inorganic and organic species were used to characterize the PM.

A total of 22 solutions obtained using the following models or model versions were reported for evaluation: EPA-PMF3 (8), PMF2 (6), EPA-CMB 8.2 (4), PCA (1), APCS (1), COPREM (1) and ME-2 (1).

Although data in the DB were partially pre-processed, participants had to scrutinize the DB in order to identify, solve and report typical imperfections of real world DBs (e.g. missing values, values below detection limits, outliers and unusual uncertainty patterns).

Participants reported the number and label of the identified sources, their contribution estimation (SCE) and uncertainty. In addition, the source/factor chemical profiles and the contribution of each source/factor in each sample were also requested.

The match between observed and modelled PM mass in every sample was assessed using regression analysis, centered RMSE and bias. More than 75% of the solutions reconstructed the PM mass satisfactorily.

The majority of participants reported between 7 and 11 source/factors. They were classified into 15 different source categories: biomass burning, gasoline, diesel, brakes, traffic, dust, sulphates, nitrates, Zn smelter, Cu metallurgy, Pb smelter, steel processing, industry & combustion, ship emissions, secondary.

The inclusion of every source/factor into a category was checked by comparing its chemical profile and time trend with all the other members of the same category and with reference source profiles, when available. The SCEs of the different solutions were compared with a reference value obtained by robust analysis (standard ISO 5725-5). The acceptability criterion was set to 50% relative standard uncertainty. For more details see Karagulian & Belis (2012, IJEP accepted for publication).

More than 90% of the 160 assessed source/factor contribution estimations met the acceptability criterion. Although no absolute reference values can be used in real-world DBs, a reasonable quantitative agreement in the SCEs is pointed out by these results. Indeed, the noise of experimental data, the variety of methodological approaches and the fact that the sampling site was completely unknown to participants (particularly crucial for those using CMB) shall be taken into account when interpreting the intercomparison outcome.

Identification of continental and marine aerosol sources in Paris using high resolution aerosol mass spectrometry

An intensive one month long field measurement campaign was performed in the Parisian region during July 2009 within the MEGAPOLI project (Megacities: Emissions, urban, regional and Global Atmospheric POLlution and climate effects, and Integrated tools for assessment and mitigation). The "SIRTA" measurement site was located in an urban background environment, 20 km SW from Paris, and a suite of instruments was deployed to characterize the aerosol chemical composition and physical properties. This work is focused on the high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) data and on source apportionment techniques, such as positive matrix factorization (PMF), applied to discriminate aerosol sources. During the period of study, the site was often influenced by oceanic air masses, resulting in very low non-refractory PM_1 levels (on average 4.3 $\mu g/m^3$) accounting for 57.2% organic aerosol (OA), 28.7% sulfates, 6% nitrates, 7.6% ammonium and 0.5% chlorine. The high resolution PMF allowed the identification of both anthropogenic and biogenic organic aerosol (OA) sources. Table 1 reports the elemental ratios as well as OM:OC ratio of each PMF factor evaluated with the high resolution AMS data analysis.

Traffic (defined as hydrocarbon-like OA, "HOA") and cooking emissions (COA) were identified as the main primary anthropogenic sources, contributing for 12% and 14.7%, respectively. However, the major part of the organic aerosol was associated with secondary sources, comprising a low-volatility oxidized OA (LV-OOA, 25.2%) and a semi-volatile oxidized OA component (SV-OOA, 32.4%). Additionally, a component attributed to marine emissions (marine organic aerosol, MOA), due to its high correlation with methanesulfonic acid (R^2=0.84), was identified. This factor seemed to be dominated by SOA derived from marine precursors (high S:C and O:C ratios (Table 1)), and it contributed on average for 15.7% to the total OA, even in a continental megacity like Paris.

Marine emissions are also recognized as an important source of inorganic primary (e.g. NaCl) and secondary aerosol (e.g. SO_4) (O'Dowd and De Leeuw, 2007). Based on sodium concentrations, primary marine aerosol contributed on average to ~10% of the total $PM_{2.5}$ mass. In order to apportion the non sea salt SO_4 (nss-SO_4) sources, PMF was applied on the measured concentrations of organics and sulfates.

Over the whole campaign the influence of air masses coming from the Atlantic Ocean produced a significant amount of secondary marine nss-SO_4 (on average 48.9%), while the nss-SO_4 apportioned to the secondary formation from continental emissions over the continent made up 39.7% (Figure 1). A detailed discussion of the results including the diurnal variations and source mass spectra will be presented.

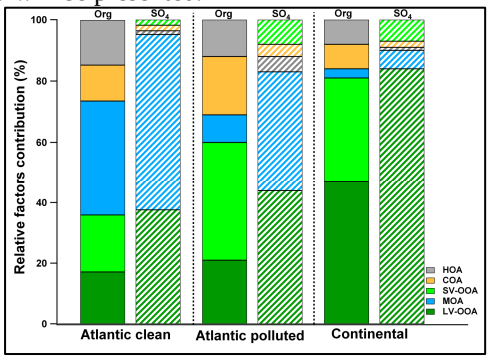

Figure 1. Organic (solid colors) and SO_4 (hatched colors) source apportionment for different air masses.

Table 1. Elemental ratios and OM:OC ratio of primary and secondary sources identified with HR-PMF.

Elemental ratios of the PMF factors					
	LV-OOA	**SV-OOA**	**HOA**	**COA**	**MOA**
OM:OC	2.12	1.66	1.38	1.32	1.94

Two extensive field campaign for the PM10 and PM2.5 characterisation in Tuscany have been performed to investigate the aerosol composition and to identify its sources. Different sites representative of areas of different typology have been selected, six sites for PM10 and three sites for PM2.5, two in Florence (urban background and urban traffic) and one in Livorno (suburban-regional background). The two campaigns lasted 1 year (PM10: from September 2005 till September 2006; PM2.5: from March 2009 till March 2010). Aerosol samples were simultaneously collected, on a daily basis (00:01-23:59), by FAI-Hydra sequential samplers (EN 12341, 2.3 m^3/h), each of them equipped with two inlets (one equipped with Teflon filters and the other one with Quartz fibre filters). PM daily mass concentrations were obtained gravimetrically. Samples collected on Teflon filters were analysed by PIXE to measure the concentrations of all the elements with atomic number Z > 10, by IC to quantify the ion content and by ICP-AES (selected metals). Samples collected on Quartz filters were analysed by TOT to measure EC and OC concentrations, and by GC-MS to determine n-alkanes and PAHs concentrations. The comprehensive chemical characterisation allowed us to obtain the aerosol mass closure.

During shorter periods, the aerosol was collected also by means of a streaker sampler. PIXE analysis of these samples allowed the assessment of hourly resolution elemental time trends. It is worth noting that many aerosol sources can vary on a time scale of few hours or less. Therefore, the use of hourly concentration datasets can be of great help because the high resolved time patterns can improve the source identification and more accurate source profiles can be obtained.

Positive Matrix Factorisation (PMF) has been applied to the whole data set (daily and hourly samples separately). Input data were prepared using the procedure suggested by Polissar and PMF results for multiple values of FPEAK were systematically explored to find out the most reasonable solution.

From PM10 daily data two natural sources, marine and crustal aerosol, were identified, with an average contribution of 20-25% (but during a Saharan dust episode the contribution was more than 50%), a secondary sulphate source (20-30%), a traffic source (20-30%), a secondary nitrates/local combustion source (20-25%). In the most polluted site a biomass burning source was identified which is the responsible of the very high PM10 values during winter months.

For PM2.5 six main sources have been identified in all sampling sites: traffic, biomass burning, secondary sulphate, secondary nitrates, soil dust and marine aerosol (Figure 1). Two contributions to traffic emissions have been disentangled in Florence. In Livorno, an additional source, connected to ship emissions and harbour activities, has been detected. Traffic and secondary sulphate are the most important sources in Florence, but also biomass-burning gives an important contribution to PM2.5 mass. The contribution of the "natural" components (mineral dust and marine aerosols) to PM2.5 is on average moderate, but it reaches higher values during Saharan dust intrusions (in the most intense episode, the mineral dust component accounted for ~ 20% of the PM2.5 concentration).

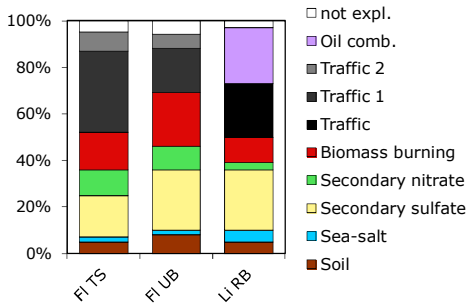

Figure 1: PM2.5 source apportionment.

High time resolution data were used to corroborate and validate these results. As an example the time trend of the BB source is reported for the winter samples (Figure 2). The BB source time pattern exhibits daily variations with peaks during evening-night period, typical of wood combustion for domestic heating; such a source is not present in the early autumn samples.

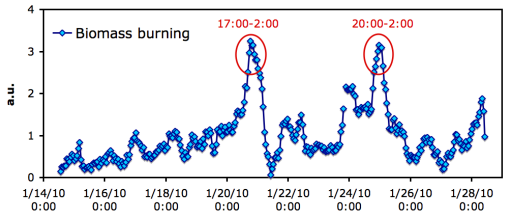

Figure 2: Hourly time trend of the BB source.

Source apportionment of indoor, outdoor and personal $PM_{2.5}$ exposure of pregnant women

Exposure to air pollution has been shown to adversely affect foetal development in pregnant women (e.g. Sapkota *et al*, 2010). The present study aims to investigate the PM composition and sources influencing personal exposure of pregnant women in Barcelona. To this end, indoor, outdoor and personal exposure measurements were carried out for a selection of 54 pregnant women between November 2008 and November 2009. $PM_{2.5}$ samples were collected during two consecutive days and then analysed for black smoke (BS), major and trace elements, and polycyclic aromatic hydrocarbons (PAHs) concentrations.

$PM_{2.5}$ concentrations were higher for personal samples than for indoor and outdoor environments. BS and sulphate concentrations showed strong indoor-outdoor-personal correlations, although some specific indoor and outdoor sulphate sources may exist. Average trace elements concentrations were quite similar indoor, outdoor and for personal exposure, but the correlations were moderate for most of them. PAHs concentrations indoor and outdoor were in general highly correlated. The ratios between different PAHs concentrations indicate that the influence from road traffic could be due to both gasoline and diesel vehicles.

A source apportionment analysis of the PM composition data by means of a Positive Matrix Factorization (PMF) resulted in the identification of six sources for the outdoor and indoor environments: secondary sulphate, fueloil+sea salt (characterized by V, Ni, Na and Mg), mineral, cigarette (characterized by K, Ce, Cd, benzo(k)fluoranthene and benzo(ghi)perylene), road traffic (characterized by BS and low weight PAHs), and industrial (characterized by Pb, Sn, Cu, Mn and Fe). Three of these sources were also identified in the personal dataset: sulphate, fueloil+sea salt, and cigarette, whereas the road traffic and industrial sources were merged in a single source, reflecting the influence of the urban background cocktail. For personal exposure two additional specific sources were found: cosmetics (characterized by abundance of Ca, Li, Ti and Sr and the absence of Al) and train/subway (characterized by Fe, Mn, Cu and Ba). Average contributions are shown in Figure 1, nevertheless, the contribution of the sources varied widely among women, especially for cigarette (from zero to up to 4 $\mu g/m^3$), train/subway (up to more than 6 $\mu g/m^3$) and cosmetics (up to more than 5 $\mu g/m^3$). The source contributions showed generally strong correlations indoor-outdoor although the infiltration efficiencies varied among homes. This study emphasizes the importance of relying on personal exposure in epidemiological studies assessing the impact of air pollution on human health.

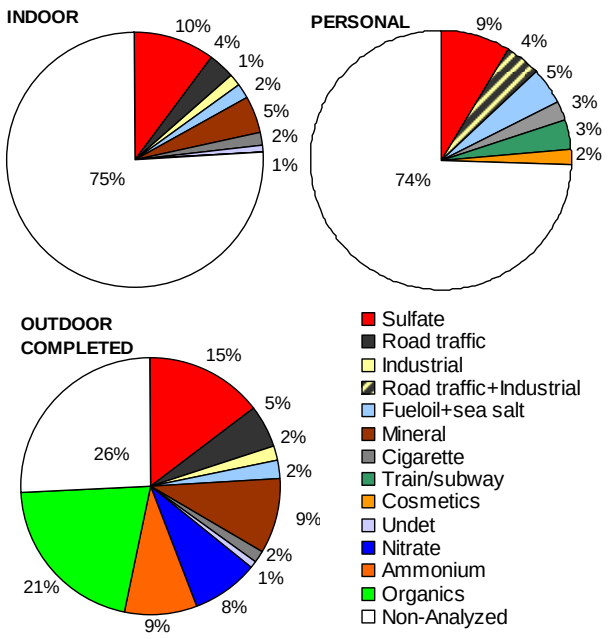

Figure 1. Average source contribution to $PM_{2.5}$ for indoor, personal and outdoor samples. Outdoor includes additional components measured in Barcelona.

New particle formation has been observed to take place in various conditions in the atmosphere. Atmospheric particles are known to affect the climate directly through reflecting the solar radiation and indirectly by affecting the properties of clouds. Both of these effects depend strongly on the size of the particle and thus knowledge of both the formation and the growth rate of the particles are needed to assess the climate effects caused by particles formed in the atmosphere.

Depending on the conditions, some of the atmospheric particles may be formed carrying an electric charge while others may be formed as electrically neutral. The fraction of charged particles in the nucleation mode changes as the particles grow to larger sizes due to various processes, including ion-aerosol attachment, self-coagulation and coagulation scavenging.

Iida *et al.* (2008) developed a method to estimate the particle diameter growth rate from the diameter dependence of the fraction of nucleation mode particles carrying a charge and the method was extended by Gagné *et al.* (2011) for situations in which it cannot be assumed that the concentrations of negative and positive small ions (diameter < ~2.0 nm) are equal.

In this study, we have conducted a simulation set with an aerosol dynamics model Ion-UHMA (Leppä *et al.* 2009), which includes neutral and charged particles as well as pools of negative and positive small ions. The simulated processes were, self-coagulation, coagulation scavenging and ion-aerosol attachment, while the condensational growth rate and the new particle formation rate were used as input in the model. The concentrations of negative and positive small ions were constant with values of 600 and 800 cm^{-3}, respectively.

We determined the particle growth rate, GR_{det}, from the simulated data using the method described by Gagné *et al.* (2011), which assumes that the ion-aerosol attachment dominates over the other processes affecting the charged fraction. We then compared GR_{det} to the real condensational growth rate, GR_{sim}, which was used as input in the model. The aim of this comparison was to assess how well we can estimate the growth rate from atmospheric measurements by using this method.

The correspondence between GR_{det} and GR_{sim} was good, if the changes in the charged fraction were dominated by ion-aerosol attachment (Figure 1), which was the assumption made in the method used to determine GR_{det}. Furthermore, the correspondence increased with increasing GR_{sim}.

If the difference in the negative and positive small ion concentrations was not taken into account when determining GR_{det}, the correspondence between GR_{det} and GR_{sim} was significantly worse than in the case in which the difference was taken into account. As a conclusion, the difference in the negative and positive small ion concentrations should be taken into account when determining the growth rate from the diameter dependence of the fraction of charged particles.

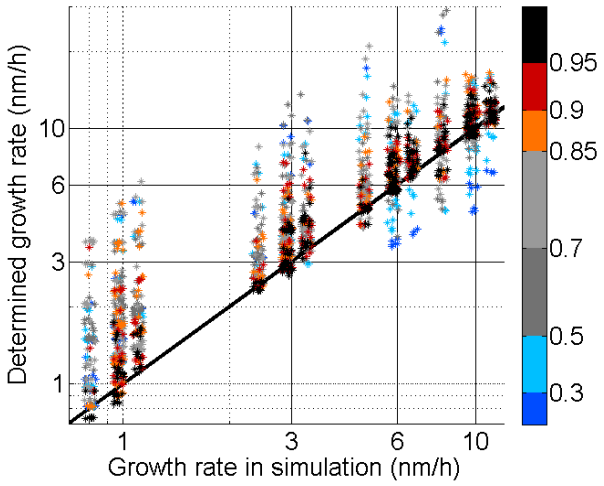

Figure 1. The particle diameter growth rates from the simulation set. Each star represents a single simulation. The colour indicates how big fraction of the change in the charged fraction is due to ion-aerosol attachment.

Nucleation rate parametrization in the CLOUD experiment over all tropospheric conditions

Almeida-Simões, João[1,2], Curtius, Joachim[1], Kirkby, Jasper[2], Carslaw, Ken[3], Dunne, Eimear[3], and the CLOUD collaboration

Keywords: CLOUD experiment, cosmic rays, atmospheric nucleation, nucleation rate, parametrisation.

The possible influence of cosmic rays on aerosols and clouds is of considerable interest (Carslaw, 2009). The CLOUD experiment at CERN aims to study under controlled conditions the effects of cosmic rays on nucleation, cloud droplets and ice particles.

The CLOUD experiment involves a 3m stainless steel aerosol chamber exposed to a pion beam from the CERN Proton Synchrotron. A suite of instruments continuously analyse the contents of the chamber via sampling probes. Each instrument has its own data acquisition system which delivers data in real-time to the CLOUD server. The CLOUD chamber is able to reproduce a wide range of well-controlled atmospheric conditions, including temperatures -90ºC to 100ºC, ion-pair concentrations 1-4000 cm^{-3} and relative humidities, RH, 0-100%. The nucleation and growth of new particles has been studied in the presence of various trace gases, including H_2SO_4 (10^6-10^9 cm^{-3}), NH_3 (35pptv to 1ppbv), amines and organics.

One of the primary goals of CLOUD is a quantitative evaluation of the dependency of the nucleation rate, J, on variables such as [H_2SO_4], [NH_3], [IONS], RH, T, etc. We have developed an accurate, automated method to determine the nucleation rate of critical clusters from the time evolution of the particle number concentration measured by each of the particle counters attached to the CLOUD chamber (CPC, DEG-CPC or PSM).

After the latest measurements in 2011 all atmospheric relevant conditions for ternary nucleation were covered by CLOUD. Using measurements from multiple instruments that analyse the CLOUD chamber, we have derived a J parametrisation based on physical equations that combines the measured J values with current theoretical understanding. The parametrisation is tuned using a nonlinear numerical Levenberg-Marquardt algorithm. The parametrisation successfully predicts all nucleation rates measured so far by CLOUD and is designed to be well-behaved when extrapolating outside the experimentally-explored region.

The CLOUD parametrisation is based on the most rigorous laboratory measurements of ion-induced and neutral atmospheric nucleation achieved so far including all ternary nucleation CLOUD results, and so constitutes an important new tool for evaluating the global contributions of nucleation in atmospheric models such as GLOMAP (Dunne, E.M., et al., this conference).

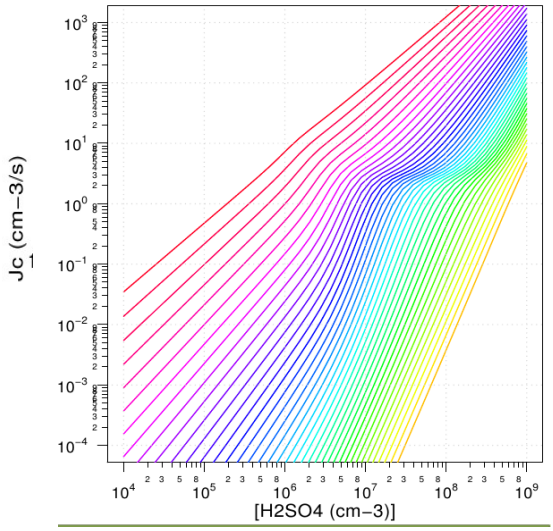

Figure 1. Nucleation rates predicted by the parameterisation over a wide range of temperatures (from -50C in purple up to 20C in red) in the presence of cosmic rays.

Presenting author email: ehrhart@iau.uni-frankfurt.de

Ion-induced aerosol nucleation could be an important mechanism to explain a substantial fraction of new particle production in the free troposphere (Lovejoy *et al*, 2004, Kirkby *et al*, 2011).

To improve the scientific knowledge about nucleation, ion-induced nucleation in particular, the CLOUD-project (Cosmics Leaving OUtdoor Droplets; Kirkby *et al*, 2011) was established at CERN (European Organization for Nuclear Research). The experimental setup consists of an aerosol chamber into which a beam of particles is sent from a Proton Synchrotron to investigate the effects of ions on the aerosol production under controlled laboratory conditions. The chamber itself provides a nearly perfectly clean environment. Concentrations of possible third nucleation agents are almost negligible or are controlled in order to study these. Furthermore the temperature of the chamber can be controlled down to 200 K.

We modelled the binary sulphuric acid/water nucleation processes in the CLOUD-chamber based on earlier work (Lovejoy *et al*, 2004; Kazil, J., and Lovejoy, E. R., 2007). The microphysical model is based on uptake and loss of single sulphuric acid molecules and spans a range from a single molecule to particles with a few nanometer size. The special conditions of a chamber experiment make certain adjustments to the model necessary for instance the main source of losses is the chamber wall. We compare measurements at low temperatures with the modelled evolution of particles. Measured cut-off functions for different particle counter are applied to the simulation for consistent conversion of calculated results to measurements.

The rate constants for charged nucleation are based on laboratory measurements, ab initio results and a smooth parameterisation to bulk phase properties as the particle size increases (Lovejoy *et al*, 2004). Neutral rate constants are currently based on the liquid drop model with corrections terms. These terms can be optimized with pure binary nucleation experiments. For the H_2SO_4 dimer and trimer measured thermodynanmic data are included in the neutral nucleation (Hanson, D. R, and Levoejoy, E. R., 2006). The detailed comparison of the measured and modeled temporal evolution of the particle concentrations for different particle sizes (Figure 1) gives a powerful tool for complete understanding and quantification of the dominant microphysical processes for a wide range of experimental conditions. The model can also be used to transfer the CLOUD results to conditions of the upper troposphere and stratosphere, i.e. lower pressures.

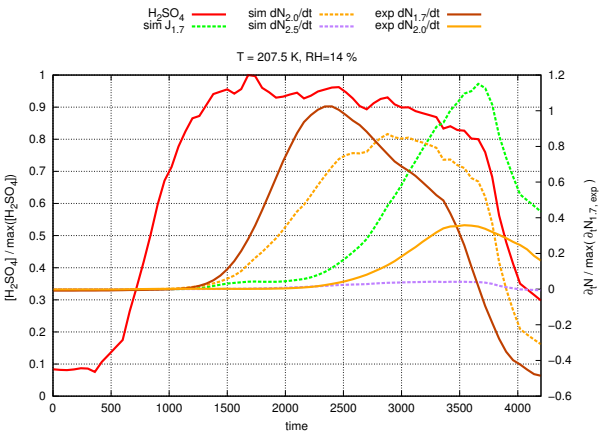

Figure 1: Example of model result without optimisation showing $\partial_t N$ vs time (right y-axis), normalised to the maximum of measured $\partial_t N$, for different particle counters. The normalised sulphuric acid is shown as function of time (left y-axis). Dashed lines are simulated results and solid lines are derived from measurements.

Atmospheric new particle is an important source of aerosol particles that can act as cloud condensation nuclei in the atmosphere. Despite the numerous efforts to determine the compounds involved in new particle formation, some of these remain unknown. Sulphuric acid certainly has a key role in atmospheric new particle formation, but, in realistic atmospheric conditions, cannot explain the observed new particle formation rates on its own. Recently, state-of-the-art experiments in CLOUD chamber at CERN (Kirby et al 2011), have showed how, although the presence of ammonia and ions can enhance new particle formation rates by a factor of 10000, the observed new particle formation rates are still far below those measured in the real atmosphere. This implies that other compound(s), yet unknown, is involved in atmospheric new particle formation.

In the recent years, many studies have suggested that amines may play a key role in atmospheric new particle formation. In the present work, we used the kinetic code ACDC (Atmospheric Cluster Dynamics Code) developed in our group (McGrath *et al*., 2011) to study the effect of ammonia and dimethylamine (DMA) on sulphuric acid new particle formation. We used the formation free energies calculated by quantum chemical methods (Ortega *et al*., 2011) as an input to obtain the evaporation rates needed in ACDC.

First we studied how the formation rate depends on sulphuric acid concentration, and how this varies with the presence of ammonia. To validate our results we have compared the model results with rates observed in the CLOUD experiment (Fig. 1). The modelled formation rates agree well with the experimental ones. Figure 2 shows how the presence of DMA, even at very low concentrations, leads to formation rates close to those observed in different field stations.

The main conclusions of this study are:

-ACDC model is able to reproduce experimental results, so it will be a useful tool to complement future experiments concerning especially the neutral clusters, which cannot be directly detected

-The presence of DMA together with sulphuric acid can explain observed atmospheric new particle formation rates

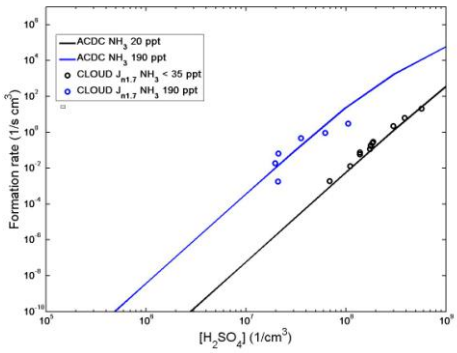

Figure 1. Formation rate versus sulfuric acid concentration at different ammonia concentrations, modelled and measured in CLOUD experiment (Kirby et al 2011)

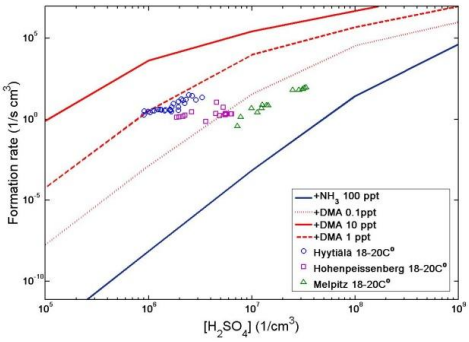

Figure 2. Formation rate versus sulfuric acid concentration at different ammonia and DMA concentrations, modelled and measured in different field stations.

Aerosol formation by nucleation is important for climate because the newly formed particles can grow through condensation of vapors (e.g., sulfuric acid and ammonia, organics) from a few nanometers up to cloud condensation nuclei (CCN)-relevant particle sizes of ~100 nm or more influencing the formation and properties of clouds. Nucleation also enhances atmospheric levels of ultrafine particles which may be especially harmful to human health. Despite its importance, our understanding of the processes of formation and growth of atmospheric nanoparticles is currently limited.

In this work, a 3D CTM with detailed aerosol microphysics, PMCAMx-UF (Jung *et al.*, 2010), was applied to Europe to simulate the contribution of direct emissions and secondary formation to total particle number concentrations. A new size-resolved Pan-European anthropogenic Particle Number (PN) emission inventory was developed for the first time and the extracted aerosol number emissions were used as inputs for PMCAMx-UF. PMCAMx-UF uses the Dynamic Model for Aerosol Nucleation and the Two-Moment Aerosol Sectional algorithm (Adams and Seinfeld, 2002) to track both aerosol number and mass concentration using a sectional approach. We evaluate the model predictions for the European domain against field observations collected during a summer and a winter period.

For the summer simulation, the model reproduces more than 70% of the hourly concentrations of particles larger than 10 nm (N_{10}) within a factor of 2. Aerosol nucleation is predicted to increase the total particle number concentration by a factor of 20 or more in some high-SO_2 areas (Figure 1) and by a factor of 7 for particles larger than 10 nm. For N_{50}, nucleation is responsible for an increase of more than 100% in Southeast Europe. The effect of nucleation in the lower troposphere on particle number above 100 nm is, on average, small with the exception of the Mediterranean area where the model predicts that nucleation can increase the number concentration of CCN-sized particles by up to 20%. On average, approximately 50% of particles above 10 nm are predicted to come from aerosol nucleation. A systematic underprediction of N_{100} at almost all studied sites implies the need for improvement of either the size distribution of the emissions and/or the growth of the ultrafine particles to this size range.

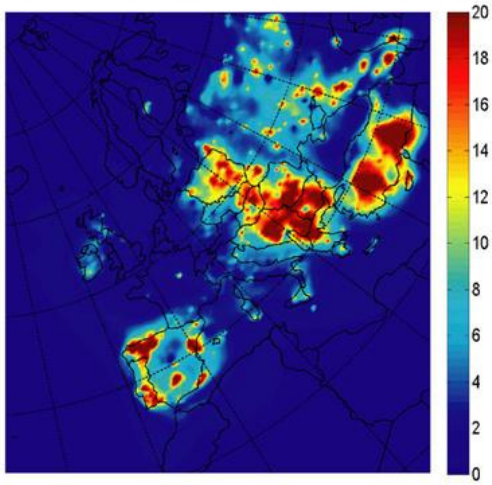

Figure 1. Ground level average fractional increase of PN concentration due to nucleation predicted for May 2008.

Results from 3 nucleation mechanisms that were tested suggest that i) the ternary mechanism performs better than the activation or the kinetic, and ii) future particle number emission inventory efforts should focus on improvements in the diurnal and geographical split of the particle numbers emitted. Reducing emissions of ammonia and sulfur dioxide impact differently certain parts of the size distribution. This could have important implications for emission control strategies that seek to mitigate future air pollution and climate change.

Modeling Reactive Aerosols in Oxidizing Atmospheres: Severe Accidents in Sodium Fast Reactors

M. García[1], L.E. Herranz[1]

[1]Unit of Nuclear Safety Research, CIEMAT, Madrid 28040, Spain
Keywords: In-containment SFR source term, Na-based aerosols.
Presenting author email: monica.gmartin@ciemat.es

Postulated Beyond Design Basis Accidents (BDBAs) in Sodium-cooled Fast Reactors (SFRs) might result in contaminated-coolant discharge at high temperature into the containment. As a consequence of the high chemical reactivity of sodium (Na) with air and steam, it would undergo Na-oxidation within the containment atmosphere. The exothermic nature of the chemical reactions taking place and the high level of turbulence in the reaction area, would determine to a good extent particle size and population. Hence, radioactive source term to the environment would depend on in-containment Na-aerosol behavior. Hence, it is of utmost importance for a full scope safety analysis of SFRs to have computation tools properly validated, particularly in the field of radionuclide transport in the containment.

Much of the analytical capability built-up until mid 80's for source term analysis of SFRs, was lost due to sharp reduction of resources spent worldwide. However, the major progress achieved in source term studies of Light Water Reactors (LWRs) and some existing similarities of LWR- and Na-based aerosols, highlights the interest of assessing the potential of LWR codes to deal with in-containment aerosol behavior in SFR scenarios. This is the goal of this work. Through a systematic application of the MELCOR code (Gauntt et al., 2005) to the ABCOVE-AB5 test, insights have been gained into drawbacks and capabilities of this computation tool. Hypotheses and approximations have been adopted so that differences in boundary conditions between LWR and SFR containments under BDBA can be properly accommodated.

The AB5 test of the ABCOVE experimental programme was conducted in the Containment System Test Facility (CSTF) vessel at the HEDL. A total of 223 kg of Na at high temperature (836.15 K) was sprayed over 872 s. The Na-air exothermic reactions yielded a source of aerosols into the atmosphere. This energetics is an intrinsic feature of Na-fire scenarios that requires some modeling hypotheses and approximations.

The energy released has been estimated by assuming that 90% of Na got oxidized to Na_2O_2 and 10% of Na reacted with steam and formed NaOH. These percentages were derived from the steam available in the containment atmosphere. This total energy is assumed to be distributed between the vessel atmosphere (50%) and the Na particles (50%). As MELCOR does not model aerosols-gas heat exchange, this 50% has been placed on an artificial surface introduced in the model. This surface is characterized by the same heat capacity as Na aerosols and its surface area (roughly 1 m^2) approximated by assuming all the Na-mass colapsed in a sphere ("fire ball"). The idea is that most Na particles are created in a relatively small region of the vessel; initially, the large amount of particles causes a heat transfer shielding effect that allows neglecting any exchange taking place within the particle cloud. In other words, most convection and radiative exchange would occur from particles at the most external layer of the cloud. This approach, called "fire ball" approximation, seems to provide a reasonable match of the thermal-hydraulic scenario (Fig. 1).

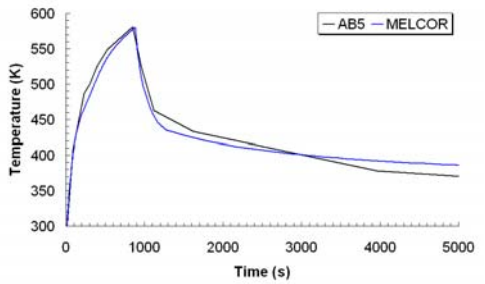

Fig.1. Gas temperature.

A systematic methodology has been developed to identify the most influencing aerosol parameters that can be chosen by the code user. Particles shape and turbulence seem to affect substantially aerosol evolution. In particular, dynamic (χ) and coagulation (γ) shape factors equal to 2.5 and turbulent energy dissipation rate (ε) equal to 10^{-3} $m^2 \cdot s^{-3}$, provided the closest agreement to data (Fig. 2). For comparison purposes, the default case (DC) is also shown ($\chi = \gamma = 1.0$; $\varepsilon = 10^{-3}$ $m^2 \cdot s^{-3}$).

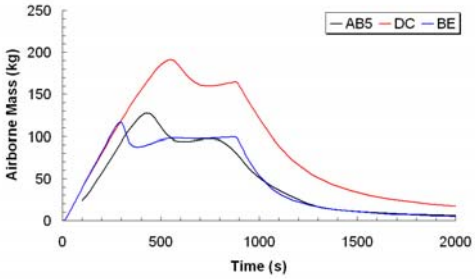

Fig. 2. Airborne mass as a function of time.

Non-spherical particles largely enhance the agglomeration process and compensate the slow-down effect of non-sphericity.

According to these results, sodium based particles produced during a spray fire might be non-spherical. Nonetheless, further experiments would be necessary.

The global distribution of aerosol model uncertainty

L.A. Lee[1], K.S. Carslaw[1], K.J. Pringle[1]

[1]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK
Keywords: aerosol modelling, model uncertainty, parametric uncertainty, statistical analysis.
Presenting author email: l.a.lee@leeds.ac.uk

Aerosols have been assessed in the last two IPCC assessments as the largest uncertainty in the radiative forcing of climate. An essential step towards reducing the uncertainty is to quantify the sources of uncertainty at the process level of global aerosol models. Here we use new techniques of statistical emulation to calculate the spatial pattern of parameter sensitivity in a complex global aerosol model. Gaussian process emulation enables a full variance based sensitivity analysis to be performed in every global grid box based on a relatively small number of model simulations.

We show global maps of simulated and emulated cloud condensation nuclei (CCN), including absolute and relative sensitivities to 8 parameters, the degree of interaction between the parameters, and probability density functions for CCN in selected grid boxes. The absolute variance is largest in polluted regions but the coefficient of variation (standard deviation divided by mean CCN) is greatest in remote regions. The maps show a high degree of spatial coherence in the causes of CCN uncertainty. In polluted regions and over the Southern Ocean the uncertainty is dominated by emissions but elsewhere the uncertainty is dominated by process parameters. The uncertainty in some regions is dominated by one or two parameters, while in other regions the overall uncertainty results from multiple parameters with up to 50% variance due to interaction effects. The variance analysis provides direct quantification of the reduction in variance that would result if a parameter could be specified precisely. When extended to all process parameters, the approach presented here will therefore provide a clear global picture of how improved knowledge of aerosol processes will translate into reduced model uncertainty.

Session WG10S2O. Aerosol Dynamics

Modeling of the behavior of droplets deposited on the smooth and rough fiber surfaces

J.M. Gac[1] and L. Gradoń[1]

[1]Faculty of Chemical and process Engineering, Warsaw University of Technology, Warsaw, 00-645, Poland
Keywords: Aerosol filtration, Droplets, Fibers, Modeling (microscale), Numerical simulation
Presenting author email: J.Gac@ichip.pw.edu.pl

The separation of the liquid droplets from the stable mist system is a crucial process in industrial technologies, natural gas cleaning, crank case ventilation systems and many other applications. The most efficient devices for such separations are fibrous filters (coalescers). A properly designed coalescer structure, defined through the space distribution of the local porosity and fiber diameter involves the phenomena of a droplet coalescing in the bulk, deposition of drops on the fiber, coalescing of the deposited droplet on the fibers and the drainage of the filter fibers.

In our presentation, a two-color lattice-Boltzmann method (LBM) is used for simulation of the behavior of droplets deposited on a fiber. This kind of well-known LBM scheme is an effective tool for simulating of two-phase flow, including surface tension effects. The interaction of the droplet with the gas flowing around a fiber having smooth and rough surfaces was analyzed.

As a results of our simulations, we derive the equilibrium of conformation of droplets. For a smooth fiber we obtain results consistent with analytical results presented in (Carrol, 1986). By contrast, the droplet on rough fiber takes often completely different conformations, what is explained by means of merging the theory of rough surfaces of Wenzel (1936) with the results of (Carrol, 1986).

Further, we investigate the axial and transversal motion of a droplet on a fiber. We have found that in case of smooth fibers the velocity of the asymmetric droplet is higher than the velocity of axisymmetric droplet, what is consistent with recent results of Gilet *et al* (2010). By contrast, the roughness of the fiber facilitates the motion of the droplet for the situation when the mean distance between the insets is big in comparison to the diameter of the droplet. The reason is that the droplet, moving through the inset, transits from the axisymmetric to the asymmetric conformation, for which the equilibrium velocity is higher. However, if the typical distance between the insets is smaller than the diameter of the droplet, its motion is rubbed. Both these situations are presented in Fig. 1.

The transverse motion of the droplet on rough fiber is slower than the motion of smooth one – so the roughness of the fiber impedes the detachment of the droplets. The difference of the times of detachment from rough and smooth fiber decreases with the value of contact angle, as it has been shown in Fig. 2.

The results of calculation show the distinguished patterns of the interaction depending on the structure of the fiber roughness and the fiber and droplet dimensions. The modeling data indicate a new approach for the designing of a novel generation of the efficient coalescers.

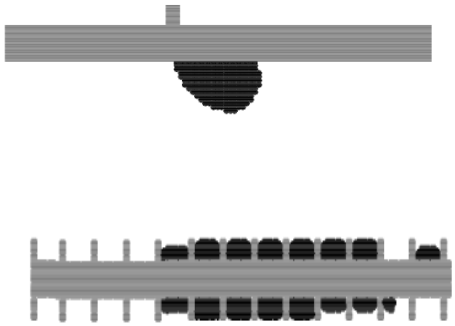

Figure 1. The shape of the droplet on rough fiber with low (a) and high (b) density of insets.

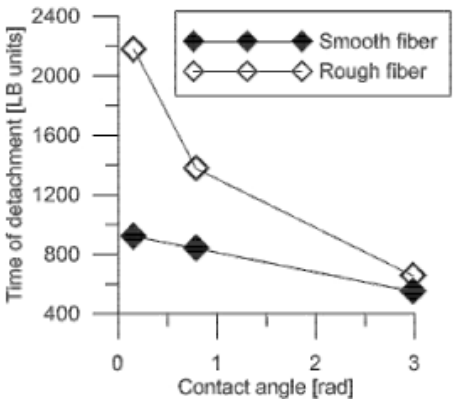

Figure 2. Dependence of time of detachment of the droplet on the contact angle for smooth and rough fiber at the same velocity of surrounding gas.

The mobility radius of small fractal aggregates in the slip-flow regime

A.D. Melas[1 2], A.G. Konstandopoulos[1 3] and Y. Drossinos[2]

Keywords: fractal aggregates, slip flow regime, mobility radius.
Presenting author email: Anastasios.Melas@jrc.ec.europa.eu

Aerosol particles may form complex structures that are fractal-like. Their fractal-like nature is described by the scaling law, $N = k_f(R_g/R_1)^{d_f}$, where N is the number of primary particles, k_f the fractal prefactor, d_f the fractal dimension, R_g the radius of gyration and R_1 the monomer radius.

Isella and Drossinos (2011) proposed a numerical method for the calculation of the mobility radius (R_m) of straight chains in the continuum regime which is applicable also to fractal aggregates. This method is based on experimental studies where it was shown that the total mass transfer times the aggregate mobility is approximately constant and independent of particle shape and chemical nature. The molecule-aggregate collision rate (K_N) is proportional to the mass transfer and consequently to the friction coefficient. By calculating the steady-state molecular diffusive flux over the aggregate surface we determine the collision rate. The appropriate boundary conditions in the continuum regime are fluid density $\rho = 0$ on the surface and $\rho = 1$ far away from it. Finally we calculate the mobility radius by

$$\eta_N = \frac{K_N}{NK_1} = \frac{R_m}{NR_1}, \qquad (1)$$

where η_N is the average monomer shielding factor.

In this study we expand this method to the slip-flow regime. The approach remains the same. The boundary condition that we use to solve the steady-state molecular diffusion equation is a Robin condition. On the aggregate surface the fluid density is $\rho(R_1) = \alpha(Kn)\frac{\mathrm{d}\rho}{\mathrm{d}r}\,|_{R_1}$ and far away from it, $\rho = 1$. Hence, from the analytical solution of the diffusion equation, we obtain

$$\frac{K_1(Kn=0)}{K_1(Kn)} = 1 + \frac{\alpha(Kn)}{R_1}, \qquad (2)$$

for a monomer where the constant $\alpha(Kn)$ is calculated from the Cunningham slip factor (Cn) to be $\alpha(Kn)/R_1 = Cn - 1$.

The diffusion simulations we carried out with the finite element software Comsol Multiphysics. In Table 1 we compare our results for a straight chain with 8, 15 monomers and different Knudsen numbers ($Kn = \lambda/R_1$, where λ is the gas mean free path) to Dahneke's (1982) calculations. The agreement is very good for $Kn = 0.1, 0.2$, getting worse for $Kn = 0.5$. This is expected as slip flow conditions should be appropriate for Kn around 0.1.

Straight chains		$Kn = 0.1$	$Kn = 0.2$	$Kn = 0.5$
8 monomers	Dahneke (1982)	0.414	0.436	0.499
	Collision rate	0.416 (0.48%)	0.447 (2.52%)	0.546 (9.42%)
15 monomers	Dahneke (1982)	0.344	0.365	0.427
	Collision rate	0.342 (0.58%)	0.372 (1.92%)	0.466 (9.13%)

Table 1: Comparison between collision rate calculations and Dahneke (1982). In parenthesis the relative difference is shown.

The R_m calculations will also be made for fractal aggregates and dynamic properties will be related to geometrical features (d_f, k_f, N). The fractals we will use are created with a tunable cluster-cluster aggregation method (CCA) proposed by Thouy and Jullien (1996). The monomers in the created fractals don't overlap, satisfy exactly the scaling law, and they have prescribed d_f, k_f, N. Figure 2 shows a typical fractal with 512 monomers, different monomer colours corresponding to the number of its nearest neighbors.

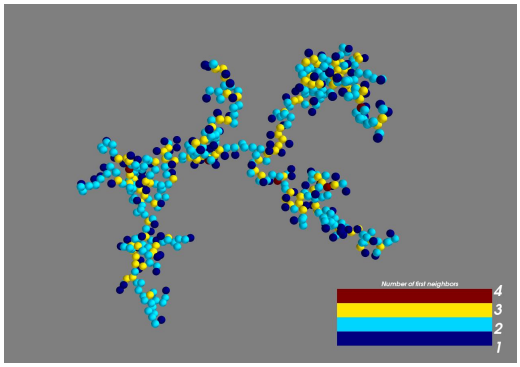

Figure 1: A 512-monomer fractal aggregate ($d_f = 1.8$, $k_f = 1.3$) created with a CCA algorithm.

Keywords: thermophoresis, fractal aggregate, deposition.
Presenting author email: edouard.brugiere@irsn.fr

Thermophoresis is an important mechanism of micro-particle transport due to a temperature gradient in the surrounding medium. Extensive studies, both theoretical and experimental, have been carried out to understand the nature of this phenomenon which is well known for spherical particles contrary to non-spherical particles like soot particles. In fact, the soot particles are characterized by a complex morphology called "fractal" and, currently, the real impact of this morphology on deposition due to thermophoresis is not well known.

The existing theory of the thermophoresis for non-spherical particles is limited and there are few solutions to formulate thermophoresis velocity in the continuum and free molecular limits regime for several simple particle shapes. The reader is referred to a comprehensive review on thermophoresis of the two major categories, spherical and non-spherical particles, by Zheng (2002).

In order to determine particle morphology influence on the thermophoretic behavior, a new experimental device is presented. This new device is a radial flow thermophoretic analyser and it is based on the concept of the radial flow differential mobility analyser (DMA): the *Spectromètre de Mobilité Electrique Circulaire* (SMEC) developed by Pourprix (1989). This device consists of a parallel arrangement of two circular plates (hot and cold). A schematic diagram is given in figure 1; a sheath air flow (Qf) and an aerosol air flow (Qa) are passed between those two plates. For different flow rates and temperature gradients, this new device will enable to determine, with a high resolution, the mean thermophoresis velocity of monodisperse particles.

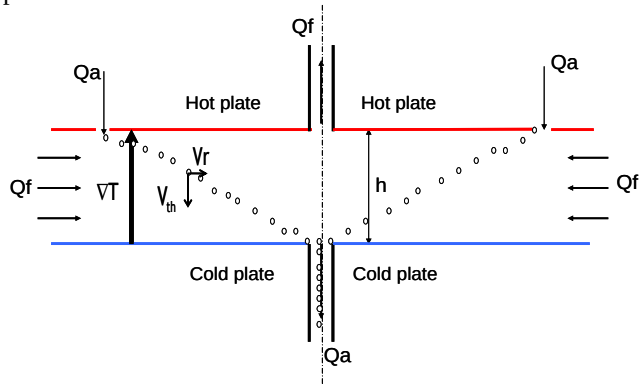

Figure 1: Schematic diagram of the radial flow thermophoretic analyser

We obtain experimental results for spherical PSL particles (polystyrene latex) in good agreement with the model proposed by Beresnev and Chernyak (1995).

A comparaison between mean thermophoretic velocity of spherical (PSL) and aggregate particles, produced by a diffusion flame propane/air generator (miniCAST), having same mobility diameters is realized. Our results show a significant difference between the thermophoretic velocity of aggregate and PSL particles. The measurements obtained with the radial flow thermophoretic analyser are reported in the figure 2. Contrary to the spherical particles, the thermophoretic velocity of aggregates increases with the diameter. For example, the thermophoretic velocity of an aggregate of 430 nm is 30 % higher than that of a PSL particle with the same mobility diameter.

The experimental results also show a dependance of the thermophoretic velocity of an aggregate with the number of primary particles and, for the first time, confirm the monte-carlo simulation of Mackowski (2006).

Forces on a porous particle in an oscillating flow

P. Vainshtein and M. Shapiro

Laboratory of Transport Processes in Porous Materials, Faculty of Mechanical Engineering, Technion – Israel Institute of Technology, Haifa 32000, Israel
Keywords: particle, permeability, oscillations, forces.
Presenting author email: mersm01@technion.ac.il

We considered dynamics of a single spherical porous particle oscillating in quiescent incompressible fluid when the instantaneous particle velocity is given by $U = U_\infty \exp(i\omega t)$. Here U_∞ is the velocity amplitude, ω is the angular frequency of harmonic oscillations, t is the time. The corresponding problem for impermeable solid particle was studied by Stokes (1851). The problem as formulated is relevant for dynamics in continuum regime of aerosol agglomerates (Shapiro et al., 2012).

We calculated theoretically the complex force reduction ratio, $\tilde{\Omega}$, between the drag force acting on an oscillating permeable sphere and the drag experienced by an impermeable oscillating particle. We solved the Stokes equations exterior to the particle and either by Darcy or Brinkman equations inside the particle. The velocity components and the pressure were required to be continuous at the particle boundary for both the Darcy and the Brinkman models. In the Brinkman model, boundary condition of the continuity of the tangential component of the stress vector, normal to the interface was also adopted. The equation of porous particle oscillations in the non-inertial frame of reference included the fictions body force $f = \rho_f \partial U / \partial t$ where ρ_f is the fluid velocity.

For the Darcy model we obtained $\tilde{\Omega}$ in the form

$$\tilde{\Omega} = \frac{2\beta^2}{2\beta^2 + 3 + 3[(1+i)Y + 2iY^2]} \qquad (1)$$

where $\beta = a/\sqrt{k}$, a is the particle radius, k is the permeability, $Y = \sqrt{a^2\omega/2\nu} = a/\delta$, ν is the dynamic viscosity, δ is the Stokes penetration depth. For the Brinkman model the real and imaginary parts of $\tilde{\Omega}$, namely Ω_r and Ω_i, were calculated numerically.

The force acting on the particle has the form

$$F = 6\pi\rho_f \nu a U C_{St} - \frac{4}{3}\pi\rho_f a^3 \frac{\partial U}{\partial t} C_{Ad} \qquad (2)$$

where the Stokes correction factor, C_{St}, and the added mass coefficient, C_{Ad} are

$$C_{St} = \Omega_r + (\Omega_r - \Omega_i)Y - \frac{2}{9}\Omega_i Y^2 \qquad (3)$$

$$C_{Ad} = \frac{1}{2}\Omega_r + \frac{9}{4Y}(\Omega_r + \Omega_i) + \frac{4}{9Y^2}\Omega_i \qquad (4)$$

The added mass coefficient in (4) describes the inviscid added mass (the first term on the r.h.s.) and also the unsteady effect of oscillations on the viscous resistance (Landau and Lifshitz, 1987). Figure 1 a, b shows the calculated dependences. For low permeability ($\beta >> 1$) C_{St} and C_{Ad} reproduce those for impermeable particles. In the limit of high-frequency oscillations of highly permeable particles, prevailing for inviscid flow, one has $C_{St} << 1$, $C_{Ad} << 1$. The inviscid added mass is always positive. However the effect of oscillations on viscous resistance gives rise to small negative values of C_{Ad} in the region approximately characterized by $\beta < Y$.

Stick and rebound of single nanoparticles and nanoparticle agglomerates

S. Rennecke and A.P. Weber

Institute of Particle Technology, Clausthal University of Technology, Clausthal-Zellerfeld, 38678, Germany

Keywords: inertial impaction, bouncing, fragmentation.
Presenting author email: stephan.rennecke@mvt.tu-clausthal.de

When a particle impacts on a rigid surface it may stick to it, or, if the impact velocity is sufficiently high, may rebound from the surface being resuspended in the surrounding gas. Once a particle hits a surface its initial kinetic energy is reversibly transformed into elastic deformation and partly irreversibly lost i.e. in plastic deformation or heat, until all of it is consumed and the particle stops. Above a critical impact velocity, v_{cr}, the energy stored in elastic deformation is sufficient to overcome the energy of adhesion and the particle will be able to bounce. Thus, whether stick or rebound occurs is dependent on the mechanical properties of the particle and the acting adhesion force. These parameters also appoint the coefficient of restitution, e, the ratio of the final to the initial velocity, usually used to characterize particle impact events.

So far, there are no systematic measurements of both, e and $v_{cr,}$ for nanoparticles stated in the literature. This lack of knowledge arises most clearly in the discussion about a possible thermal rebound of nanoparticles. Wang and Kasper (1991) reported the possibility that nanoparticles may penetrate through personal protection filters when their size approaches the size of a cluster, as their mean thermal velocity due to Brownian motion may overcome v_{cr}. As the latter is unknown, the discussion did so far not lead to a closing result even after two decades. Thus, a new experimental technique is necessary that allows systematic investigations of the rebound of nanoparticles.

In this contribution a method for the investigation of particle bounce in a single stage low pressure impactor is presented. Size selected and singly charged spherical particles and dense spray dried agglomerates in the size range from 10 nm to 100 nm were impacted on a smooth surface at process conditions far above the critical Stokes number for deposition. The onset of particle rebound and the coefficient of restitution have been determined by using special structured collision substrates. The actual impact velocity of the nanoparticles has been determined numerically by calculating the particle trajectories with Lagrangian Particle tracking, similar to the methods recently published by Arffman et al. (2011). The setup allows defined collision experiments for impact velocities up to approximately 200 m/s.

Experimental results show that particles bounce with 100 % efficiency even at moderate impact velocities of some m/s, with v_{cr} increasing with decreasing particle size. An example dataset is shown in fig. 1 for dense silver particles. It can be clearly seen that with decreasing particle size the Stokes number necessary for particle bounce increases. The corresponding value for 10 nm particles is about 30 m/s.

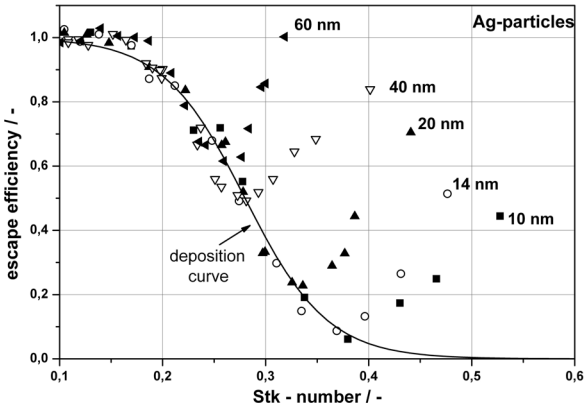

Figure 1. Escape efficiency as a function of Stk-number for silver particles of different size

Experiments were also performed with spherical dense silica particles and compared to spray dried silica agglomerates. The data shows that agglomerates bounce at much reduced v_{cr} values as their uneven surface (see fig. 2) acts as spacer, effectively reducing the contact area, and thus, adhesion force.

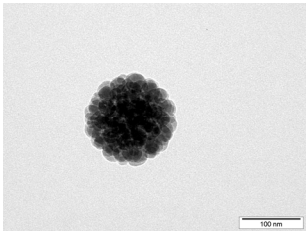

Figure 2. Dense, spray dried silica agglomerate

Further experimental results, including the coefficient of restitution and data on fragment bouncing, will be part of this contribution. The data will be used to identify an appropriate stick/bounce criterion for nanoparticles.

The Friction Factor and Collision Kernel for Aggregates in the Mass and Momentum Transition Regimes

Christopher J. Hogan Jr[1], Chonglin Zhang[2], Thaseem Thajudeen[1], Ranganathan Gopalakrishnan[1], Carlos Larriba[1], Tom Schwartzentruber[2]

[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, 55455, USA
[2]Department of Aerospace Engineering and Mechanics, University of Minnesota, Minneapolis, MN, 55455,
USA Keywords: Aggregates, Direct Simulation Monte Carlo, Brownian Dynamics, Drag
Presenting author email: Hogan@me.umn.edu

The transport of aggregate aerosol particles is of considerable importance, given that particles fitting into this morphological class (ensembles of spherical primary particles connected in quasifractal configurations) are formed prevalently in combustion environments. Nonetheless, aggregates are difficult to examine: their non-spherical, complex geometries often preclude calculation of the drag force they experience as well as calculation of the rate of aggregate-aggregate collisions (aggregation). Further complicating analyses, for nanoparticle aggregates, both mass (aggregation) and momentum (drag) transfer processes occur within the transition regime, in which rates of mass and momentum transfer depend upon appropriately defined Knudsen numbers.

The purpose of the work shown in this presentation is two-fold. First, dimensional analysis is used to predict a functional form for the low Reynolds number, low Mach number drag on an arbitrarily shaped aerosol particle, such as an aggregate. The drag under these conditions is quantified in terms of the friction factor, for which dimensionless analysis provides a functional form similar to the adjusted sphere model of Dahneke (1973). This functional form for the friction factor is tested using direct simulation Monte Carlo (DSMC) of the flow field around test aggregate particles at selected Knudsen numbers, as shown in Figure 1. Good agreement is found between the predicted friction factor from dimensional analysis and the DMSC calculated friction factors in the transition regime.

Second, with the friction factor of an aggregate as input, an expression is developed to predict the collision rate (quantified by the collision kernel) of two arbitrarily shaped particles (such as aggregates) in the mass transfer transition regime, where the collision rate depends upon a suitably defined diffusive Knudsen number (in contrast to the traditional Knudsen number used in momentum transfer problems). For this purpose Brownian dynamics based mean first passage time calculations and dimensional analysis are employed, and it is found that a proper non-dimensionalization of the collision kernel (H), can be described solely as a function of the diffusive Knudsen number Kn_D (Figure 2), and that with suitable definitions of these parameters, the $H(Kn_D)$ relationship found applicable previously for sphere-sphere collisions applies to collisions between arbitrarily shaped particles as well.

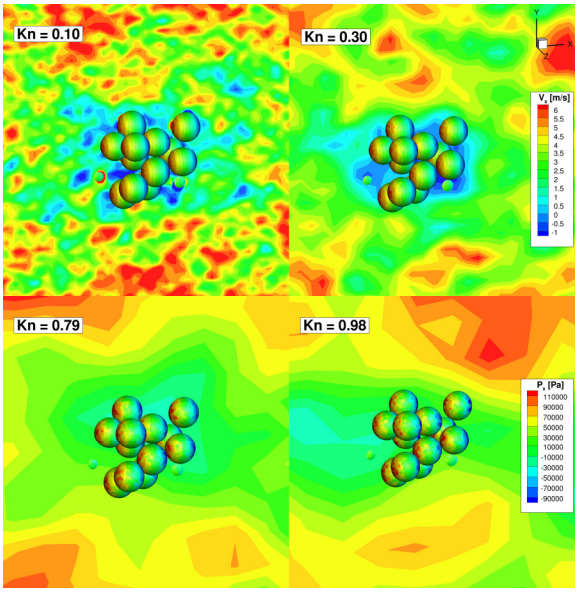

Figure 1. Contour plots of the x-direction component of the gas flow velocity around a 20-mer test aggregate at selected Kn. Also shown by contour plot are the x-direction stresses ($\mathbf{P_X}$) on the aggregate in a single DSMC time step.

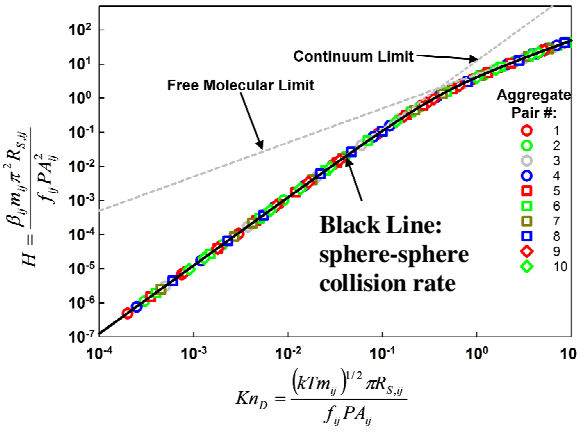

Figure 2. Summary of the $H(Kn_D)$ results obtained with mean first passage time simulations for the 10 test aggregate pairs.

Separation of gas-borne nanoparticles in bubble columns

D. Koch, A.P. Weber
Institute of Particle Technology, Clausthal University of Technology, Clausthal-Zellerfeld, D-38678, Germany
Keywords: nanoscale carbon particles, surfactants, deposition, bubble column.
Presenting author email: koch@mvt.tu-clausthal.de

The transfer of nanoparticles from the gas phase into a liquid in bubble columns is employed for gas cleaning purposes (e.g. Pich and Schütz, 1991) and for the production of stable nanosuspensions (Verma *et al*, 2009). However, there are no systematic studies on the influence of particle size and structure, bubble size and surfactants on the particle separation efficiency. Therefore, the separation of gas-borne nanoparticles in bubble columns with heights of up to 1 m is studied. Nanoparticles used here are agglomerated carbon particles. In order to study the influence of surfactants on the separation efficiency, the results for pure water are compared with the ones obtained for polymeric stabilisers such as polyvinylpyrrolidone (PVP) K25 at various concentrations. The separation efficiency is determined from the measurements of the aerosol concentrations before and behind the bubble column. In addition, the concentrations in the solution is monitored on-line by an extinction technique.

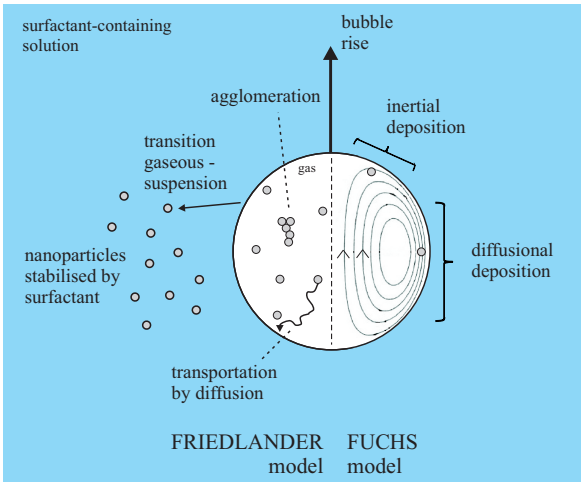

Figure 1: Processes inside the bubble with internal circulation

For pure water, the experimental results are compared to calculated values of the separation efficiency obtained with the Fuchs model (Fuchs, 1964) by using the experimental determined relative bubble rise velocity. The good agreement of theoretical and experimental results verifies the applicability of the Fuchs model to describe the separation efficiency of nanoparticles in pure water in the bubble columns, where mobile interfaces of the bubbles are assumed. In particular, it is shown that the particles exhibit a sticking probability of one at the gas-liquid interface. Supplementary, it was found that, for surfactants, the dissolved

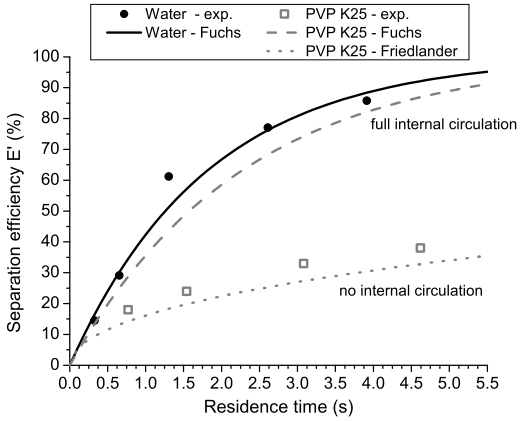

Figure 2: Influence of 0.4%(wt) PVP K25 on the separation efficiency

polymer in the solution reduces the internal circulation in the bubbles (shown in Fig. 1) due to reduced interface mobility and that, therefore, the Fuchs approach is no longer valid. For this case, the separation efficiencies are well described by the Friedlander model (Kronig and Brink, 1951; Friedlander, 2000) as shown in Fig. 2 for a 0.4%(wt) PVP K25 solution.

In this contribution, the Friedlander model, which takes only Brownian diffusion into account, will be discussed for surfactant solutions with changed interface properties by using surface active detergents.

Keywords: Aerosol radiative forcing, Aerosol size distribution, Biomass burning.

The biomass burning particles have a direct effect on the global radiative balance, conditioning the energy balance by means of dispersion and absorption processes of the solar radiation reaching the Earth (Calvo *et al* 2010), so the study of these particles is crucial to identify energy variations in the atmosphere.

This study contains an analysis of the wildfires in the province of Leon on the 22nd and 23rd of August 2001 (400 ha were burnt) and their influence on the particulate matter concentration registered on the 23rd of August 2001 and on the size distributions. The optical characteristics of the aerosols and the associate radiative forcing were also analyzed.

The measurements were carried out in the district of Carrizo de la Ribera, in the center of the province of Leon, Spain, at 873 m asl, a rural farming area.

A PCASP-X laser spectrometer was installed in a field and 8 daily measurements during 15-minute intervals every 3 hours. The refraction index of the particles was estimated for each relative humidity. Then, raw size bins were corrected using a program based on Mie Theory from the estimated refraction indices.

The short-wave radiative forcing (SW) was analyzed using the Radiative Transference Model (RTM) GAME (Global Atmospheric Model) (Dubuisson *et al* 2004). The methodology used to compute the radiative impact is described in detail in Mallet *et al* (2008) and Roger *et al* (2006).

On the study day the measurements affected by the wildfires are the ones taken at 1300 UTC and at 1600 UTC, and the average increase in the number of aerosols is of around 500% when compared with the unaffected measurements. The increases corresponded mainly to particles smaller than 0.2 μm (fine mode).

The instantaneous surface forcing estimated by GAME (ΔFBOA) can reach up to -38.7 W/m^2 and -10.4 W/m^2. This significant decrease of solar energy at the surface might strongly modify the surface energy budget.

Moderate instantaneous forcing simulated at the top of the atmosphere (ΔFTOA) has been computed by GAME reaching up to -20.5 W/m^2 and -7.8 W/m^2. For most of our case studies, the aerosol forcing is negative (cooling effect) and much higher at the surface than at the top of the atmosphere due to absorption.

The estimation of the positive instantaneous radiative forcing (ΔFATM) given by GAME indicates the absorption of solar radiation in the atmosphere by the smoke aerosol considered. It ranges from + 2.7 to + 22.8 W/m^2. This positive atmospheric radiative forcing is reflected in an atmospheric heating by absorbing particles, which may affect both cloud cover and planetary albedo and atmospheric stability.

In Fig. 1 we can observe that the direct atmospheric radiative forcing reaches maximum values when fire events occur. Indeed, the aerosol number concentration is 8 times higher at 1300 UTC than during the morning for the fine mode. These high loads of aerosols in the fine mode clearly interact with visible radiation through absorption and scattering processes, which is reflected in a lower downward radiative flux reaching the surface (ΔFBOA highly negative).

The wildfires not only alter the atmospheric composition increasing the number of particles and modifying their size distributions, but they also alter the local radiative balance.

Direct radiative forcing (DRF) by aerosols over East Asia was investigated with the assimilated aerosol optical properties discussed in Park et al. (2011). For radiative transfer modeling, Monte-Carlo Aerosol Cloud Radiation (MACR) model, updated by Chung et al. (2010), was used, because it provides the more accurate radiative fluxes than those obtained with two-stream approximations (Baker et al., 2003). The input data for MACR simulation was described in Table 4.1. The angstrom exponents for AOD and SSA and the low-level, mid-level, high-level and convective cloud fractions and cloud optical depths were calculated, based on Chung et al. (2010).

Based on the seasonal variations of DRF by aerosols (Fig 1), the importance of dust was emphasized. At the top of atmosphere, the strong negative forcing was mainly affected by sulfate, and partly by nitrate, dust, and sea-salt. Especially, the dust effect was very strong in spring. At the atmosphere, the positive forcing was mainly affected by BC, and a little by organic matter,

Table 1. Description of input data used for MACR simulation.

Input data	Sources
AOD	combination of CMAQ-simulated and MODIS-retrieved AODs (Park et al., 2011)
SSA	CMAQ-simulated SSA (Park et al., 2011)
asymmetric factor	constant value (=0.69), which is based on AERONET data
angstrom exponents for AOD and SSA	using the parameterization in the literature (Chung et al., 2005)
cloud fractions	combination of ISCCP and terra MODIS data (Chung et al., 2010)
cloud optical thickness	combination of ISCCP and terra MODIS data (Chung et al., 2010)
albedo	ECMWF data
ozone	terra MODIS data
precipitable water	terra MODIS data
height	USGS data
