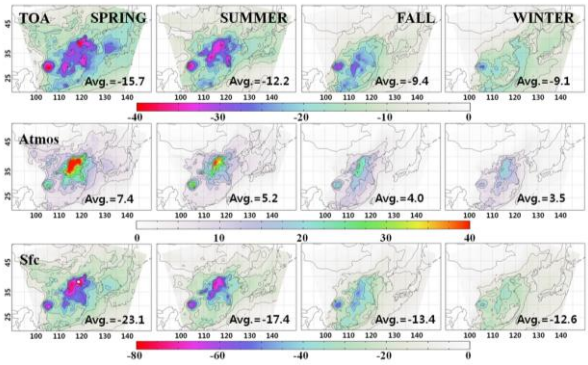

Figure 1. Seasonal variation of DRF (W m^{-2}) by aerosols at the surface, within atmosphere, and at the top of atmosphere with assimilated AOD.

but the DRF by organic matter is uncertain, because SSA for OC was controversial. The MACR-simulated DRF from assimilated AOD was evaluated with MODIS-retrieved DRF over ocean. The comparison was conducted only over ocean, but that over the Yellow sea and East China sea can be validation of MACR-simulated DRF, indirectly.

The DRF by aerosols, obtained from model simulation, have large uncertainty, caused by the uncertainty of aerosols and their properties. To reduce these uncertainties, the more accurate aerosol optical properties were applied for MACR model simulation, but there are still other uncertainties in several variables. SSA was already evaluated by Park et al. (2011), but can be improved through assimilating with AERONET SSA. The angstrom exponents and asymmetric factor could be developed, using Mie calculation. This study is only one of approaches to improve the modeled DRF by aerosols, and should be updated.

Presenting author email: Anna.Esteve@uv.es

Atmospheric aerosols, both of natural and anthropogenic origin, directly affect the Earth's radiative balance through the scattering and absorption of the incident solar radiation (Charlson *et al.*, 1992; Kiehl and Briegleb, 1993). The determination of this effect, named direct aerosol radiative forcing, is still characterized by a great uncertainty, both at regional and global scale, due to the variability of the optical properties and the spatial-temporal distribution of the aerosols (IPCC, 2007).

In this study we present an analysis of the aerosol radiative forcing using measurements of global solar irradiance and aerosol properties, as well as simulated data, during the period from 2003 to 2011 in Burjassot, Spain, an urban coastal site on the western extreme of the Mediterranean, subject to the influence of particles brought from such distant regions as the Sahara, industrial continental Europe, and oceanic regions.

Measurements of global solar irradiance on a horizontal surface were made every 5 minutes with a Kipp and Zonen CM-6 pyranometer, which has a spectral range between 305 and 2800 nm. The solar irradiance without aerosols was simulated with the SBDART (Santa Barbara DISORT Atmospheric Radiative Transfer) multiple scattering model (Ricchiazzi *et al.*, 1998). The input parameters used by the SBDART were a mid-latitude model atmosphere, a fixed surface albedo of 0.15, the total ozone column from TOMS and OMI (ftp://toms.gsfc.nasa.gov), and the values obtained by a Cimel CE318 photometer of the water vapor amount. To obtain the solar irradiance with aerosols, the aerosol optical properties (aerosol optical depth, single scattering albedo, and asymmetry parameter) obtained by a Cimel CE318 photometer were also included as input parameters in the SBDART.

The aerosol radiative forcing, which is defined as the difference in net fluxes with and without aerosols, was calculated at 5 minutes intervals, and then integrated over 24 hours to obtain daily mean values for 200 complete days under cloud-free skies during the period from 2003 to 2011. The monthly mean aerosol radiative forcing (Figure 1) showed a clear variation during the year, ranging from -6 to -29 Wm^{-2} at the surface, and from -2 to -4 Wm^{-2} at the top of the atmosphere, with mean values for the whole period of -17 and -2 Wm^{-2}, respectively. The aerosol radiative forcing efficiency (Figure 2), which represents the change in net flux per unit of aerosol optical depth at 500 nm, was found to be -111 Wm^{-2} at the surface and -17 Wm^{-2} at the top of the atmosphere. These negative values, which correspond to cooling effects, show the important role of atmospheric aerosols in this urban site of the Mediterranean coast.

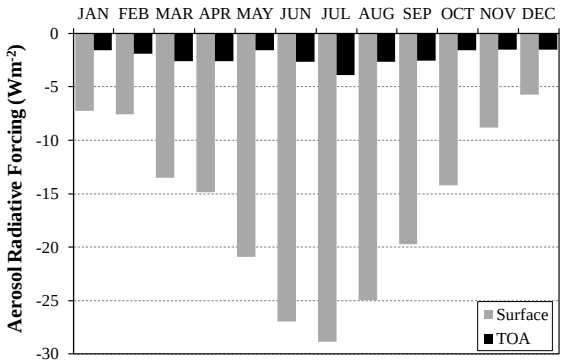

Figure 1. Monthly mean aerosol radiative forcing at the surface and at the top of the atmosphere.

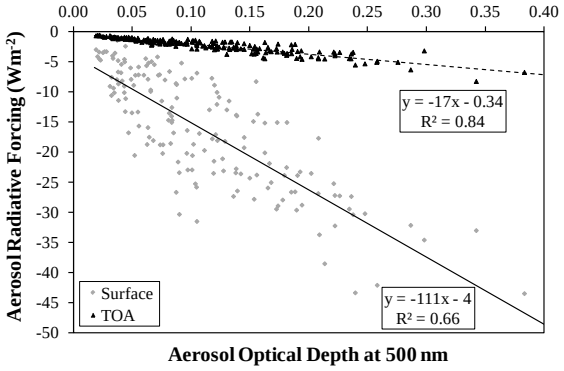

Figure 2. Aerosol radiative forcing as a function of the aerosol optical depth at 500 nm.

Keywords: aerosol size distribution, Himalayas

The Finnish Meteorological Institute together with The Energy and Resources Institute, TERI India have conducted continuous measurements of aerosol physical properties in Mukteshwar, India since September 2005. This is a background location in the foothills of Central Himalayas, and aerosol size distribution measurements with such a time span are unique from the area. Long-term trends in aerosol concentrations can be observed to emerge from the data set.

Mukteshwar is located about 350 km northeast of New Delhi. The site is at 2180 m above the sea level in a rural region at the Himalayan Mountains. The station is surrounded by an agricultural test field. No major local pollution sources are known to affect the site. The nearest towns, Nainital and Almora, are located 25 km to the west and north of the site, respectively. The size distribution measurements are made with a DMPS (Differential Mobility Particle Sizer) system. The instrument is set to measure the dry particle diameter in the size range 10–800 nm in about 5.5-min cycles (Komppula et al. 2009).

The total particle concentration for the 5-year measurement period shows high variability (Fig. 1). The maximum concentrations are observed in April, before the annual monsoon season (mid June-end of September). Not accounting year 2011, the maximum concentrations have shown an increase throughout the measurement period. This reflects the population growth, urbanization, and rapid industrial development occurring in India.

The highest concentrations which are observed during the warm summer are due to air lofted from the Indo-Gangetic plains below, when the boundary layer height is at its yearly maximum. This is also a time when nucleation mode particles are observed in Mukteshwar (Neitola et al. 2011). Typically the size distribution is unimodal, with a peak at ~ 100 nm (Fig. 2).

The seasonal concentration variation is similar for all the years: after the highest concentrations in spring, the monsoon season brings the concentrations down to the lowest values of the year with different wet deposition processes. These include impaction and diffusion scavenging by the falling rain drops and activation to mountain fogs and clouds. This also decreases the geometric mean diameter of the size distribution. Several studies suggest that the aerosol concentrations before the monsoon season may modulate the monsoon characteristics; this in turn would affect the aerosol concentrations during monsoon. In practice, such an observation is difficult to draw from *in situ* observations alone (Hyvärinen et al. 2011).

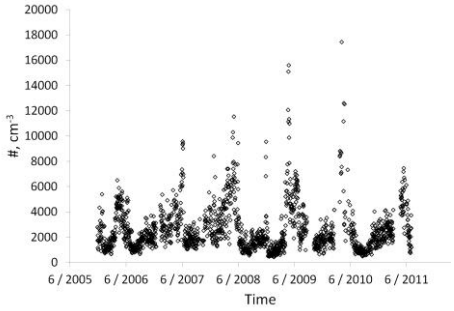

Figure 1. 1-day total particle concentrations from Mukteshwar.

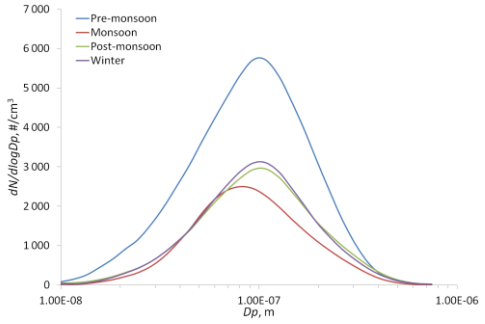

Figure 2. Seasonal average size distributions: Pre-monsoon 1.3-30.6.; Monsoon 1.7.-30.9.; Post-monsoon 1.10.-30.11.; Winter 1.12.-28.2

Soot consists mainly of light absorbing carbon. When deposited on snow, it decreases the snow albedo, increases the absorption of radiation in snow and thereby enhances melting. This process has been studied for decades (e.g. Clarke and Noone, 1985) and it has been recognized to be one of the major sources of warming in the Arctic regions (Flanner et al., 2007). The link between soot, snow albedo, and climate change is still not known in enough detail for quantitative analysis (Hansen and Nazarenko, 2004). To provide more insight into these connections,the Finnish Meteorological Institute and Helsinki University have started the Soot on Snow (SoS 2012) measurement campaign for the whole melting season 2012 at Jokioinen, southern Finland. This project is a continuation of a similar experiment carried out at Nurmijärvi, southern Finland in spring 2011 (Virkkula et al., 2011).

On February 16th we produced three spots of different concentrations of soot on snow on an agricultural field. A fourth measurement spot was created as reference with no soot. The soot we used was produced in residential heating with wood and oil, and was collected by chimney cleaners in eastern and northern parts of Helsinki during winter 2012.

The soot was dispersed in air inside a closed barrel by blowing in ambient air. Then the air with the soot was led to a cyclone where larger particles were separated. The air with the smaller soot particles was led to a specially manufactured soot tent (an open-bottom cylinder 4 m in diameter, 1,3 m in height) via two inlets on the opposite sides of the tent. The sample inlet for the measurement devices was located approximately in the middle of the soot tent. Excess air was led out from the tent via a chimney on top of the tent.

Sample inlet was a six meters long approximately straight copper tube. Because the soot particle concentrations inside the tent were extremely high, the air sample was diluted with fraction: 1 part sample air, 25 parts filtered ambient air.

During the time when the tent was up, there were several instruments measuring the sampled air. Particle number concentration was measured with a Condensation Particle Counter (CPC) and particle size distribution with a Differential Mobility Particle Sizer (DMPS, 15-750 nm) and an Optical Particle Sizer (OPS 300 – 10 000 nm). The absorption of the airborne soot was measured with a three-wavelength Nephelometer and a three- wavelength Particle Soot Absorption Photometer (PSAP). The size distribution of the soot was measured with a Single Particle Soot Photometer (SP2, 70-500 nm).

After the soot was blown into the tent for a measured time and it was allowed to settle, the tent was carefully removed and snow samples were taken from the spot. These samples were melted and filtered. Filters were analysed with a Thermal/Optical Carbon Aerosol Analyzer (OC/EC) for their EC concentration. Each spot had also two poles for measuring the snow depth. Structure, grain size and temperature of the snow layer were also analysed.

Two broad band (300-42000 nm) albedo sensors were installed about 20 cm above the snow surface at each spot to measure the global net radiation. Each soot spot was also instrumented with a Scalar Irradiance Sensor (400-700 nm). These were installed on the ground in December before the snow pack was formed.

More snow samples will be taken and analysed during the spring. Also the evolution of the snow layer structure and temperature on the soot spots and on the reference spot will be monitored. The snow depth is measured daily, and the albedo and transmittance of the snow are measured continuously.

With this data our goal is to make a calibration curve for estimating how much soot is needed to cause observable differences in different parameters of the snow pack. We will also try to quantify of the effects of the soot on snow for modelling purposes. Other parameters of interest are the settling velocity of the soot, the aging of the soot in the snow and the transfer of radiation through the snow layers.

This work was supported by Tor and Maj Nessling foundation, Academy of Finland, and the international co-operation programs CRAICC and MACEB. We also thank Consti Talotekniikka for providing us the soot.

Influence of a kappa-Köhler theory based water uptake scheme on a global aerosol/climate model

D. O'Donnell[1]

[1]Climate Change Research, Finnish Meteorological Institute, 00101 Helsinki , Finland
Keywords: aerosol modelling, atmospheric aerosols, hygroscopic growth, climate effect.
Presenting author email: declan.odonnell@fmi.fi

The scattering of radiation by aerosol particles is a strong function of the aerosol size compared to the radiation wavelength. Furthermore, the number of particles in a given aerosol population that can act as cloud condensation nuclei (CCN) is also strongly size-dependent. Particle size is thus important for both the direct and indirect aerosol effects on climate. Hygroscopic growth can substantially alter both the size and optical properties of aerosol particles; moreover, observations in many regions show that condensed water makes up a significant proportion of the aerosol mass. It is thus deisrable that global climate/aerosol models are able to capture not only the regional and temporal distributions of particle mass and number, but also their hygroscopic growth with reasonable accuracy.

Kappa-Köhler theory is a comparatively recently developed method that allows the quantification of aerosol water uptake in terms of a single free parameter (κ) per compound in the aerosol phase (Petters and Kreidenweis, 2007). It obviates the need for detailed thermodynamic calculations and is for this reason highly attractive to global climate/aerosol modelling, where computation of aerosol physics is computationally very costly.

In this study, the global climate/aerosol model ECHAM5/HAM version 2 (Stier et al. 2005; Zhang et al. 2012) is used. The introduction of a based water uptake parameterization into this model is described. The impact of the new water uptake scheme is described in terms of observables by its influence on aerosol optical depth (AOD, a wide-area observable quantity), and in terms of aerosol direct effects on climate. Aerosol indirect effects are for future study.

Historically, ECHAM5/HAM (version 1) has been an outlier among the global models that have been compared within the AeroCom framework (Textor et al., 2006), with an annual mean global aerosol water burden of 75 Tg under year 2000 conditions, compared to the AeroCom median value of 35 Tg. With the introduction of the κ-Köhler based parameterization in its standard configuration, this figure falls to 51Tg for ECHAM5/HAM.

The global mean AOD falls from 0.16 to 0.13 with the introduction of the new scheme, with the largest reduction seen over the Southern Ocean. The modelled clear-sky aerosol forcing at the top of the atmosphere weakens from -4.2 Wm^{-2} to -3.6 Wm^{-2}.

The sensitivity of the model to the possible choices of the free parameter κ for each of the model hygroscopic compounds (sulphate, sea salt and organic carbon) is also studied and the results presented, again in terms of AOD and direct aerosol forcing,

Boxmodel studies

In order to better understand the model behaviour, the global modelling results are complemented by boxmodel studies in which dry aerosol size and composition, as well as ambient temperature and relative humidity, can be prescribed, and the resulting hygroscopic growth factors calculated.

It is found that, in the κ-Köhler based model, hygroscopic growth is:

i. insensitive to temperature
ii. moderately sensitive to κ
iii. highly sensitive to relative humidity (RH)

It is concluded that the κ-Köhler framework is well suited to global aerosol modelling. Indeed, it has already been adopted as the default water uptake scheme in ECHAM5/HAM2 (Zhang et al., 2012).

Aerosol and cloud SW radiative forcing in the south of Portugal

V. Salgueiro[1], M.J. Costa[1,2], A.M. Silva[1], and D. Bortoli[1, 3]

[1]Évora Geophysics Centre (CGE), University of Évora, Évora, 7000, Portugal
[2]Department of Physics, University of Évora, Évora, 7000, Portugal
[3]Institute Atmospheric Sciences and Climate, ISAC-CNR, Bologna, 40129, Italy
Keywords: aerosols, clouds, radiative forcing
Presenting author email: vandasalgueiro@gmail.com

Clouds and to a certain extent aerosols, constitute the most important factors regulating the Earth's radiation budget because they absorb and scatter solar radiation and absorb and emit terrestrial radiation. Therefore, the characterization and understanding of their radiative effects are tremendously important.

Accordingly, the study of the variability of the solar radiation at the surface is highly dependent on clouds and aerosols and their optical properties, particularly the optical thickness is essential for any radiation parameterization, which are still major priorities for regional and global climate models (Kassianov et al., 2011; Santos et al., 2011).

In this work, results of the cloud and aerosol radiative forcings obtained from ground-based irradiance measurements in the shortwave (SW) spectral region are presented. These irradiance measurements are taken continuously in the Atmospheric Physics Observatory of the Evora Geophysics Center, with an Eppley Black & White Pyranometer that presents a spectral range comprehended between 285 and 2800 nm. Surface aerosol and cloud radiative forcings are defined as the instantaneous increase or decrease in net (downwelling minus upwelling) irradiances at the surface level, due to instantaneous changes of these atmospheric constituents. The clear sky irradiances are calculated with a radiative transfer model. Cloud and aerosol radiative SW radiative forcings are normalized dividing the absolute values by the net clear sky irradiances. This quantity is useful because it allows for eliminating the solar zenith angle dependence.

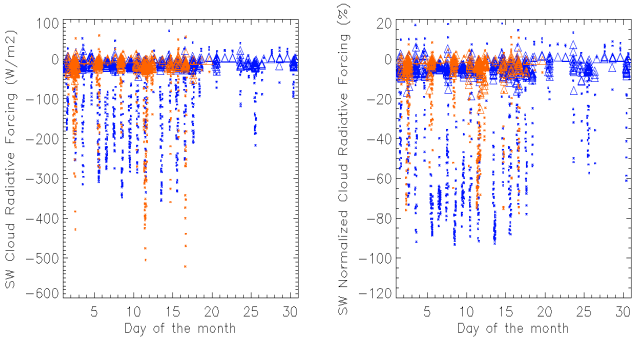

Figure 1. Absolute and normalized SW cloud radiative forcing at the surface, for January (blue dots) and July (red dots) 2008, in the region of Évora, south of Portugal. The triangles represent the latter quantities per unit cloud optical thickness.

Moreover the absolute and normalized SW cloud and aerosol radiative forcing values are also divided by the respective optical thickness, obtained from ground-based spectral measurements, to yield the cloud / aerosol radiative forcing efficiencies, and results are presented and analysed.

Figure 1 presents the absolute and normalized SW cloud radiative forcing values at the surface, for January (blue dots) and July (red dots) 2008, in the region of Évora, south of Portugal. To note that the strongest SW cloud radiative forcings are obtained in July, with values reaching -500 W/m^2, while the values obtained in January are around -350 W/m^2. When the normalized SW cloud radiative forcing is considered, the opposite situation is found, with the cloud radiative forcing in January reaching values around 95% and in July with values of about 75% (absolute values).

Figure 1 also shows both radiative forcing quantities per unit optical thickness, represented by the triangles. Results indicate that the summer and winter cloud radiative forcing efficiencies do not differ much, presenting a relatively constant behaviour.

The aerosol radiative forcing is also evaluated in terms of absolute and normalized values and results will be presented at the conference.

The work is financed through FEDER (Programa Operacional Factores de Competitividade – COMPETE) and National funding through FCT – Fundação para a Ciência e a Tecnologia in the framework of projects FCOMP-01-0124-FEDER-007122 (PTDC / CTE-ATM / 65307 / 2006), FCOMP-01-0124-FEDER-009303 (PTDC/CTE-ATM/102142/2008) and FCOMP-01-0124-FEDER-014024 (PTDC/AAC-CLI/114031/2009).

Investigating aerosol – radiation feedbacks in high-emission areas using WRF/Chem model

A.Balzarini[1], G.Pirovano[1], G.M. Riva[1]

[1]RSE S.p.A., via Rubattino 54, 20134 Milano, Italy
Keywords: WRF/Chem model, feedback, aerosol, climate
Presenting author email: alessandra.balzarini@rse-web.it

Aerosols are known to affect both weather and climate. The scattering of solar and terrestrial radiation by aerosol particles exerts a direct radiative forcing on climate system ("direct effect"; Foster et al., 2007). Additionally, aerosols, serving as cloud condensation nuclei, modified microphysical and optical properties of clouds and then precipitations ("indirect effect"; Forkel et al., 2011).

Also climate can influence air quality. The impact of climate on air quality may affect future air quality policy planning, especially in urban areas, through modifications of gas-phase chemistry, transport, diffusion, removal processes and natural emissions (Giorgi and Meleux, 2007).

Although the existence of these mechanisms has been documented in recent years, only few studies considered the interactions between aerosols and meteorology in air quality simulations over Europe (e.g. Forkel et al., 2011; Tuccella et al., 2012).

Traditional "off-line" chemical and transport models, in fact, do not allow the estimation of the coupled interactions between climate change and air quality and, hence, their effects on policies. Otherwise, in the fully coupled Weather Research and Forecasting/Chemistry model (WRF/Chem; Grell et al., 2005) the chemistry transformations are embedded into the meteorological model WRF (Skamarock et al., 2008), so that such interactions can be investigated with a full modular approach.

In order to evaluate the effect of direct and indirect effects of aerosols on meteorology and surface PM10 concentrations, numerical simulations of the WRF/Chem model (version 3.3.1; 2011) have been performed over the Italian Peninsula. Italy often suffers high PM concentrations, due to the interaction of both anthropogenic and natural emissions, enhanced by rather complex circulation conditions, making it a very interesting case study.

Particularly, this paper provides a quantitative evaluation of the interaction between aerosol and meteorological processes due to limited but strongly emitting areas, thus contributing to the investigation of possible regional climate impacts.

The fully coupled meteorology and chemistry model has been applied for both winter and summer episodes of the year 2005. WRF/Chem has been set up for the whole Italian domain with a grid resolution of 15 km, using emissions and configuration schemes adopted in previous studies and sensitivity test. The chosen gas phase chemistry and aerosol modules are coupled to some aqueous reactions and microphysics, as described in Peckham *et al.* (2011).

As a first step computed results have been evaluated against ground-based observations, providing PM10, PM2.5 mass concentrations together with their main components. Then, three WRF/Chem simulations have been compared in order to investigate aerosols-radiation feedbacks and their effect on clouds and precipitation. The first simulation does not account for any feedback mechanisms. The second simulation includes the direct aerosol effect and the third one accounts for the indirect effect of aerosols on clouds and precipitations.

For each simulation, the influence of the different model formulations is presented and discussed as well as the effects on meteorological processes and PM10 concentrations.

Moreover, whenever possible, the different impact of anthropogenic and natural aerosol loads is discussed.

Soot particles consist of light absorbing carbon, or black carbon (BC) and organics. If soot particles get deposited on snow they will absorb solar radiation, decrease the snowpack albedo and so heat the snow and accelerate its melting. This process has been studied for decades (e.g., Warren and Wiscombe, 1980; Clarke and Noone, 1985) and it is recognized as one of the most important climate forcers in the polar areas (e.g., Quinn et al., 2008). Hansen and Nazarenko (2004) concluded that there is a need for better quantification of the links of BC to snow albedo, melting ice, and climate change.

The Soot on Snow (SoS) project is aimed for studying and quantifying the effects of soot on snow, for example the effect on albedo, snow grain size, and melting. The plan is to make experiments during several consequent winters. The first one of the series was conducted in spring 2011, the second in spring 2012 (Kivekäs *et al.* 2012).

In the first campaign soot particles were produced and let them deposit on a snowpack on a farming field in southern Finland on Friday, 4 March 2011. Soot was produced by burning organics, such as rubber from used car tires in a wood-burning stove. The purpose was to get as high soot concentrations in air as possible, so that the effects become clear. The smoke was lead through a pipe, cooled by snow surrounding the pipe, and lead into a tent carage that was built on top of the snow. The other end of the tent carage was left open so that the smoke went out and a clear gradient was produced. An inlet was set at the open end of the carage tent and sample air was drawn to a measurement container approximately 5 meters apart. Aerosol number size distributions were measured with an SMPS, light scattering with a TSI 3λ nephelometer and absorption with a Radiance Research 3λ PSAP. Outside the tent aerosol number concentrations were measured at several locations to get an estimate of the dispersion.

After the soot production was over, the tent carage was removed carefully from the area. Snow samples were taken from the deposit area and a background reference area, to be analyzed for organic and elemental carbon. The albedo of the snowpack was measured both over the deposit and the reference area. Snowpack thickness was measured by inserting 18 measurement sticks in a grid around the deposit area and the reference area, and inspecting them regularly. On 1 April, just when the fastest melting started, two snow pits were dug, one in the deposit area and the other in the reference area. In both pits a physical characterization of snow stratigraphy was done, including thickness, density, hardness, grain size and shape. After that, temperature profiles were measured at a 5 cm intervals. In addition, the spectral irradiance at the depth of 20 cm was measured in the wavelength range 400 – 900 nm.

The experiment demonstrated very clearly the effects of soot on snow: the albedo decreased, the snow grain size, the whole stratigraphy and temperature profile in the snow pack changed compared with the reference site. All these lead to a faster melting of snow in the area where soot was deposited.

The problem in the experiment was the very large variation in aerosol concentrations. This, on the other hand, was due to the method of soot production: organics were burned in a simple wood-burning stove. The use of this kind of a stove results in batch-like burning: refilling is not continuous, the stove is filled in after the previous batch has burned. Therefore, in the following experiments soot will be produced by blowing cold soot particles without burning. This method was already used in the SoS 2012 campaign (Kivekäs *et al.*, 2012)

This work was supported by the EU Life+ project Mitigation of Arctic warming by controlling European black carbon emissions (MACEB) and Maj and Tor Nessling foundation. The work of Mr. Timo Vainio in constructing the measurement site and Mrs. Anita Virkkula in assisting in the snowbed thickness measurements are gratefully acknowledged.

Presenting author email: Outi.Meinander@fmi.fi

The effect of Black Carbon in snow layers is of importance to climate change and also for forecasting snow melt. Snow reflectivity, i.e. albedo, varies with wavelength, and therefore depends on a number of factors, such as the depth and age of the snow cover, snow grain size, solar zenith angle, cloud cover, and absorbing aerosols on snow. Currently, the effect of BC on snow albedo and melting is improperly understood. Our work on project A4 (Arctic Absorbing Aerosols and Albedo of Snow, 2012-2015) aims to reduce these uncertainties. On the basis of literature, the effect of BC on snow albedo is the larger, the shorter the wavelength. Therefore, as a special feature, we also consider snow albedo at ultraviolet (UV) wavelengths. Here an overview on the project is given, together with some preliminary results. The work forms a research ensemble for the life cycle of BC, effects on Arctic snow albedo, and using the elaborated information for modeling and satellite approaches.

The origin of airborne BC is studied by combining data from at least 5 measurement stations measuring BC and air mass transport history. We will use the Air Quality and Emergency modeling system SILAM to study the transport of soot from the sources in the Northern Hemisphere to the Arctic. The results will be verified against our experimental results on concentration of soot in snow. Multi-pollutant simulation outcome will also be compared with the remote-sensing AOD observations and in-situ PM measurements.

Our continuous albedo measurements are made at established measurement stations, north from 60 ^{o}N. In addition, short-term albedo experiments will be carried out. For the use of albedo data, ancillary data on snow properties, aerosols (BC) and various environmental parameters are essential. Albedo measurements will be analyzed in the context of atmospheric aerosols, BC in snow samples, snow grain size, and meteorological automatic weather station (AWS) data on the beginning of rain, snow depth, and cloud cover, etc.

We will also work to produce physically based improved albedo parameterizations that can be applied, for instance, in RT-models and in climate models with special emphasis on snow melt and BC; and to study the effect of BC on melting snow on the satellite measured top-of-atmosphere (TOA) reflectance; and to use the measured and modeled snow albedo to enable the retrieval of aerosol optical properties over snow covered areas during snow melt.

We will use continuous 1-min surface UV albedo data from the Sodankylä Arctic Research Centre (67^{o}22'N, 26^{o}39'E, 179 m asl); measurements started in 2007 by FMI as a part of the IPY activities. The site is also a WMO GAW station (www.wmo.int/gaw/). In addition, we will make use of long-term Sodankylä Arctic Centre mast albedo and weekly samples on BC in snow. In 2009, the maximum concentrations in snow were up to 38 ppb for BC, and 1734 ppb for organic carbon. On the other hand, on 23 April 2010, with new snow originating from an Eyjafjallajökull ash cloud, the snow sample contained 59 ppb elemental, and 4312 ppb organic carbon.

In 2012, the experiment Soot on Snow (SoS-2012), took place at the Jokioinen Observatory, a synoptic FMI weather station in the southern Finland. Three spots of different concentrations of soot on snow on an agricultural field were produced. A fourth measurement spot was a reference with no soot. The soot we used was produced in residential heating with wood and oil, and was collected by chimney cleaners. Two erythemally weighted UV-B sensors (280-310 nm) were installed about 20 cm above the snow surface to measure the UV albedo of the dirty snow continuously, until the end of snow melt. Also, albedo was measured periodically using a multichannel NILU-UV radiometer at UV and PAR channels.

The main objective of the A4 project is to quantify the interaction of Arctic snow albedo and absorbing aerosols, and to gain more in-depth understanding of the globally important aspects of BC and albedo feedback, as well as BC and snow melt in the Arctic.

This work is supported by the Academy of Finland.

Keywords: Atmospheric aerosols, radiative forcing.
Presenting author email: jlal@correo.ugr.es

Ground-based measurements of aerosol optical depth (AOD) and surface shortwave irradiance carried out in South-Eastern Spain during 2006–2010 are used to evaluate the surface aerosol direct radiative forcing. The data were recorded at the radiometric station located on the rooftop of the Andalusian Center for Environmental Studies (CEAMA, 37.17°N, 3.61°W, 680 m a.s.l) in Granada, southeastern Spain. The station is operated by the Atmospheric Physics Group (GFAT) of Granada University.

The ground based station is equipped with a CM11 pyranometer (resolution better than ±5 W/m2) manufactured by Kipp & Zonen (Delft, Netherlands) for measuring the surface shortwave solar irradiance (310-3200 nm), recorded every minute by a data logger (CR10X model, manufactured by Campbell Scientific, Inc). This instrument was calibrated periodically with a reference CM11 pyranometer showing a great stability.

A CIMEL CE318 Sun photometer included in the NASA AERONET network (Holben et al., 1998) and located near the CM11 radiometer, provided AOD data at 340, 380, 440, 500, 670, 870 and 1020 nm. In this work, the AERONET AOD data of level 2 (cloud screened and quality assured), with accuracy of about ± 0.01 for λ>440 nm and ±0.02 for shorter wavelengths, were used. Furthermore the spectral dependency of the AOD has been considered through the Angström exponent evaluated in the range 440–870 nm. Cloud cover was characterized by the clearness index (kt) obtained from the ratio of the shortwave solar irradiance to the extraterrestrial shortwave solar irradiance on a horizontal surface. In addition, an All Sky Imager developed by the GFAT team was used to obtain the cloud cover in oktas (eighths of sky) (Cazorla et al., 2008).

The surface shortwave aerosol radiative forcing, ARF, is defined as the difference between the observed net shortwave irradiance (downward minus upward irradiances) at the Earth's surface and the aerosol-free surface shortwave net irradiance. The net irradiances in the presence and absence of atmospheric aerosols can be written in terms of the downward irradiance and the surface shortwave albedo.

Different methodologies can be used to estimate the surface shortwave aerosol forcing efficiency (AFE, aerosol forcing per unit of AOD). In this study we employed the direct method (e.g., Satheesh and Ramanathan, 2000) which is based on a linear fit of the net irradiance at the Earth's surface versus the AOD at a fixed solar zenith angle (SZA).

We evaluated the ARF and AFE for SZA ranging between 20º and 75º. Our results showed negative AFE values indicating that the atmospheric aerosols produce a cooling of the surface. In addition, AFE exhibited a clear dependence on SZA, increasing its absolute value from 20º to 60º, while a decreasing trend was observed for SZA larger than 60º. All these results are in agreement with previous studies developed in the study area using a different approach (Horvath et al., 2002; Lyamani et al.,2006).

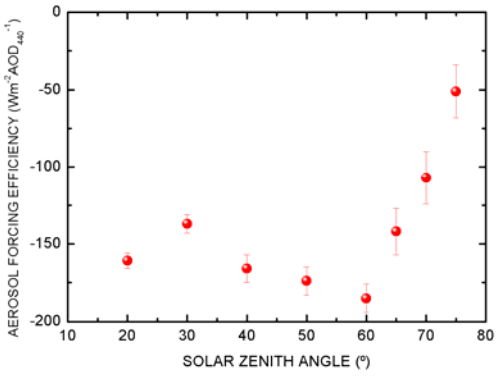

Figure 1: Aerosol forcing efficiency as a function of the SZA.

Hebei province is located in the north of China, Beijing and Tianjin is surrounded with it, the Bohai sea gulf is in the east of Hebei province. In this study, the data from the Piper Cheyenne twin urbo-prop aircraft was used to observe the clouds and precipitation, since 2005 year. The aerosol was measured by a PMI Aerosol Spectrum Probe (size range 0.1～3.0 micron). The cloud droplet was measured by a FSSP probe (size range set up as 2 ~ 47μm). The 2D – C (25 ~ 800μm) and 2D - P (150 ~ 9300μm) probes can provide two-dimensional particle image. In addition, the aircraft is also equipped with other devices to obtained corresponding data. CCN were measured by a DMT continuous flow streamwise thermal gradient CCN counter. The supersaturation is set at S=0.3% in observed period.

The concentration and size with spatial and temporal distribution of aerosol particles ,CCN and cloud droplet over Hebei area, northern China, are analyzed. The preliminary results show that the distribution of them are very different during the precipitation in stratiform. Synthetical research results show that the aerosols played an important role in formation of clouds and precipitation processes.

Figure 1 shows that the aerosols and cloud condensation nuclei (CCN) with spatial and temporal distribution in the aircraft detection time at May 27, 2010. The vertical left axis indicates the aerosol and cloud condensation nuclei concentration, the units is cm^{-3}. The vertical right axis indicates height of aircraft flight, its units is meter.

The results shown in the figure 1, light blue curve shows the altitude change with time, the red solid point is the temporal and spatial distribution of aerosol concentration, the black solid point is the spatial and temporal distribution of CCN concentration.

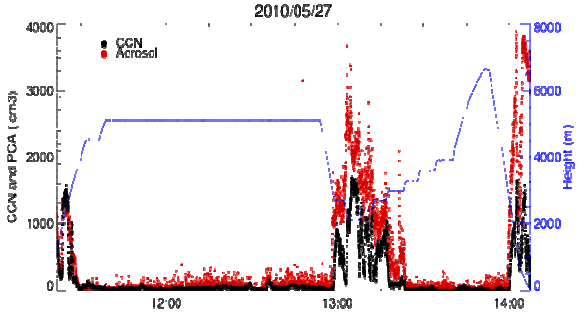

Fig. 1 the temporal and spatial distribution of aerosol and CCN concentration

In order to analyze aerosols, cloud condensation nuclei and cloud droplets in cloud base and cloud inside, the corresponding concentration and scale distribution between the spectra shown in figure 2. The results showed that the aerosol concentration and cloud condensation nuclei are very different, in two different conditions of inside and outside of cloud.

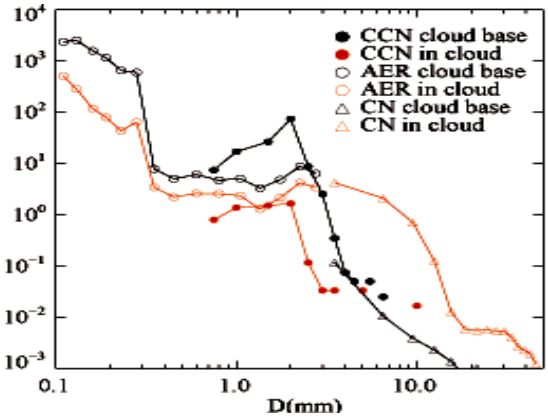

Figure 2. aerosol and CCN spectra comparison inside and outside of cloud

A note of caution concerning particle evaporation during measurements of their Cloud Condensation Nucleus potential

H. Wex[1], P. Herenz[1], J. Voigtländer[1] and F. Stratmann[1]

Particles consisting of either levoglucosan or of succinic acid were examined with respect to their ability to act as CCN (cloud condensation nucleus). Measurements of the activation were made with two different instruments, the Leipzig Aerosol Cloud Interaction Simulator (LACIS, Wex et al., 2006) and the Cloud Condensation Particle counter (CCNc) from DMT (Droplet Measurement Technologies, Roberts & Nenes, 2005). Both instruments were used to measure critical dry diameters (d_{crit}) for activation at different super-saturations. The calibration of both instruments (with respect to their supersaturation) was done by using ammonium sulphate particles.

In LACIS, super-saturations are produced via cooling of a humidified airstream, and the temperatures in LACIS are below 20°C at its inlet and go down to 2°C in the section where the particles are activated and where the activated droplets grow.

In the CCNc, super-saturation is produced by the effect that water vapour diffuses faster than heat, and the section responsible for the activation of the particles is heated from the inlet temperature (which usually is slightly above the temperature of the surrounding laboratory) up to almost 50°C, with the temperature-increase being linearly related to the super-saturation adjusted in the instrument.

Based on Köhler-theory, d_{crit} can be calculated when properties of the substances that make up the particle (as e.g. density and molecular weight) are known (e.g. Wex et al., 2007). As both, succinic acid and levoglucosan, are comparably well characterized substances, values for d_{crit} can be determined via Köhler-theory. Calculations were done for the super-saturations at which measurements had been performed. The resulting values were then compared to values obtained from the measurements, as shown in Figure 1.

In Figure 1 it can be seen that the measured activation of levoglucosan in LACIS and the CCNc are in agreement. This was also the case for the measured activation of succinic acid in LACIS. This can be taken as proof that in general the activation behaviour of the substances examined here can be modelled with Köhler-theory. However, for the activation of succinic acid derived from CCNc measurements, the measured d_{crit} was clearly larger than the calculated value for $d_{crit,measured} < 85$nm. For succinic acid, d_{crit} of 85nm corresponds to a super-saturation $> 0.32\%$, and to temperatures in the CCNc at the point of activation of the particles of roughly > 30°C.

The vapour pressure of succinic acid is about 3 orders of magnitude above that of levoglucosan. The results presented here can be used to deduce that a certain fraction of each succinic acid particle evaporates in the CCNc before it is activated to a cloud droplet, i.e. a larger particle than expected has to be fed into the instrument to account for loss of particle mass through evaporation. The evaporated fraction of the particles increased with increasing super-saturation and was up to 70% of the total particle mass at the highest super-saturations used in our measurements (1%).

Substances with vapour pressure as e.g. succinic acid can be present in the atmospheric aerosol, and therefore a note of caution has to be given here: It is possible that also some atmospheric aerosol particles may lose a certain fraction of their mass when their activation behaviour is measured with the CCNc we used for our study.

Presenting author email: Manu.Thomas@smhi.se

The scientific understanding of the climate effects of the different aerosol species as well as their representation in models and the physical and chemical transformation that the aerosols go through under different meteorological conditions is still low. Apart from the direct effects of aerosols on climate, the aerosols can also act as cloud condensation nuclei thereby altering the microphysical properties of clouds which is formulated as the indirect aerosol effect (IAE) (Lohmann and Feichter, (2005) and references therein). The uncertainty range of the IAE estimates is so high that in order to reduce this uncertainty one need to represent the aerosol dynamics and chemistry more accurately. In this study, we attempt to estimate the IAE from a full-fledged chemistry transport model that is coupled to a detailed aerosol dynamics model that also includes a cloud activation module.

The chemistry transport model, MATCH (Multiple-scale Atmospheric Transport and Chemistry) (Andersson et al., 2007) that accounts for transport, chemical transformation and deposition of chemical tracers in the atmosphere based on the EMEP emissions is used for this study. This model is coupled to an aerosol dynamics model, SALSA (Kokkola et al., 2008) that considers the physical processes such as nucleation of particles from gas phase, growth of particles by condensation and coagulation and thereby computes the size distribution, number concentration and chemical composition of the aerosol species in the different size classes. This information is coupled to a cloud activation model that computes the cloud droplet number concentrations (CDNC) based on the prognostic parameterization of Abdul-Razzak and Ghan (2002). By this scheme, the efficiency of an aerosol particle to be converted to cloud droplet depends on the size, number and chemical composition of the particle as well as the updraft velocity and maximum supersaturation of the air parcel. The CDNC thus obtained are offline coupled to the Rossby Center regional climate model, RCA4 (RCA4 is an improved version of RCA3 (Samuelsson et al., 2011)) that would give us information on the cloud microphysical properties such as cloud effective radius, cloud liquid water path as well as the radiative fluxes on the regional scale over Europe. The offline coupling is only one way for the present study. The merit of such a study is that more detailed description of emission, transport, particle growth, deposition processes of aerosols can be included and hence, such studies can give us a more accurate description of the climate impact of aerosols on a higher spatial resolution compared to global models. This can also help us assess the level of detail that will be needed in describing the effects on a regional climate. Also, the effects of future climate change on air pollution can be assessed in detail. Simulations are carried out for present day scenario with meteorology from RCA4. The seasonal distribution and vertical distribution of cloud microphysical properties resulting from this coupling will be presented. Also, comparisons with other studies and satellite observations will be discussed.

During the dust season (April - October), Saharan dust is transported over long distances from Africa to the Caribbean, influencing the radiative properties and the cloud formation properties of the aerosol. The project PRADACS (Puerto Rico African Dust and Clouds Study) was established to study the role of Saharan dust in cloud formation over the Caribbean. Within PRADACS, we performed a one-month field campaign on the mountain station at Pico Este (1000 m asl), Puerto Rico (Figure 1).

The measurements were performed between August 16 and September 13, 2011. Cloud residuals, interstitial aerosol particles and out-of-cloud aerosol particles were sampled by a counterflow virtual impactor and by an interstitial inlet, respectively, and analyzed by two different types of aerosol mass spectrometers: One Aerodyne C-ToF-AMS and one single particle laser ablation instrument (ALABAMA). Additionally, we measured the number concentration, the black carbon mass concentration and the size distribution of the interstitial and out-of-cloud aerosol.

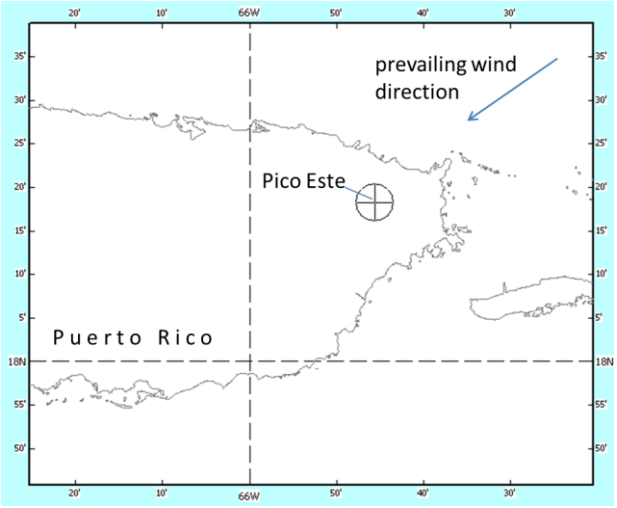

Figure 1. Map of the east coast of Puerto Rico showing the prevailing wind direction and the location of Pico Este.

Results show that the non-refractory fraction of the submicron cloud residual particles was mainly composed of sulfate. This finding is similar to the results of the RICO/PRACS (Rain In Cumulus over the Ocean experiment/Puerto Rico Aerosol and Clouds Study) that was performed at the same site in December 2004 (Allan et al., 2008; Gioda et al., 2009). In contrast to the 2004 study, the present study also included a single particle laser ablation instrument that detected the abundance of dust particles in the cloud residuals (Figure 2). These data allow for the determination of the importance of dust particles for cloud formation.

Additionally, the C-ToF-AMS was equipped with a light scattering probe that enables single particle analysis with the thermal desorption/electron impact ionization method (Freutel et al., 2011). These data will complement the single particle data obtained by the laser ablation method.

The black carbon content of the interstitial aerosol was generally low (below 100 ng m^{-3}), with a few exceptions that represented local pollution. Interstitial particle number concentrations ranged up to 4000 cm^{-3} in cloud-free periods while during intense cloud events the interstitial aerosol concentration was below 100 cm^{-3}.

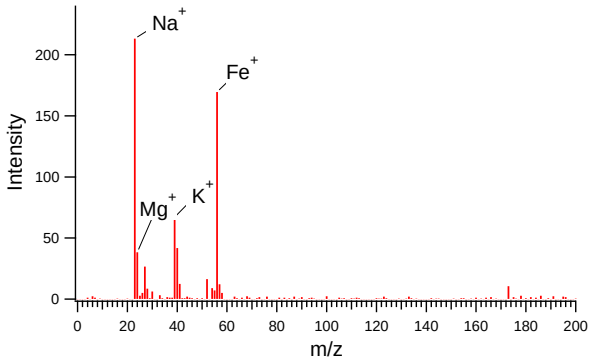

Figure 2. Example for a mass spectrum of a mineral dust particle detected by ALABAMA in the cloud residuals.

New cloud chamber experiments on the crystallization and heterogeneous ice nucleation ability of sodium chloride dihydrate particles

R. Wagner, O. Möhler, H. Saathoff and M. Schnaiter

Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology, Germany
Keywords: sea salt, crystallization, heterogeneous ice nucleation
Presenting author email: robert.wagner2@kit.edu

Recently, Wise *et al* (2012) have investigated the efflorescence of aqueous sodium chloride (NaCl) solution droplets as well as the heterogeneous ice nucleation ability of the crystallized particles in the temperature range between 221 and 238 K using optical microscopy coupled with Raman spectroscopy. The NaCl particles (size range 1 – 10 μm), used as a proxy for sea-salt aerosol, were deposited onto a hydrophobic quartz disc for analysis.

Raman spectroscopy allowed for differentiating between anhydrous sodium chloride crystals and the crystalline dihydrate form of NaCl ($NaCl \cdot 2H_2O$). According to the NaCl phase diagram, the dihydrate is the stable crystalline solid below the NaCl/ $NaCl \cdot 2H_2O$ peritectic at 273.3 K (Koop *et al*, 2000). In agreement with earlier results from Koop *et al* (2000), it was found that above 252 K only anhydrous NaCl effloresced. Between 252 and 236 K, the aqueous NaCl solution droplets effloresced into a mixture of anhydrous and dihydrate NaCl crystals whereas only $NaCl \cdot 2H_2O$ was observed below 236 K.

Concerning the heterogeneous ice nucleation ability of the crystallized particles in the deposition mode, Wise *et al* (2012) have detected that the dihydrate NaCl particles are highly efficient ice nuclei forming ice at about ice saturation (S_{ice} = 1.02 ± 0.04). Slightly higher threshold values were found for the anhydrous crystals (S_{ice} = 1.11 ± 0.07). The lower ice nucleation threshold of the dihydrate crystals could be related to a higher degree of surface roughness as revealed by the optical microscope images. In addition, the two molecules of hydration water could be particularly active sites for the further addition of water.

Using the new laboratory data as input in a trajectory model, the fraction of hydrated NaCl particles present in the troposphere at temperatures below 220 K was estimated to 40-80%. It was therefore concluded that deposition ice nucleation onto these crystals could be a new mechanism for ice formation in the troposphere.

In this contribution, we present novel results from crystallization and heterogeneous ice nucleation experiments with airborne NaCl particles which were performed in the large coolable cloud chamber AIDA at the Karlsruhe Institute of Technology. Our experiments cover the temperature range from 216 to 244 K using particles with median diameters between 0.1 and 0.9 μm. Ice formation was studied via controlled expansion cooling runs which mimic the adiabatic expansion cooling of rising air parcels in the atmosphere. We used in situ laser light scattering and depolarization measurements to detect the phase change between aqueous and crystalline NaCl particles and to infer the onset of ice nucleation. The chemical nature of the crystallized NaCl particles was probed by in situ infrared extinction spectroscopy. The spectrum of $NaCl \cdot 2H_2O$ particles bears a prominent signature in the mid-infrared regime due to the hydration waters which is absent for anhydrous NaCl crystals (Fig. 1).

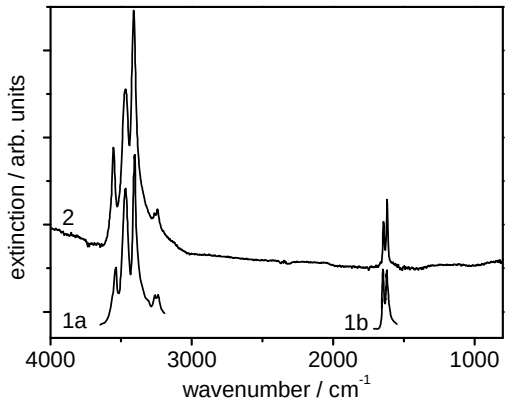

Figure 1. Infrared extinction spectrum of effloresced $NaCl \cdot 2H_2O$ particles at 226 K from this study (trace 2) in comparison with literature spectra of the dihydrate (traces 1a and 1b) from Schiffer and Hornig (1961).

In addition to determining the threshold saturation ratios for ice nucleation, the AIDA experiments allow for quantifying the ice nucleation ability in terms of the frozen fraction as well as the ice active surface site density of the seed aerosol particles. Our results corroborate the general findings from Wise *et al* (2012), namely the effect of temperature on the crystallization of either the anhydrous and/or the dihydrate form of NaCl and the good heterogeneous ice nucleation ability of $NaCl \cdot 2H_2O$ particles in the deposition mode. Closer inspection of the data, however, also reveals some variations: Firstly, the threshold where exclusively the dihydrate forms upon efflorescence is shifted in our experiments to a lower temperature, and, secondly, deposition mode ice nucleation onto the hydrated NaCl particles occurs at a somewhat higher threshold ice saturation ratio of about S_{ice} = 1.15 ± 0.05.

Experimental and modelled characterization of diffuse spectral UV irradiance under cloudy conditions: impact of aerosol properties

D. Mateos[1], A. di Sarra[2], J. Bilbao[1], M. Cacciani[3], G. Casasanta[3], D. Meloni[2], G. Pace[2], and A. de Miguel[1]

Measurements of total and diffuse spectral UV irradiance, cloud optical thickness (COT), liquid water path (LWP), cloud effective radius (r_{eff}), cloud base and top heights, columnar ozone and spectral aerosol optical depth are used, together with radiative transfer simulations, to evaluate the spectral cloud transmittance or cloud modification factor (CMF) for the total and for the diffuse components under overcast conditions. The observations were carried out during a 2-month measurement campaign held in May and June 2010 at the ENEA-Trisaia Research Centre (40.16ºN, 16.64ºE, 40 m a.s.l.), in Southern Italy.

The total and diffuse UV irradiances were measured by an Ultraviolet Multifilter Rotating Shadowband Radiometer (UV-MFRSR) at seven narrowband channels. The HATPRO (Humidity And Temperature PROfiler) microwave radiometer allowed to derive the cloud LWP. With the spectral irradiance measurements by a visible MFRSR, COT and r_{eff} are derived, using the cloud LWP (Min and Harrison, 1996). Cloud top and base heights were measured by a LIDAR.

The spectral cloud transmittances (for the total and the diffuse components) of two cases with overcast conditions at the same solar zenith angle (SZA) are plotted in Figure 1. The two cases only differ in the cloud properties, i.e., the COT, LWP and r_{eff} values. Previous studies (e.g., Kylling *et al.*, 1997; Mateos *et al.*, 2011) showed that the total CMF decreases with wavelength above 315-320 nm and increases at shorter wavelengths (280-315 nm). These results for the total component were confirmed by the measurements of the campaign (see solid lines of figure 1). Conversely, the CMF of the UV diffuse irradiance component increases with wavelength throughout the spectral interval (the CMF depends also on SZA, not shown here), significantly different from the total CMF.

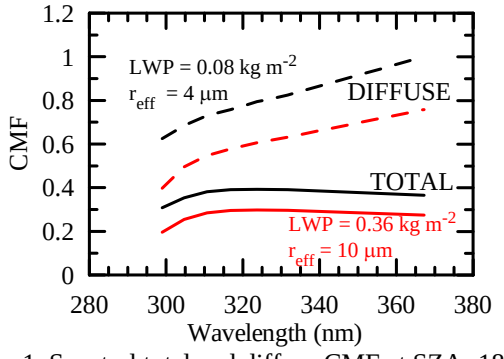

Figure 1. Spectral total and diffuse CMF at SZA=18º for overcast conditions with different LWP and r_{eff}.

A specific case was analyzed with the aim of understanding the aerosol impact on total and diffuse CMF comparing measurements and model simulations. The case study case presents an aerosol layer below the cloud during a desert dust event. The COT was 30, and the aerosol optical depth at 550 nm was 0.2. The radiative transfer model libRadtran was initialized with all the available measurements. The model reproduced both the experimental total and diffuse CMF within ±5% at all wavelengths. Varying the aerosol optical properties (single scatting albedo and asymmetry factor) did not significantly affect the total CMF, while did not allow the model to reproduce diffuse CMF within the same uncertainty range. Figure 2 shows the ratio of the spectral modelled and measured diffuse CMF as a function of the aerosol type.

This study highlights the need of an adequate characterization of the aerosol optical properties under cloudy conditions, if the effects on the diffuse component have to be analyzed.

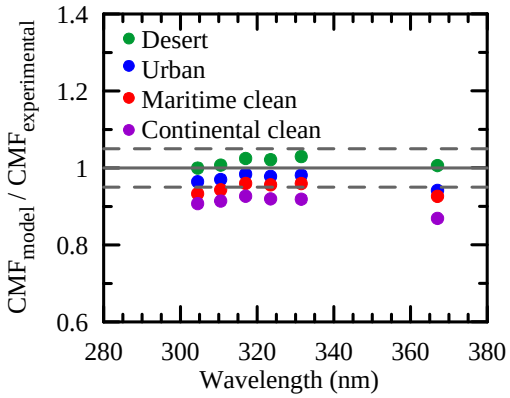

Figure 2. Ratio between modelled and experimental spectral diffuse CMF for different aerosol types.

It is known that both the size and chemical composition of aerosol particles affect cloud droplet activation (Dusek *et al.* 2006). Effect of particle size is already well known but the role of chemical composition is not yet completely understood. Some field studies have already been done (e.g. Drewnick *et al.* 2007) but more research is needed.

The Puijo measurement station has provided continuous data on aerosol-cloud interactions since summer 2006. The station is located on top of the Puijo observation tower (306 m a.s.l, 224 m above the surrounding lake level) near the town of Kuopio, Finland in a semi-urban environment (Portin *et al*, 2009). The top of the tower is covered by cloud about 15 % of the time, offering perfect conditions for studying aerosol-cloud interactions. With a special inlet setup (total and interstitial inlets) and a switching valve system we are able to separate the activated particles from the interstitial (non-activated) particles. The continuous twin-inlet measurements include aerosol size distribution (differential mobility particle sizer, DMPS), light scattering (nephelometer) and absorption (absorption photometer) (Leskinen *et al.* 2012). Activation properties of these parameters are retrieved continuously. In addition, cloud droplet size distribution is observed continuously with a cloud droplet probe (CDP) as well as weather parameters.

In autumns 2010 and 2011 intensive measurement campaigns were performed at the tower, during which the twin-inlet system was additionally equipped with aerosol mass spectrometer (AMS) and Single Particle Soot Photometer (SP-2). This way we were able to define the differences in chemical composition of the activated and non-activated particles. Other additional measurements included Hygroscopic Tandem Differential Mobility Analyzer (HTDMA) for particle hygroscopicity. Potential cloud condensation nuclei (CCN) in different supersaturations were measured with two CCN counters (CCNC). The other CCNC was operated with a Differential Mobility Analyzer (DMA) to obtain size selected CCN spectra. The full usage of this special data set will provide new information on the properties and differences of activating and non-activating aerosol particles.

In total, 38 cloud events took place during the campaigns, varying between 1-31 hours in duration. An example of the particle size distribution data from the twin-inlet system during a cloud event is shown in fig. 1. In this case, average out-of-cloud particle number concentration during the event was 820 cm^{-3}. Particles larger than 80 nm in diameter already form cloud droplets, and the diameter where 50 % of particles are activated (D_{50}), is 156 nm. For 400 nm particles, already 95 % are activated. Mean concentration difference between the sampling lines during this event was 230 cm^{-3}, representing the mean number concentration of activated particles. By comparing these activation data from different cloud events with AMS data, it is possible to get valuable information about the role of particle chemical composition in cloud droplet activation.

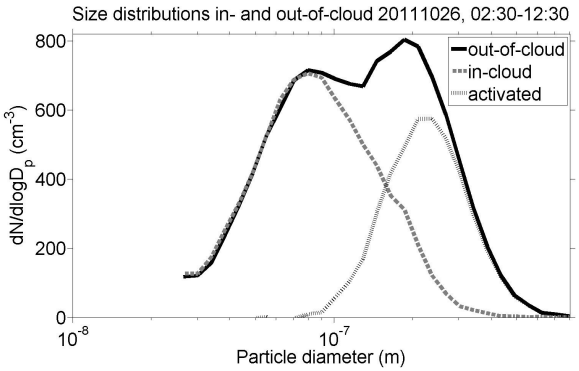

Figure 1. Example of cloud droplet activation during a cloud event. Mean size distributions during the event for out-of-cloud, in-cloud and activated particles are shown.

Experimental study in situ conditions of below-cloud scavenging of aerosol particles

G. Depuydt[1], O. Masson[1], J.L. Brenguier[2], P. Boissery[3]

[1]IRSN/PRP-ENV/SESURE/LERCM, Cadarache, BP3, 13115 St Paul lez Durance, France

Keywords: scavenging, wet removal, aerosol size distribution, in-situ measurements

Removal of atmospheric aerosols by the below-cloud scavenging is a wet deposition process particularly fast and efficient. This interaction between aerosols and raindrops is characterized by the washout coefficient Λ, which can be estimated from the temporal evolution of the size distribution of aerosols during rainfall events and macro-physical characteristics of this event (event duration, rain amount, rainfall intensity ...).

Up to now, few studies have defined below-cloud scavenging of particles from direct measurements of aerosol size distribution variations due to precipitation (Volken and Schumann, 1993; Laakso *et al.*, 2003). The large discrepancies noted between theory and field observations (Wang *et al.*., 2011) show the need to perform experimental in-situ studies of below-cloud scavenging in various environments.

For several months, two types of instruments were installed on sites in France having different features in terms of dust levels and climatic conditions, to have the largest scale of environmental conditions. A laser disdrometer PARSIVEL (for PARticule SIze and VELocity) measured hydrometeors size between 0.2 and 25mm and falling speed from 0.2 to 20m.s^{-1}. Particles were counted with an optical spectrometer with measuring range of 0.25 to 32µm or a wide range spectrometer (5nm to 32µm) depending on the site. Coupling of these two types of instruments allowed us to measure simultaneously, with high precision and short time interval, raindrops or snowflakes characteristics and aerosol size distributions during many various precipitations.

Washout coefficients (Λ) were calculated using the following formula :

$$\Lambda(D_p) = \frac{1}{\Delta t} \ln\left[\frac{c_0(D_p)}{c_1(D_p)}\right]$$

where Δt is the duration of precipitation, D_p the particle diameter, and c_0 and c_1 the concentration of particle respectively before and after precipitation.

Washout coefficients for each particle diameter have been calculated, and a typology of precipitation has been established according to their washout potential. Figure 1 is an illustration for one site of the mean washout coefficient vs. particle diameter accounting for data belonging from 20 to 80 different rain events. Dependence of washout coefficient with rainfall intensity has been estimated. Results were compared with previous experiments or theoretical models, and discussed.

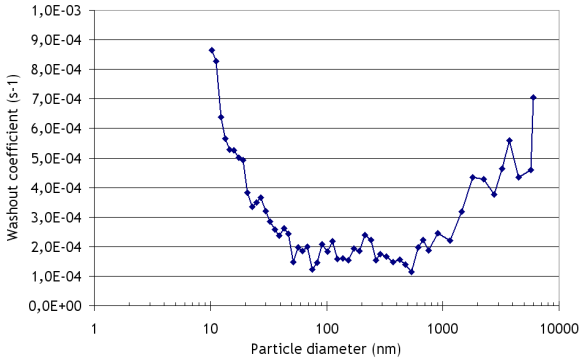

Figure 1. Washout coefficient vs. particle diameter (data of one site)

Identifying cloud processed aerosol particles with light depolarization

D. Baumgardner[1], R. Newton[2], O.L. Mayol-Bracero[3], C.J. Valle-Diaz[3], F. Zurcher[3], S. Mertes[4]

The interaction of aerosols and clouds is a complex process during which some aerosol particles form cloud droplets and crystals while others may be scavenged by diffusion or inertial collisions. The result of these interactions is often to transform the properties of the aerosol population such that after cloud processing the physical, optical and chemical characteristics are significantly different.

In an effort to better understand how cloud processing alters aerosol particle properties, an Aerosol Particle Spectrometer with Depolarization (APSD) was operated on Pico Este of Puerto Rico from August 19 to September 11, 2011 during the Puerto Rico African Dust and Cloud Study (PRADACS), attached to an inlet that selectively sampled interstitial aerosols or cloud droplet residuals derived from a Counterflow Virtual Impactor (CVI).

The APSD, developed by Droplet Measurement Technologies (DMT), measures the size distribution of aerosols between 0.5 and 20 µm and can distinguish the degree of asphericity or roughness of particles based upon the amount of depolarization caused by individual particles. An optical shape factor is derived by comparing backscattered light, from individual particles, measured with two detectors, one with and one without filters to detect the degree of depolarization.

As shown in Figures 1 and 2, the shape factor to optical diameter relationship is quite different depending on the source of the air mass and whether the particles are ambient (no cloud), droplet residual (CVI) or interstitial. Figure 1 shows the shape to size relationship for all periods when the air was coming from the islands upwind and southeast of Puerto Rico and Figure 2 are averages during a two day African dust event. The dashed lines show the shape to size relationships from reference particles measured in the laboratory.

From Fig. 1 we conclude that:

- Particles in SE flow look more like urban dust.
- Cloud residues have larger shape factors than cloud free particles.
- Particles > 5 µm during no cloud look like Azores (island) dust
-

From Fig. 2 we conclude that:

- Particles in SE flow + African dust look more like mixtures of urban and Azores dust.
- No interstitial particles > 5 µm (cloud removal?)
- Particles > 3 µm during no cloud look like pollen (biological?)

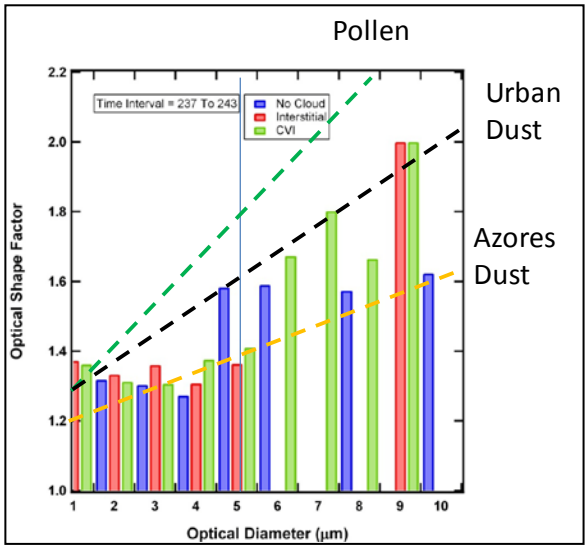

Figure 1. This graph shows how the average shape factor varies with optical diameter when air arrives at the mountain from the SE.

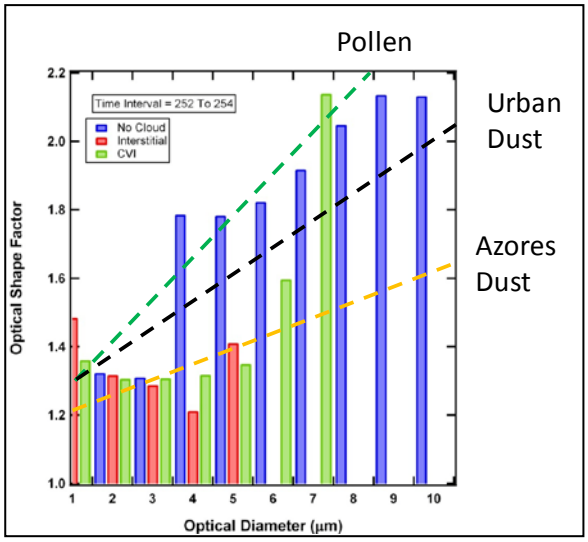

Figure 2. This graph shows how the average shape factor varies with optical diameter when air arrives at the mountain carrying African dust.

Inhibition of Heterogeneous Ice Nucleation of Mineral Dust Particles Exposed to Ozone

Aerosols can cool or warm the atmosphere directly via interaction with incoming solar radiation (aerosol direct effect), or via their ability to act as cloud condensation or ice nuclei (IN) and thus play a role in cloud formation (indirect effect). The physical properties of aerosols such as size and solubility as well as chemical composition can influence their behavior and fate in the atmosphere. Ice nucleation is known to be especially sensitive to surface properties. Ice nucleation taking place via IN is termed as heterogeneous ice nucleation and can take place via deposition (ice forming on IN directly from the vapor phase), condensation/immersion (freezing via formation of the liquid phase on IN) or condensation (IN colliding with supercooled liquid drops).

Motivation for quantifying ice formation in the troposphere is many-fold. First, to understand the hydrological cycle since ice is the primary initiator of precipitation forming clouds. Second, the tropospheric budget of water vapour, an especially active greenhouse gas is strongly influenced by ice nucleation and growth. Third, ice surfaces in the atmosphere act as heterogeneous surfaces for chemical reactions of trace gases (e.g., SO_2, O_3, NO_x). Being able to quantify ice formation rates and ice surface concentrations allows an accurate calculation of trace gas budgets in the troposphere. This work addresses how mineral dust particles chemically aged from O_3 exposure influence deposition and immersion mode freezing under tropospherically relevant temperature (**T**) and relative humidity (**RH**) conditions.

Ice nucleation measurements were conducted using home-built chambers of the thermal gradient continuous flow diffusion principle capable of measuring immersion freezing (Lüönd *et al.*, 2010) (IMCA) and deposition freezing (Stetzer *et al.*, 2008) (PINC). In IMCA an ice optical depolarization detector was used to discriminate between frozen and liquid drops, whereas an optical particle counter was used to detect ice crystals in PINC. Poly-disperse samples of sub-micron diameter kaolinite and Arizona test dust were aerosolized in a stainless steel chamber and allowed to age for 15 – 90 minutes in known amounts of O_3 in the range 0.4 – 4 ppmv under dark conditions at ~298K. Destruction of O_3 was observed due to initial rapid decline of concentrations beyond background decay upon addition of dust particles to the aerosol tank. Deposition and immersion mode freezing experiments were conducted for both particles exposed to O_3 and unexposed particles.

Results for deposition mode freezing of kaolinite particles at RH_i = 130% are shown in Figure 1. It is observed that exposure to low levels of O_3 marginally enhance the ice active fractions as function of T. In contrast, when high O_3 concentrations are used for the ageing process, the ice active fractions are significantly repressed.

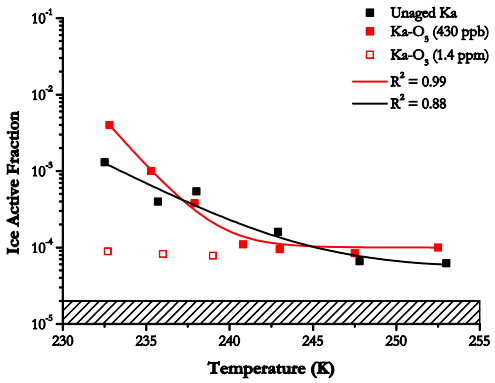

Figure 1. Ice active fraction as a function of T for kaolinite particles quoted at RH with respect to ice of 130%. The hashed region indicated the instrument background.

Ozone is known to react at surface sites of mineral dusts, including kaolinite (Karagulian and Rossi, 2005) to produce oxygenated surface species. It is possible that these surface species lower energies of ice germ formation for ice nucleation on the kaolinite surface. In contrast, when higher O_3 concentrations are used, the active surface species are chemically destroyed or physically occupied by adsorbed O_3, therefore making active sites for ice nucleation unavailable. Similar trends in ice nucleation behavior were observed for immersion freezing.

The results imply that mineral particles exposed to low ozone concentrations for longer periods of time in the atmosphere could have a significantly different ice nucleation behavior depending on the particle history compared to untreated particles typically used in laboratory measurements. These are the first results to show an inhibition of freezing in the immersion mode due to chemical ageing of aerosol particles.

Aerosol activation behaviour in liquid-phase clouds at the Jungfraujoch: A comparison of in-situ measurements and box modelling data

Aerosols cause a radiative forcing directly through absorption and scattering of solar and infrared radiation in the atmosphere but also indirectly by modifying the properties of clouds. However, climate models still suffer from large uncertainties as a result of insufficient understanding of aerosol-cloud interactions.

An important parameter is the critical supersaturation, SS_{crit}, at which a particle forms a cloud droplet. SS_{crit} is described by the Köhler theory and depends on the particle's dry size and chemical composition. At ambient conditions, the prevailing supersaturation determines the activation diameter of the particles (i.e. the cut-off dry diameter above which all particles are able to act as cloud condensation nuclei, CCN, at a given supersaturation). We define the highest supersaturation that a particle experiences in an ambient cloud, leading to the formation of the cloud droplet, as the effective peak supersaturation (SS_{peak}). Since a higher updraft velocity results in a faster cooling of the surrounding air, this parameter is also dependent on the updraft velocity. To date no measurement device is available that is able to measure SS_{peak} within a cloud. Thus, the cloud peak supersaturation has to be retrieved indirectly from other measurements (e.g. Fors et al., 2011).

In summer 2010 and 2011, the Cloud and Aerosol Characterization Experiments (CLACE) were conducted at the high alpine research station Jungfraujoch (JFJ; 3580 m asl, Switzerland). Two different inlet systems were used to collect the total and interstitial aerosol separately. The in-cloud activation diameter was determined by comparing total and interstitial particle number size distributions. SS_{peak} was then inferred by comparing the in-cloud activation diameter with the supersaturation dependence of the activation diameter measured in parallel for the total aerosol using a CCN counter (CCNC) measuring at the JFJ (Jurányi et al., 2011).

The above approach yielded SS_{peak} values between 0.13% and 0.99% (10th and 90th percentile). While air masses coming from the north showed a wide range of values, SS_{peak} values for air masses coming from the south were more constant at around 0.2% (see Figure 1). This can most likely be explained by the different topography between south and north of the JFJ resulting in different cloud updraft velocities and thus higher cooling rates and higher SS_{peak} values.

The simulated influence of particle number concentration and size distribution on the SS_{peak} as a function of updraft velocity is currently being investigated in detail with a cloud box model. First results from a sensitivity study of the model show that SS_{peak} in convective clouds is strongly dependent on the accumulation particle number concentration. Hence, the difference in the SS_{peak} with air masses coming from south and north can to some extent also be explained by the difference in particle number concentration, additionally to the difference in topography.

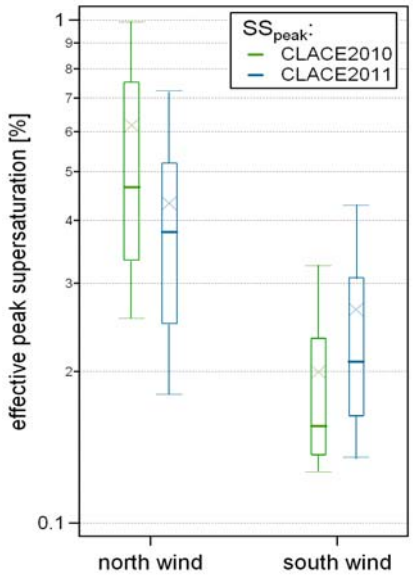

Figure 1. Effective peak supersaturation values distinguished by north and south wind conditions for CLACE2010 and 2011.

Currently, the model results (origin of cloud activation) are being validated with water isotope measurements from a Picarro H_2O isotope instrument provided by the Climate and Environmental Division of the Physics institute from the University of Bern.

This work was supported by MeteoSwiss in the framework of the Global Atmosphere Watch program. We thank the International Foundation High Altitude Research Stations JFJ and Gornergrat for the opportunity to perform experiments on the Jungfraujoch.

Keywords: SOA, Aerosol Coating, AMS, CCN
Presenting author email: agot.watne@chem.gu.se

Mixed organic-inorganic particles will have different cloud condensation nuclei (CCN) properties compared with pure particles. In order to predict and represent the effect these mixed particles will have on cloud formation and climate, an accurate description of how changed organic mass loading of will affect the CCN properties is needed. The CCN properties and composition of mixed organic-sulphate particles were investigated in the Göteborg-Flow Reactor for Oxidation Studies at low Temperatures (G-FROST). The G-FROST facility has already shown to be valuable in studying properties and formation of pure SOA (e.g Jonsson et al., 2006; Jonsson et al., 2008). G-FROST is a laminar flow reactor where secondary organic aerosol (SOA) is produced under well-controlled conditions.

Mixed organic-sulphate particles were produced by condensation of secondary organic material (SOM) from dark ozonolysis of a SOA precursor on polydisperse inorganic seed particles. The CCN property of mixed organic-sulfate particles was measured as the supersaturation at which 50 % of the particles were activated as cloud droplets (SS_{50}) by a cloud condensation nuclei counter (CCNC, Droplet Measurement Technology DMT-100). The composition of the particles was measured by an aerosol mass spectrometer (AMS, Aerodyne Research Inc High-Resolution Time of Flight Aerosol Mass Spectrometer). The AMS and CCNC sampled monodisperse particles, size-selected by a Differential Mobility Analyser (DMA, TSI 3071), from the flow reactor. In each experiment, SS_{50} and composition was determined for 50, 75, 100 and 125 nm particles. In total six experimental conditions were carried out, see Table 1.

Table 1: List of experiments with corresponding conditions. Flow reactor kept constant at 298 K and at 30% RH.

	SOA precursor	Inorganic Seed	Ozone (ppb)
I	α-pinene	$(NH_4)_2(SO_4)$	500
II	Limonene	$(NH_4)_2(SO_4)$	500
III	Limonene	$(NH_4)(SO_4)$	4000
IV	Limonene	$(NH_4)_2(SO_4)$*	500
V	Limonene**	$(NH_4)_2(SO_4)$	500
VI	Limonene	NH_4HSO_4	500

*Seed particles were dried up-streams the flow reactor.
**2-butanol was used as OH scavenger.

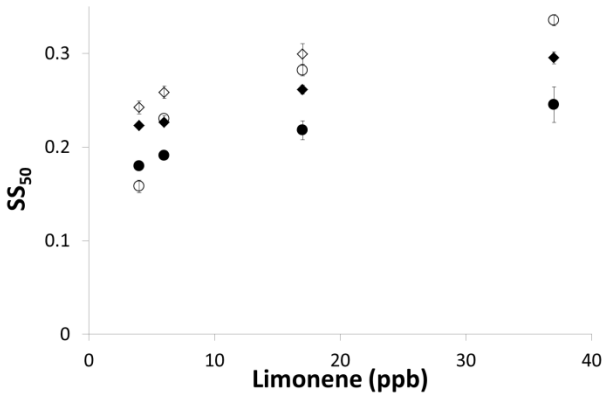

Figure 1: The SS_{50} for 100 nm particles in experiment II (open circle), III (open diamond), IV (closed circle) and VI (closed diamond) for 4, 6, 17 and 37 ppb of limonene.

Figure 1 shows the SS_{50} for 100 nm mixed organic-sulfate particles for four concentrations of limonene in four experiments. As can be seen, particles coated at higher limonene concentration were harder to activate compared to lower limonene concentrations. Furthermore, the 100 nm particles coated at high ozone concentration was harder to activate compared with lower ozone concentration. Interestingly, at high ozone concentration no activation of the 100 nm particles was seen for the highest limonene concentration.

These results demonstrated that the G-FROST facility, with its possibility to control and vary the conditions in the flow tube, combined with AMS and CCNC is a valuable tool in investigating the CCN properties of mixed organic-sulphate particles.

Mixed-phase clouds observations at Pallas subarctic background site

D. Brus[1,2], K. Neitola[1], J. Svensson[1] and H. Lihavainen[1]

[1]Finnish Meteorological Institute, Erik Palménin aukio 1, P.O. Box 503, FI-00101, Helsinki, Finland

Keywords: mixed-phase clouds, arctic, CAPS
Presenting author email: david.brus@fmi.fi

The Arctic region is slowly heading towards a new climatic state with substantially less permanent ice cover. The Arctic environment is very specific and full of not very well understood feedbacks, thus very hard to be predictable with current global models. Central role in these feedback processes are supposed to play Arctic clouds (Vavrus, 2004).

The winter cloud experiment has been conducted in first week of February 2012 at Finnish Meteorological Institute's Pallas-Sodankylä Global Atmosphere Watch (GAW) station located in northern Finland. The measuring site - Sammaltunturi station (67°58′N, 24°07′E) - resides on a top of the second southernmost fjeld, a round topped treeless hill, in a 50-km-long north and south chain of fjelds at an elevation of 565 m above sea level. Sammaltunturi station is due to topography of the surrounding terrain a great place for ground-based observations of orographic clouds. Thus providing an opportunity to investigate not only the cloud droplet activation of aerosol particles but also directly the cloud particle phase (Komppula *et al.*, 2005).

The Cloud, Aerosol and Precipitation Spectrometer (CAPS, DMT, CO, USA) which includes three instruments: the Cloud Imaging Probe (CIP), the Cloud and Aerosol Spectrometer (CAS) with depolarization, and the Hotwire Liquid Water Content Sensor (Hotwire LWC), were used in this campaign together with Cloud Condensation Nuclei counter (CCN-100, DMT, CO, USA) and Hygroscopic Tandem Differential Mobility Analyser (HTDMA). The CAPS probe was equipped with tailored inhalator to make it suitable for ground-based measurements. The average airspeed in the system was approximately 22 ms^{-1}. The shattering (Schwarzenboeck *et al.*, 2009) and thus overestimation of the concentrations of ice crystals obtained with the CIP probe is not expected to be observed.

Through the one week of intensive campaign five arctic cloud or freezing fog events lasting several hours were observed. The maximum and minimum temperature during the campaign was between -14 and -27°C. The maximum droplet concentrations were observed up to 100 cm^{-3} and 400 cm^{-3} for CIP-Greyscal probe and CAS-DPOL probe, respectively. Liquid water content was observed up to 1.5 g m^{-3}.

Figure 1 shows overlap of number concentration distributions obtained with CAS-DPOL and CIP-Greyscale probes in a range 0.5 μm – 1 mm. Images taken by CIP probe show both small spherical super-cooled drops together with larger irregular particles, figure 2.

The next step of the analysis will include all available experimental data on cloud particles together with physical and chemical properties, and activated fraction of aerosol particles (CCN and HTDMA).

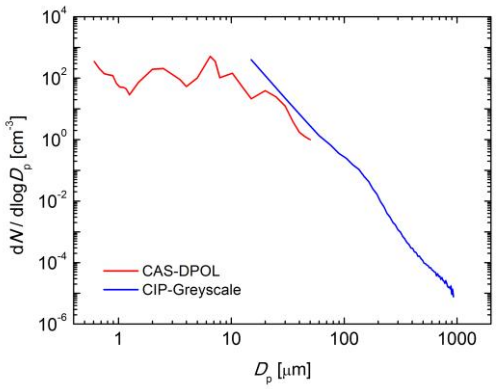

Figure 1. Example of raw size distributions obtained with CAS-DPOL and CIP-Greyscale probes during the campaign at Sammaltunturi, between 01:50-02:30, February 1st 2012.

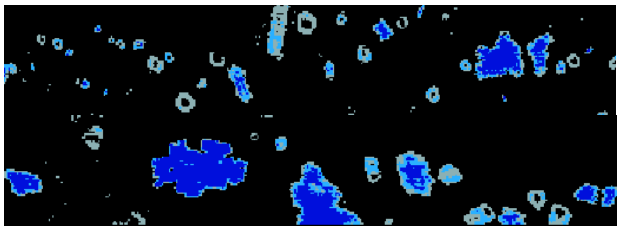

Figure 2. Example of image taken with CIP-Greyscale probe, particle sizes found on the picture are between 25-850 μm.

One of the most important uncertainties affecting the climate models are the processes related with cloud-aerosols interactions. The aerosols act as cloud condensation and ice nuclei, so they can modify the clouds in many ways. Thus it is essential to account with an accurate database of microphysics cloud and aerosols properties. The Canary Islands are located in one of the most important marine stratocumulus regions in the world. The orography of some of these islands allows us to locate a suitable station to establish long-term programs to measure the main mechanisms in cloud-aerosol interactions. With these aims, a new ground-based station has been installed in the North-East part of the Tenerife Island, Friolera Peak Lab. (28°33'1.16"N, 16°12'1.79"W, 720 masl). The main objectives for measurements programs taking place in this station are:

1.- Development of a measurements program with high-standard QA/QC requirements to obtain long-term time series.

2.- Study of the interrelations of the cloud properties with main aerosols types arriving to this region: marine, desert and anthropogenic aerosol from Europe.

3.- Estimation of the role of the marine stratocumulus in the energy budget

4.- Validation of satellite products with the data of microphysical properties made in this station.

In a first step two instruments have been installed: a FM100/DMT and an UFP 3031/TSI. The FM100 is a robust cloud-particle spectrometer, and allows for computation and real-time display of particle concentration, median volume diameter, equivalent diameter, and liquid water content. The UFP 3031 provides continuous size distribution and number concentration of particles between 20 and 850 nm, with six channels of size resolution: 20-30 nm, 30-50 nm, 50-70 nm, 70-100, 100-200 nm and 200-850 nm. It is an instrument specially designed for long-term monitoring with minimum maintenance.

The first results obtained are presented showing that this station is situated in a very clean environment, with values for the number of ultrafine particles lower than 1000 particles/cm^3 adding the six channels. An exception for this rule is clear when Saharan dust outbreaks reach the island. Thus it was recorded peak values that exceed the 20000 part/cm^3 during the last dust invasion in the second week of this year. Moreover, in cloudy conditions and a trade winds regime we observed for a minimal concentration of 300 droplets per cm^{-3}, an effective diameter of these droplets about 10 μm. The continuous monitoring of these parameters in a long term schedule will permit to analize any impact of climate change on processes related with the interaction cloud-aerosols.

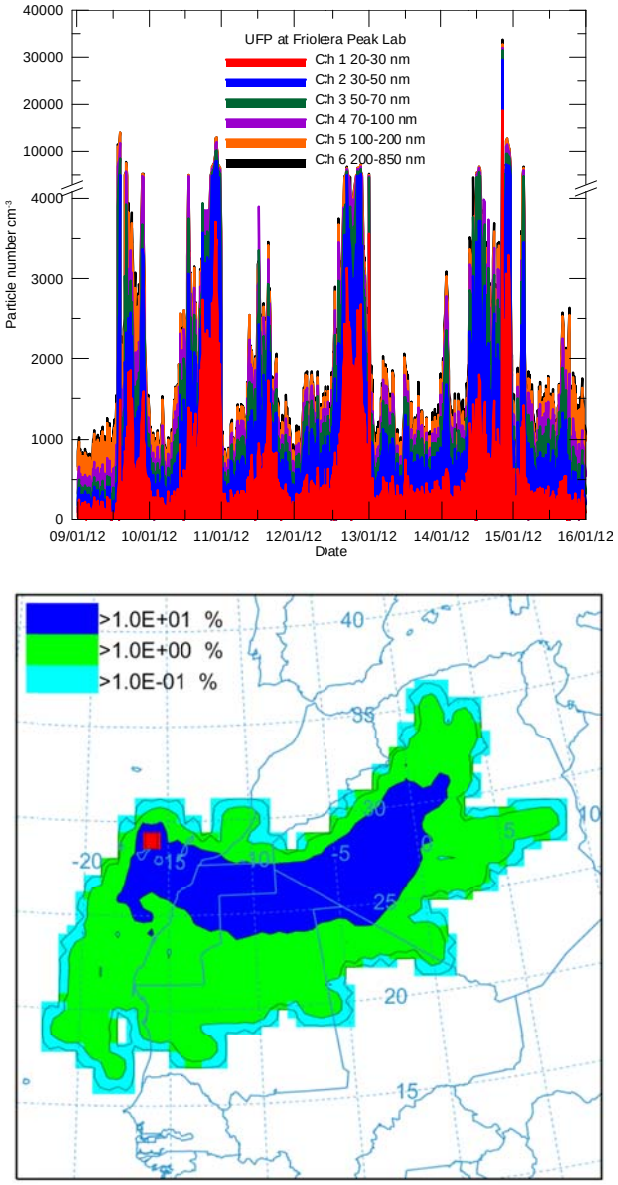

Figure 1. Particle concentration (upper) and frequency of backtrajectories (lower) during a Saharan dust invasion on January 09-16, 2012 recorded at Friolera Peak Lab.

Combustion Particles as Ice Nuclei in an Urban Environment: Evidence From Single-Particle Mass Spectrometry

J.C. Corbin[1,2], P. J. G. Rehbein[2], G. J. Evans[2] and J.P.D. Abbatt[1]

[1]Department of Chemistry, University of Toronto, 80 St George St, ON, Canada
[2]Southern Ontario Centre for Atmospheric Aerosol Research, University of Toronto, 200 College St, Canada

The subset of atmospheric particles that trigger heterogeneous ice nucleation in the atmosphere can strongly influence the ice-crystal concentrations of cirrus and mixed-phase clouds. These particles, termed ice nuclei (IN), may catalyze ice formation under conditions ranging from a few degrees of supercooling down to about 237 K, below which a rapid increase in the rate of homogeneous ice nucleation renders heterogeneous nucleation less significant (Pruppacher and Klett, 1996). IN number concentrations affect cloud crystal size, number and shape, thereby influencing cloud precipitation and lifetime. However, the significance of IN to Earth's climate remains uncertain.

IN may trigger freezing from the vapour phase (deposition freezing), after immersion within liquid water (immersion freezing), or upon the collision of an IN with the surface of a liquid droplet (contact freezing). Aerosols that may contain IN include mineral dust, soot, biological material, and effloresced salts. Anthropogenic activity may affect the concentration of some of these IN via either direct emission, or the emission of precursors which may deposit upon pre-existing IN. However, most recent field studies have focused on relatively pristine environments, and the relative importance of anthropogenic IN is uncertain.

Direct measurements of the chemical composition of IN are a valuable tool for identifying potential IN sources. In this study, such measurements were made by activating IN to form ice crystals, using a counterflow virtual impactor to separate the ice crystals from background aerosol, and subsequently characterizing the evaporated crystals using a single-particle mass spectrometer (SPMS) (Cziczo et al., 2003). This CVI-SPMS technique provides valuable information on both the internal composition of IN and their external mixing state.

In this work, the CVI-SPMS technique was employed in the urban centre of Toronto, Canada, during winter 2011. The University of Toronto Continuous-Flow Diffusion Chamber (CFDC, Kanji and Abbatt, 2009) was used to activate IN before their introduction into a pumped counterflow virtual impactor (PCVI), followed by their chemical characterization using a TSI Aerosol Time-Of-Flight Mass Spectrometer (ATOFMS).

The CFDC was operated at 239 ± 1 K, 134 ± 2% RH_i (96 ± 2% relative humidity with respect to water, RH_w), under which conditions the chamber remains just below the experimentally-determined homogeneous freezing and droplet activation limits. Thus a maximal number of IN are activated under "deposition mode" conditions, although some degree of water was likely adsorbed to particle surfaces.

The number concentrations of particles measured by the CVI-SPMS at high RH_i (134%) and low RH_i (<105%) were compared to account for leakage by the PCVI. Single-particle mass spectra from the CVI-SPMS were sorted into 7 categories: dust, EC (elemental carbon), BB (biomass burning), metal-rich organic carbon (M/OC), potassium-rich OC (K/OC), OC potentially mixed with EC (OC/EC), and "unclassified." The resulting ratios, shown in Figure 1, were greater than unity for EC, BB, and dust particles. However, only the increase in EC was statistically significant (1 σ level) due to a low number of detected particles.

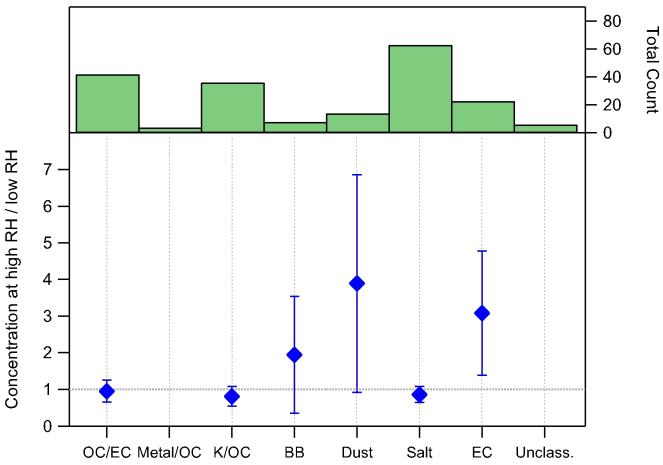

Figure 1. ***Upper panel:*** **Total numbers of particles measured by the CVI-SPMS at both high and low RH_i.** ***Lower panel:*** **Ratio of particle concentrations at 138% versus < 105% RH_i over ~35 measurement hours. No enhancement for metal/OC or unclassified particles is shown due to insufficient data. Error bars show one standard deviation.**

Finally, to complement the direct PCVI observations and enhance the number of spectra available, a second study was performed where particle composition and IN concentrations (C_{IN}) were measured in parallel. Backward elimination regression of C_{IN} against the same categories as above identified dust, BB and EC particles as the best C_{IN} predictors. Consistency between these two methods provides increased confidence in their individual results and encourages additional study of these potential IN.

Atmospheric aerosol can act as cloud condensation nuclei (CCN) to affect the amount of cloud on the earth and thus global climate. Such aerosol-cloud interactions comprise the largest uncertainties in our understanding of human-caused climate change. The composition of aerosol plays an important role determining its CCN activity. Thus direct and long-term observations of effects of chemical composition of aerosol on aerosol-cloud interactions are especially welcomed.

One campaign for the observation of cloud events was carried out in a aerosol-cloud interaction observation station in Kuopio, Finland in 2010 (Leskinen et al., 2009). We have succeeded to measure one intensive cloud event in this campaign. An Aerodyne high resolution aerosol time-of-flight mass spectrometer (TOF-AMS) was used to measure the chemical composition of cloud particles. During the cloud event, AMS sampled through two sampling lines: One is PM1.0 line. Samples from this line provides the chemical information of inactivated particles (cloud interstitial particles); The other is PMtot line, which collected all particles, presenting the information of cloud interstitial plus residual particles. We also applied positive matrix factorization (PMF) analysis to track the aerosol origin (Ulbrich et al., 2009).

Figure 1 displays the observation of cloud event along with meteorological conditions. There are several features shown in this figure: (1) wind direction and speed are roughly constant during cloud event, which can be roughly assumed the aerosol source to be constant, so does the chemical composition. Upon this assumption the information of cloud residual can be derived from the difference of PMtot to PM1.0 lines; (2)ratio of measured ammonia to predicted (orange curve) follows the trends of black curves and (3) the ratio of NO/NO_2 ions ($R_{NO/NO2}$, blue curve) shows an opposite trends to the orange curve.

Variations of $R_{NO/NO2}$ are able to indicate the nitrate origin. $R_{NO/NO2}$ for NH_4NO_3 is around 2.5 and much higher for organic nitrate. In this study, $R_{NO/NO2}$ from PMtot line is 4.7 and 3.7 for PM1.0 line during cloud event. Deconvolution of organic matrix plus NO/NO_2 ions extracts out ammonia nitrate factor and other four organic factors. The derived organic nitrate accounts for 27.7% of total nitrate for the cloud interstitial plus residual particles, 47.7% for cloud interstitial particles and 21.1% for cloud residual particles.

Contents of organic nitrate can further be estimated from AMS measurements. Assuming the possible contributions to nitrate included only organic nitrate and NH_4NO_3 in this campaign, we have:

$$NO_{org}+NO_{inorg}= NO_{tot} \quad (1)$$
$$NO_{2,org}+NO_{2,inorg}= NO_{2,tot} \quad (2)$$
$$NO_{org}/NO_{2,org}=10 \quad (3)$$
$$No_{inorg}/NO_{2,inorg}= 2.8 \quad (4)$$

where NO_{tot} and $NO_{2,tot}$ are from AMS measurement. From (1)-(4), we can estimate organic and inorganic nitrate fraction:

$$\text{Organic nitrate}=NO_{org}+NO_{2,org} \quad (5)$$
$$\text{Inorganic nitrate}=NO_{inorg}+NO_{2,inorg} \quad (6)$$

Based on this method, the estimated organic fraction to total nitrate is 48.1% for cloud interstitial particles and 22.6% for cloud residual, which are very close to the PMF deconvolution results.

Ratio of measured NH4 to predicted shows much lower values in PM1.0 lines, where the predicted $NH_4=18*(2*SO_4/96+NO_3/62+Chl/35.5)$. Much lower values in PM1.0 line indicated the higher fraction of NH_4HSO_4 in the cloud interstitial particle than in cloud residual particles.

A new ice selective inlet for the characterization of the atmospheric ice phase

P. Kupiszewski[1], P. Vochezer[2], M. Schnaiter[2], E. Weingartner[1]

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland
[2]Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology (KIT), D-76021 Karlsruhe, Germany

Keywords: ice nucleation, mixed-phase clouds, CLACE 2013
Presenting author: ernest.weingartner@psi.ch

Uncertainties in climate projections are largely due to an insufficient understanding of aerosol-cloud interactions. One particularly poorly understood process is formation of mixed-phase clouds, where ice nuclei (IN), an aerosol sub-population, facilitate heterogeneous ice nucleation. IN influence the ice mass fraction, strongly affecting cloud radiative properties and lifetime. Meanwhile, the physico-chemical characteristics of IN in ambient mixed-phase clouds and the anthropogenic contribution to IN are not well known. Field studies of IN are hampered by difficulties with sampling the chemically complex ice residuals and separating them from liquid droplets.

A new Ice Selective Inlet (ISI) (Figure 1) is currently being developed. It is based on the design of an existing inlet (Mertes *et al.*, 2007) with the vital difference that the liquid droplets are separated from ice crystals in their airborne state via evaporation and thus minimizing artifacts like ice crystal breakup. Interstitial particles are removed by a pumped counterflow virtual impactor, ensuring only ice crystals remain in the sample air stream. The small crystals are evaporated and their residuals (considered representative of original IN) are transferred into the lab for physico-chemical analysis with state of the art instrumentation (e.g. AMS, SP2, SMPS).

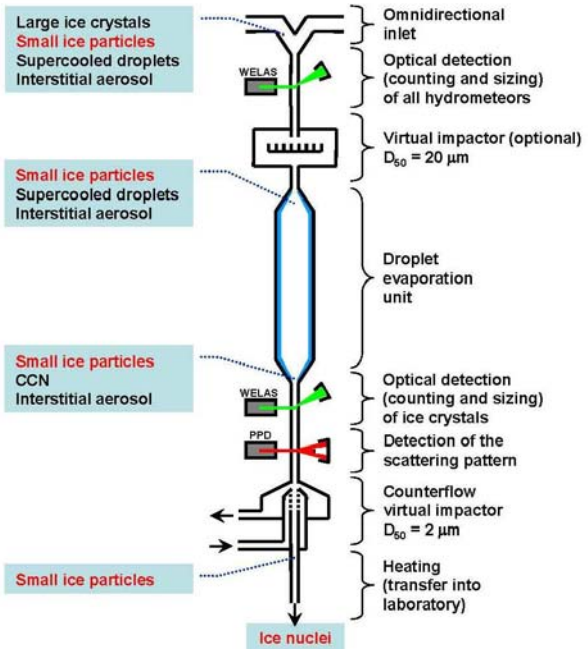

Figure 1. A schematic of the Ice Selective Inlet (ISI)

The new design includes an evaporation unit with ice-covered inner walls causing droplet evaporation using the Wegener-Bergeron-Findeisen process. The design is based on calculations of droplet evaporation rates (Figure 2), to allow for sufficient residence time of droplets to evaporate from a diameter of 20 µm (upper size limit of particles set by the virtual impactor) to 2 µm (particles smaller than 2 µm are removed by the counterflow virtual impactor).

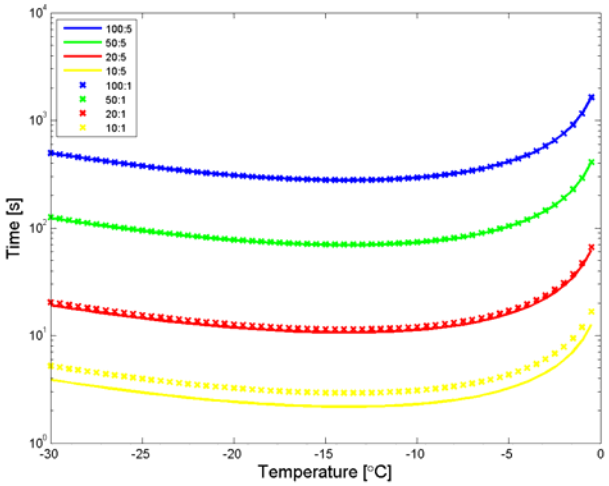

Figure 2. Evaporation times of cloud droplets in the evaporation unit for different droplet start and end diameters (in µm) as a function of temperature.

Optical particle counters are employed before and after the evaporation unit to retrieve information on droplet and ice crystal number size distributions. The ice particle microphysical properties, such as size, habit and surface roughness are inferred based on the scattering pattern measured with the novel Particle Phase Discriminator (PPD2). The PPD2 is also very important for the unambiguous detection of droplets that have survived the evaporation unit.

The inlet will first be tested in supercooled clouds generated at the AIDA cloud chamber at KIT. Subsequently, a field campaign (CLACE 2013) will be conducted at the high alpine Jungfraujoch site (3580 m.a.s.l) in order to characterize IN in ambient clouds.

This work is funded by the Swiss National Science Foundation and the German Research Foundation.

Cloud resolving model simulations of geoengineering of marine stratocumulus cloud by sea salt injections

Z. Maalick[1], H. Korhonen[2] , H. Kokkola[2] , A. Laaksonen[1,3] and S. Romakkaniemi[1]

[1]Department of Applied Physics, University of Eastern Finland, Kuopio, 70211, Finland

Keywords: marine clouds, sea spray, aerosols.
Presenting author email: zubairm@uef.fi

Increase in the brightness of marine clouds through sea spray particles is considered as one of the quickest way to slow down global warming. The modification of marine clouds has received some attention as a relatively inexpensive method of achieving rapid cooling of climate.Hoverer, in most of the previous climate model studies a very high cloud droplet concentration is imposed on the clouds over the world's oceans and concluded that this geoengineering method can counteract warming from up to quadrupled CO_2 concentrations (Latham *et al* 2008).
Recent calculations using global models with size-resolved aerosol representations indicate that previously proposed sea spray producing vessel designs and emission fluxes are unlikely to lead to uniform cloud fields with such high drop concentrations, which may have important implications on the size of the spray vessel fleet required to achieve desired cooling (Korhonen *et al* 2010, Partanen *et al* 2011). Furthermore, in the recent study by Wang *et al* (2011) it was shown that this kind of geoengineering is efficient only in the cases where drizzle formation is suppressed by the increased number of cloud droplets.

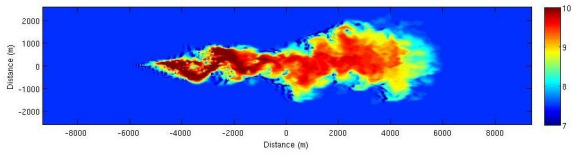

Figure 1. An example of the dispersion of particles emitted from the point source. The colour is logarithm of aerosol particle number concentration.

In this study we will use cloud resolving model UCLALES (Stevens and Seifert 2007) with the aerosol module SALSA (Kokkola *et al* 2007) to study aerosol cloud interactions in a cloud resolving scale. With SALSA we are able to represent aerosol size distribution found in marine environment and the number of cloud droplet formed is parameterized as a function of updraft velocity in the cloud base and aerosol size distribution present in the air parcel forming the cloud. With the model we are able to study aerosol cloud interactions in realistic conditions. We will use typical profiles for potential temperature and moisture content as well as surface fluxes to produce boundary layer dynamics with UCLALES.

In the simulations we will assumes that the moving vessel emits sea spray particles with a wind dependent flux similar to Wang *et al.* (2011) study. The results will show the changes in cloud drop number concentration with different wind speeds, emission rates and the size of the emitted particles. We will further study how well aerosol is dispersed in the boundary layer before they are removed through sedimentation. This will provide us information about how realistic is the proposed scheme and the number of vessels that should be employed to achieve the wanted change in cloud properties.

This study has been supported by the Academy of Finland (Project number 140907) and by the strategic funding of the University of Eastern Finland.

Size distribution and chemical composition of ice nuclei at a rural site in Germany

M. Ebert, T. Hermann, H. Bingemer, H. Klein, J. Curtius, and S. Weinbruch

[1]Environmental Mineralogy, Institute of Applied Geosciences, Technical University Darmstadt, 64287 Darmstadt, Germany
[2] Institute for Atmospheric and Environmental Sciences, Goethe - University, Altenhöferallee 1, D-60438 Frankfurt/M., Germany
Keywords: ice nuclei, electron microscopy, individual particle analysis
Presenting author email: mebert@geo.tu-darmstadt.de

By the static vacuum diffusion chamber FRIDGE. atmospheric ice nuclei (IN) concentrations are determined at Kleiner Feldberg (826 m asl, Rhein-Main Area, Germany) on a daily basis since more than 3 years (Bingemer et al., 2012).

The monthly mean number concentrations of IN vary by about one order of magnitude, with high values in early summer and low values in winter. This could have a significant effect on primary ice formation in mixed phased clouds and the development of precipitation over large areas of Central Europe.

Based on these measurements the aerosol optical thickness of mineral dust (AOD_{Dust}) turned out to be an especially important proxy for the IN-concentrations.

In order to proof the origin of the IN at Kleiner Feldberg the chemical composition, morphology and size of particles that had been identified as ice nuclei by FRIDGE were determined by environmental scanning electron microscopy (ESEM) combined with energy-dispersive X-ray microanalysis (EDX). In total more than 1000 individual IN were analyzed in 23 selected FRIDGE samples. The unambiguous identification of the analyzed particles as IN was enabled by a high precision laser engraved coordinate system on the substrates, which allowed to locate the positions of the ice crystals and the nucleating particles on the substrate both in FRIDGE and ESEM.

Nine groups of IN were distinguished: alumosilicates, quartz, Ca- and Mg-carbonates, Ca-sulfates, metal/metal oxides, biological particles, soot, other C-rich particles, and sulfates/nitrates/ chlorides. All other particles were summarized in a tenth “mixtures/other” group. This classification reflects the major composition of a particle. Minor compounds, which are present as coating, agglomerate or heterogeneous inclusion within individual particles were not considered for classification.

In total 30% of all identified IN belongs to the sulfates/nitrates/chlorides group. Because of methodical considerations this group was removed from the graphs in Figure 1 and 2

The size resolved particle group number abundance of the IN is shown in Figure 1, the total size distribution in Figure 2. Most abundant particle groups acting as IN are the soil groups alumosilicates, quartz and carbonates (orange bars) with in total 53%, followed by biological particles (plant fibers, pollen) with 27%, soot (8%) and metal/metal oxides (4%). While higher amounts of soot (average geometric diameter $d_{\varnothing}$ = 0.7 µm) were only found in the smallest size bin (<2 µm), biological particle dominate within the largest size bins (> 16 µm). Because of the large particle diameters of the biological IN ($d_{\varnothing}$ = 15.3 µm), these particles are very likely originating from local sources, while a major part of the alumosilicates ($d_{\varnothing}$ = 3,3 µm) also originates from long range transport (desert dust).

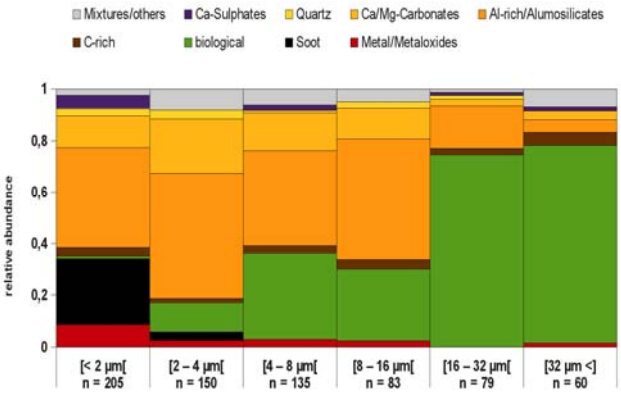

Figure 1. Relative particle group number abundance of IN at Kleiner Feldberg for six size classes.

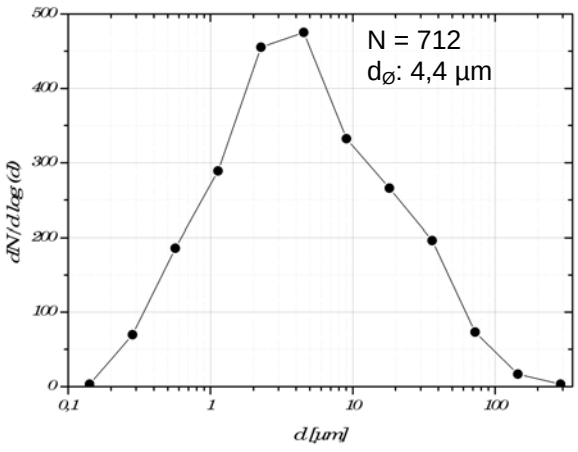

Figure 2: Size distribution of IN at Kleiner Feldberg (N = number of analyzed IN; d = average geometric diameter).

The regime dependency of the susceptibility of convective mixed-phase clouds and precipitation

Presenting author email: d.chang@mpic.de

Clouds have great influence on the vertical redistribution of energy and moisture, and consequently have impacts on weather and climate change from regional to global scales. Biomass burning is an important factor that could affect deep convection in clouds, and within this work, we used the ATHAM (Active Tracer High Resolution Atmospheric Model) model to study the properties of pyro-convective clouds and precipitation in 2- and 3-dimensional simulations. The two-moment microphysical scheme of Seifert (2002), including the hydrometeor categories cloud water, rain water, cloud ice, snow, graupel and hail, was utilized to investigate the interaction between atmospheric aerosols and cloud microphysics. The Chisholm fire that occurred in Alberta, Canada, in May 2001 was used as a base case. By assuming typical aerosol concentration conditions, we calculated the cloud droplet number concentrations under different fire intensity conditions and evaluated the effects of aerosol concentration and fire intensity on the formation of precipitation. The simulation results showed different control regimes for cloud and precipitation formation, including an aerosol-limited regime, a fire intensity-limited regime and a transitional regime, which are consistent with the results from a recent parcel model study (Reutter *et al* 2009).

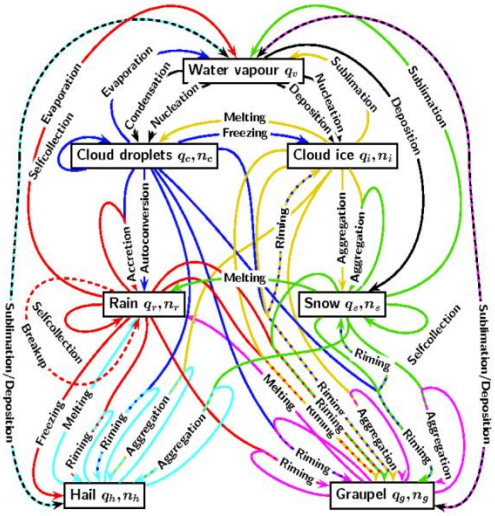

Figure 1. Simplified schematic diagram of the microphysical interactions in the two-moment Seifert scheme with respect to the particle classes cloud- and rain droplets, cloud ice, snow, graupel and hail.

Ice nucleation is one of the most basic processes that leads to precipitation. Ice initiation and secondary ice multiplication in clouds are poorly understood processes that result in large uncertainties in the ability to model precipitation production and to predict climate change. Therefore, progress in modeling precipitation accurately requires a better understanding of ice formation processes.

In 2007, during the Ice in Clouds Experiment-Layer Clouds (ICE-L), measurements were focused on heterogeneous nucleation in clouds where secondary processes are not thought to occur. More recently, for the Ice in Clouds Experiment – Tropical (ICE-T), we turned our attention to tropical convective clouds, where both primary and secondary ice formation processes might play significant roles.

Tropical maritime cumulus clouds represent an important component of the global water cycle, but the relative roles of primary and secondary ice production in these clouds are poorly understood. Heterogeneous ice nuclei (IN) are responsible for ice initiation in towering tropical cumulus clouds, so information regarding their abundance, distribution, source compositions and dependence on cloud temperature is crucial to understanding the ice production processes.

We present recent measurements of cloud particle residual chemical composition and ice nuclei (IN) concentrations measured from an airborne platform (NSF/NCAR C-130) during the ICE-T field campaign, which took place in July 2011 over the Caribbean Sea.

Chemical composition of cloud particle residuals were measured with an Aircraft version of an Aerosol Time-of-Flight Mass Spectrometer (ATOFMS) (Pratt *et al* 2009a) sampling from a Counterflow Virtual Impactor (CVI) inlet. IN measurement techniques included airborne ambient (from an isokinetic inlet) and cloud particle residual (from the CVI inlet) measurements using a continuous flow diffusion chamber (CFDC) (Rogers *et al* 2001) and off-line analysis of samples collected from the aircraft. The presence of ice was confirmed with the cloud imaging probes installed on the wings of the C130, the Cloud Particle Imager (3V CPI) and the Two Dimensional Optical Array Probes 2D-P and 2D-C.

A total of 13 flights were performed during ICE-T and some of them had a strong Saharan dust influence. In particular, during the Research Flight 6, on 15 July 2011, dust particles were detected in ice crystal residuals with the ATOFMS and also resulted in higher IN concentrations compared to clean maritime conditions. Other flights showed the presence of biogenic particles detected in cloud ice crystals, suggesting that these also could be a source of ice nucleation, as identified also during ICE-L (Pratt *et al* 2009b).

Hygroscopic and CCN properties of submicron atmospheric aerosol in a boreal forest environment during the summer of 2010

J. Hong[1], M. Paramonov[1] and T. Petäjä[1]

[1]Division of Atmospheric Science, Department of Physics, University of Helsinki, Gustaf Hällströmin katu 2, 00014, Helsinki, Finland

Keywords: hygroscopicity, CCN activity, κ, growth factor.

INTRODUCTION

Hygroscopic properties of atmospheric aerosol particles describe the interaction between the particles with ambient water molecules at both sub and super-saturated conditions in the atmosphere. Although the size of the particle is dominant factor (Dusek et al. 2006) determining whether a particle is a potential cloud condensation nuclei (CCN), the hygroscopicity plays a role at the size close to the limit of activation. Furthermore, hygroscopicity can give essential infor-mation on particle compositions (Swietlicki et al. 2008).

METHODS

This study was performed as a part of Hyytiälä United Measurement of Photochemistry and Particles – Comprehensive Organic Particle and Environmental Chemistry (HUMPPA-COPEC-2010) intensive field campaign (Williams et al. 2011).

Hygroscopicity properties measurements were per-formed using a Hygroscopicity Volatility Tandem Differential Mobility Analyzer (HVTDMA, Hakala et al. 2010), while the CCN properties were measured with a commercial continuous-flow Cloud Con-densation Nucleus Counter (CCNC, Roberts and Nenes, 2005).

PRELIMINARY RESULTS

In this study, preliminary results were obtained from CCNc measurements. For all data sets of super-saturation and activation diameters, derived from the CCN activation spectra, the effective hygroscopicity parameters κ were calculated from "*κ*-Köhler theory" equation (Petters and Kreidenweis, 2007). The effective hygroscopicity parameters (κ), were plotted against time during July of 2010, see Fig. 1. Larger particles activates earlier, thus have a larger kappa values, which means larger particles are more hygroscopic than smaller particles.

Critical diameters were plotted against supersaturation of this study from both CCN results and HTDMA data, with comparison of the ones from Sihto et al., 2010. The figure shows within the uncertainties, the results of this study agree well with Sihto et al., 2010, see Fig. 2.

Hygroscopic properties do not only depend on particle size, but also chemical composition. It is necessary to compare with the results from aerosol mass spectrometer to characterize the influence of chemical compositions.

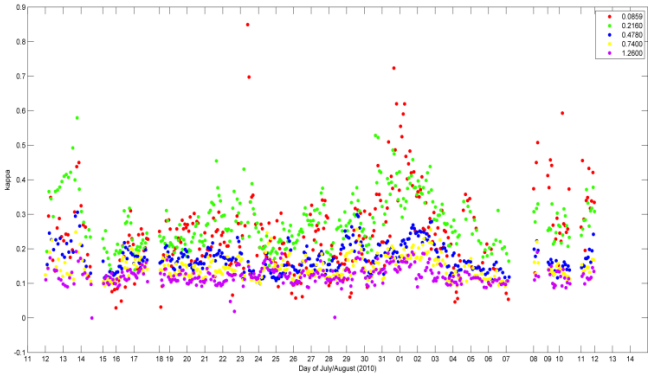

Figure 1. Hygroscopicity parameters obtained from CCN for different supersaturation as a function of time during July of 2010 for boreal environment aerosols.

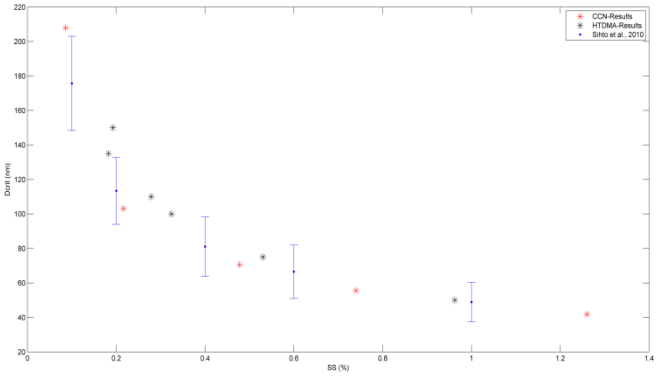

Figure2: Critical diameter as a function of critical supersaturation from this study and Sihto et al (2010).

Keywords: ultra-fine aerosol, Amazon, nucleation.
Presenting author email: modris.matisans@itm.su.se

Amazon rainforest undergo rapid changes due to increasing anthropogenic influence. Natural aerosol concentrations and pristine conditions are more perturbed by biomass burning associated with human driven deforestation. This study shows analysis of ultrafine aerosol number concentration over the rainforest canopy.

Events of new particle formation in tropics and over the rainforest followed by consecutive growth towards Aitken mode size range are sparse compared to mid-latitudes (Kulmala et al., 2004). More often short episodes of elevated ultrafine aerosol particles concentrations in a range of 20 – 40 nm are observed over the tropical rainforest, but their origin and process behind these episodes of new particle formation is unclear.

In this study scanning mobility particle sizer (SMPS) aerosol size distribution measurements in the range of 10 to 500 nm at the location of TT34 tower, 40 km NNW from the city of Manaus, Brazil were used. Measurements represent time period from April 2009 to February 2010. Ultra-fine particle range in this study is defined as smaller than 70 nm, including nucleation mode and Aitken mode. Meteorology, as wind speed/direction, temperature, relative humidity and solar irradiation, were measured nearby TT34 site.

Methods and results

The aerosol size distributions were analyzed using cluster analysis and 8 different clusters of characteristic size distributions were identified. One of the clusters includes data likely influenced by local pollution from diesel generator and were removed from dataset.

Obtained clusters were analyzed with respect to local meteorological data and mainly with respect to preferred source regions. Majority of measurements (~ 60 %) falls into clusters where aerosol size distribution is clearly dominated by accumulation mode aerosol, typical feature for Amazon during both, wet and dry seasons (Artaxo et al., 2002). Only modal size and magnitude of the accumulation mode is different with significantly higher concentrations during dry season when biomass burning take place. *Fig.1* shows median aerosol size distributions for various clusters. Accumulation mode dominated clusters were combined into one as they show very similar properties. Episodes with elevated concentrations of the ultrafine aerosol particles represent approximately 5 % of measurements. They are distinct by presence of aerosol mode with maxima around 20 – 30 nm and "closed" shape of size distribution indicating that new particle formation happened recently, but it is not still ongoing. Analysis of wind direction and other meteorological parameters does not show any preference to specific conditions. However, when seasonality is taken into account, ultrafine aerosol episodes occur dominantly during wet season when biomass burning is suppressed. The mechanism behind source and processes responsible for the ultrafine aerosol particle episodes are still under investigation. Hypothesis linking new particle formation in and in vicinity of shallow convective clouds is being at the moment in focus of ongoing analysis.

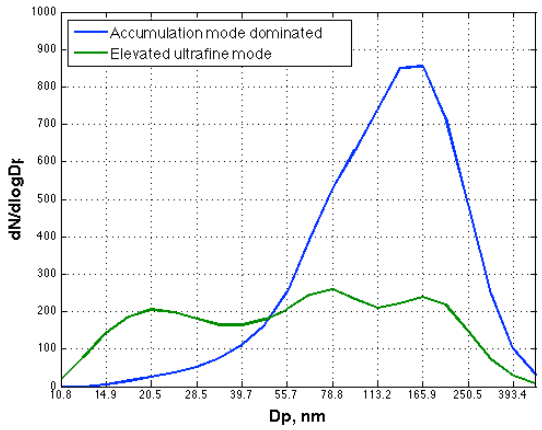

Fig 1. Median aerosol size distributions for clusters dominated by accumulation mode (blue) and for cluster with elevated ultrafine aerosol concentrations (green).

The data were collected with support from the AMAZE and EUCAARI project funded by National Science Foundation, Brazil LBA Millennium Institute, the Max Planck Society and European Union. Data analysis was supported also by Swedish Research Council.

A fully-coupled meteorology-chemistry-aerosol model (WRF-Chem) is used to assess the impacts of emission controls and perturbations on a summer intense convective precipitation event from August 9-11 during the 2008 Olympic Games. A four-nested domain configuration, from 81 km covering the whole China down to 3 km covering Beijing/surroundings, are used. Different emission scenarios are studied, including: (1) emissions targeting the 2008 Olympic period (OLY08); (2) INTEX-B emissions targeting the year 2006 (INTEXB06); (3) a zero-out of BC primary emissions in both anthropogenic (OLY08) and fire emissions (no-BC); and (4) a zero-out of anthropogenic emissions (no-AnthropE). MEGAN biogenic, MODIS fire and WRF-Chem embedded sea salt emissions are employed. INTEXB06 emissions are in general higher than OLY08 due to the long/short-term emission controls, especially for SO_2 and PM.

The WRF-Chem model (OLY08) is able to accurately predict both aerosol mass and number concentrations in the urban area of Beijing. The shapes of particle number size distributions are similar between observations and simulations. Column simulated aerosol optical depth (AOD) is also in a good agreement with MODIS AOD.

The emission scenario simulations suggest that even small perturbations in the concentration and/or compositions of aerosols can lead to either enhancement or suppression of this summer intensive precipitation event.

Compared with a pure WRF run (with no chemistry and feedbacks), WRF-Chem OLY08 simulations, including the coupled feedbacks, improve the predictions of precipitation and compare well with the satellite retrieval, while the WRF simulations predict a shift of ~ 1 to 2 degree in areal precipitation distribution and produces no convective rain in the Beijing area.

The pure WRF run produces the highest accumulated rainfall in the Beijing area. The next highest is produced by the no-AnthropE case, with over 50 mm more than predicted by the OLY08 scenario. Compared with OLY08, the INTEXB06 case produces slightly lower average rainfall accumulation, with nearly no change in convective precipitation but with suppression of non-convective precipitation by ~5 to 10 mm. The reduction of BC emissions makes nearly no change in non-convective precipitation, but suppresses convective precipitation by ~10 to 15 mm.

Without anthropogenic emissions, the predicted precipitation is strengthened in both precipitation area and intensity. Perturbation on emissions leads to a reorganization of precipitation. With OLY08 there are high precipitation patterns that sit at the center of Beijing and to the south. However, with INTEXB06, the precipitation center moves to the northwest mountain area, and with no-BC emissions, the high precipitation center shifts towards northeast of Beijing and with very low precipitation in the downtown area. The convective cloud-system in OLY08 case is more organized than that from INTEXB06 case, with maximum accumulated convective and non-convective precipitations, respectively over 50 and 20 mm more than the INTEXB06 case. With no-BC emission, the cloud-system is even more organized with double the differences in the extreme rainfall accumulation to the INTEXB06 case than the OLY08 case.

Presenting author email: tatu.anttila@fmi.fi

Incomplete understanding of the interactions between aerosols, clouds and climate form a large source of uncertainty in climate change predictions. The predictions are done with large scale models which rely on parameterizations of microphysical processes. One of the aims for the Pallas Cloud Characterization Experiment 3 (PaCE–3) was to provide more data on the microphysical processes related to the cloud formation. Such data is valuable in developing parameterizations that can be used in the global climate models.

The campaign took place during Autumn 2009 in a measurement located in a northern Finland. Here we present an analysis for measurement data for selected cloud periods. Measurements cover the particle size distribution, size resolved activated fraction of particles (performed within a dual DMPS set-up), particle hygroscopicity as well as their cloud condensation nuclei (CCN) activity at several different supersaturations ranging from 0.2 to 1.0%.

The average total particle concentrations, CN_{tot}, varied from 385 to 1518 cm^{-3} between the events. Table 1 shows further that particles with dry diameters above 100 nm, CN(>100 nm), made only a small contribution to the total number concentrations: the ratio between CN_{tot} and CN(>100 nm) varied in the range 0.07 to 0.25, implying that Aitken mode sized particles dominated the total particle concentrations. The average number of cloud droplets inferred from the dual-DMPS setup, CDNC, varied between 49 and 99 cm^{-3}. Such numbers are somewhat smaller than the average numbers obtained from an analysis of a longer data set from the site (Komppula et al., 2005) and are also smaller than observed in the previous campaign, PaCE-2, which took place in the same time of the year as the current campaign (Anttila et al., 2009).

The average value of the diameter at which 50% of the particles are activated into cloud droplets, D_{50}, varied in the range 80 to 102 nm between the cases. These numbers are somewhat lower than observed in the previous campaign (Anttila et al., 2009) but compare well to those reported by Komppula et al. (2005). Comparing the corresponding values of CN(>100 nm), CDNC and D_{50}, it can be concluded that Aitken mode particles made only a small contribution to the number of activated cloud droplets.

Table 1. Observed features of the analyzed cloud events. For each event, an average value of the quantity is shown followed by the value range during the event in parenthesis. Here CN_{tot} is the total particle number concentration, CN(>100 nm) is the concentration of particles with dry sizes above 100 nm, CDNC is the inferred number of cloud droplets and D_{50} is the diameter corresponding to the 50% activation efficiency.

Case	A	B	C	D	E
Time	9.9. 08:00-13:45	22.9. 06:45-8:15	22.-23.9. 22:30-08:30	25.-26.9. 23:30-04:15	4.10. 01:30 - 12:15
CN_{tot} (cm^{-3})	531	1518	449	385	499
CN(>100 nm) (cm^{-3})	127	131	100	29	119
CDNC (cm^{-3})	93	97	89	49	99
D_{50} (nm)	101	98	92	80	102
CDNC/ CN_{tot}	0.17	0.06	0.22	0.13	0.23

Here we have reported the key observed features of the cloud cases. In the future work, we will analyze the data further using the modelling tool presented in Anttila et al. (2009). Also, results from CCN closure study will be presented.

Fate of volatile and non-volatile elements from biomass burned in stoves and boilers

Torben Seidel & Hans Ruppert

Dept. of Sedimentology and Environmental Geology, Geoscience Center, Goettingen University, Goldschmidtstrasse 3, D-37077 Goettingen, Germany
Keywords: biomass burning, emission, concentration, fluxes, heavy metals
Presenting author email: tseidel1@gwdg.de

Biomass burning as an alternative energy supplier may play an essential future role due to the greenhouse effect, the shortage of fossil energy sources and the striving autonomy from fossil fuels. The growing contribution of biomass burning may have adverse effects such as higher emissions of harmful inorganic and organic substances in contrast to fossil fuels such as oil and gas.

Especially for in-house facilities burning biomass reliable measurements of concentrations and fluxes of heavy metals in the flue gas are lacking. For a reliable reconstruction of element fluxes and for input/output balances, the originating ashes such as grate ash, heat exchanger ash and fly ash are collected.

In the ideal case the amount of an element contained in the fuel should be identical with the combined element amounts in the different ash fractions. Especially the recovery rates of the environmentally and health relevant elements such as Cd, Zn, Sn, Tl, and Pb from burnt wood or straw in automatically fuelled furnaces are fairly low (Figure 1) suggesting that they either leave the chimney as molecules or ultrafine particles or that they "disappear" in the refractory lining material. The volatile property of these elements can be affirmed by a crucial lower presence in others than fly ashes. Other elements such as Co, Mo, Cr and Ni likewise show recovery rates lower than 100% attributed to a contamination of the fuel, but this may be caused by an abrasion of the cutting mill during preparation. On the other side elements like Ca, Ti, Mn, Ba, Fe, REE and Zr have recovery rates higher than 100% what may indicate a contamination by the refractory lining materials of the furnaces.

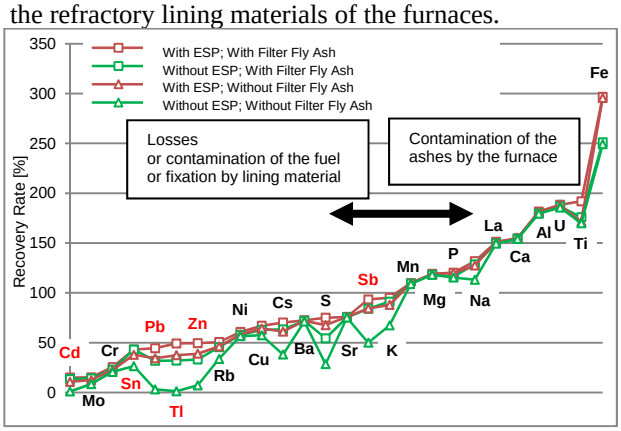

Figure 1. Recovery rate (%) of elements by burning wood-chips in a 30 kW boiler (combined element amounts in grate ash, internal heat exchanger ash and ESP ash (△) and fly ash (☐) divided by the element amounts contained in the wood chips).

Electrostatic precipitators (ESP) in the exhaust gas stream diminish the dust load e.g. from 55mg/Nm^3 to 18mg/Nm^3 at 13% O_2 respectively for a 30kW boiler fuelled by spruce wood-chips. Therefore the amount of risky elements can be diminished by the ESP if the elements are bound on particles but not if they are in an ESP non-retainable state. Figure 1 shows the recovery rates of elements in a 30kW boiler with downstream ESP. The boiler is fuelled by spruce wood-chips. The application of an ESP decreases the dust load and lowers the emission of associated elements such us Cd, Zn, Pb, and Tl. Nevertheless, main fractions of the most volatile elements are not retained what suggests either a very fine particulate or gaseous state of the elements which is not retained by ESP or by a baghouse filters.

The second explanation for the low recovery rate could be fixation by refractory lining materials such as chamotte. First analysis used lining materials show highly variable element concentrations and partly extreme enrichments especially of Cd in contrast to unused material form the same furnace or the continental crust (Table 1). The enrichment of some elements may be facilitated by the large open porosity (>20%) of these materials and may explain in part small recovery rates. But very high extraction efficiencies would be necessary to remove appreciable amounts of these elements from the flue gas. For example: 80% of Cd released during wood burning should be stored in the lining.

Table 1: Element concentration (µg/g) of used and unused refractory lining materials.

	Cd	Cr	Sn	Pb	Tl	Zn	Ni	Sb
1	0.12	156	0.26	3.29	0.38	99.5	143	0.02
2	20	54.5	20.7	89.2	1.29	47.0	59.7	2.92
3	109	155	1.51	157	0.41	186	134	1.47
4	0.06	56	8.22	27.2	0.23	12.1	52.1	0.33
5	0.09	92	2.1	17	0.9	67	47	0.4

1 From Wood-chip boiler, 30 kW; material used
2 From Stove, 8 kW; material used
3 From Pellet boiler, 25 kW; material used
4 From Wood-chips boiler, 30kW; material unused
5 Reference material, Upper Continental Crust

To assess the environmental impact of a furnace, flux calculations for elements are much more relevant than listing of simple concentration data. In addition, only element fluxes enable the comparison of emissions from different furnaces and fuels under different burning conditions, etc. But the fate of elements with low recovery rates has to be ascertained (losses by gaseous or fine particulate emission versus retention in refractory lining material versus contamination of the fuel).

Introduction.

Combustion processes, such as waste incineration, are currently a relevant source of trace contaminants such as heavy metals or aromatic hydrocarbons, preferably contained in the particulate matter (PM) accompanying emissions. Heavy metals and other, such as copper or iron, can participate as catalysts in the formation process of dioxins and furans (PCDD/F) (Stanmore, 2004), along the way of flue gas through emissions control devices.

The behaviour of metals in general and heavy metals in particular, depends on several factors. These factors include their concentration and the chemical form in which they are incorporated, the type of matrix, the temperature and time of treatment, the composition and the speed of the gas flow, the presence of chlorine or other species, such as sulphur compounds, carbon monoxide or aluminium silicates.

The volatility of the elements depends not only on their boiling point, but also on the possibility of formation of more or less volatile compounds. In addition, mineral matter that forms the bulk of the fluidised bed may exhibit some ability to absorb some of the metals.

Table 1. Mass concentration reduction for selected metals in solid phase

Test	Fuel	% reduction Pb	% reduction Cu
A190Dx	A	84.73	93.94
B190-09	B	97.16	97.58
C190Dx	C	79.17	93.63

Experimental and results

A series of tests were done in a semi-industrial scale facility (Sanz, 2009). An hybrid filter comprising electrostatic precipitation (ESP) and baghouse (BH) modules was connected to a fluidised bed combustor. Tested fuels were olive tree pruning biomass (C), olive biomass/compost (A) and olive biomass/municipal waste RDF (B).

Fly-ash samples and fly-ash collected in hoppers of the hybrid filter was chemically analysed. The hybrid filter removes 99% of PM, thus reducing metals concentration (table 1).

Fly-ash collected in BH module, the fine fraction, is enriched in chloride, sulfates, K, Na, Pb, Cd and Hg compared to ESP module (table 2). Lower operating temperature in the filter resulted in higher content in volatile elements, such as mercury (figure 1) and cadmium, in the fly-ash collected in the filter.

Table 2. Average concentration in fly-ash collected in hybrid filter hoppers.

	Fuel A		Fuel B	
	ESP	BH	ESP	BH
Pb (ppm)	83	294	673	1350
Cu (ppm)	420	635	2667	4600
Cd (ppm)	1.82	6.76	10.00	23.00
K (%)	4.53	19.15	1.80	5.90
Fe (%)	0.80	0.44	2.63	1.50

Higher concentrations of PCDD/Fs were found downstream the filter in all the tests. This is probably related to high metals concentration in fly-ash. Formation of precursors in the ESP could also contribute to the effect (Kolluri, 1994).

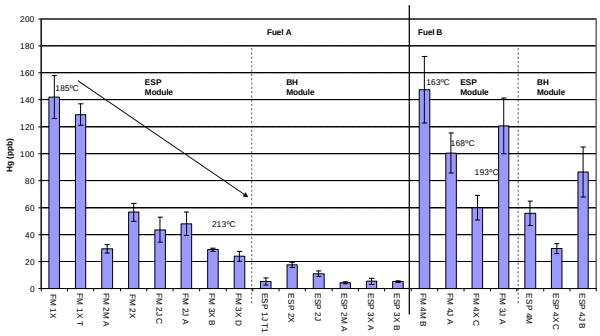

Figure 1. Mercury content in fly-ash collected in ESP and BH modules of the hybrid filter.

Residential wood combustion is producing heat and high amounts of gaseous and particulate aerosol into atmosphere. The usual products, ash, carbon and alkali metals (Tissari, 2009), cause known climate and health effects, and therefore the evolution of combustion reactions need to be understood thoroughly. In many recent studies, the chemical composition of particulate emissions from residential wood combustion has been analyzed using filter samples. However, these methods don't share temporal information on aerosol chemical composition. This study aims to fill the gap in knowledge of real-time tracking of aerosol particles chemical composition in different combustion situations.

The experiments were performed by burning wood chips and controlling the air conditions in a grate fired burner (40 kW), and measuring the emission products with dilution ratio ranging approximately from 600 to 1000 depending on the emission yield. The experiments were distributed into efficient, medium and poor combustion conditions according to the emission rates of CO (low, elevated and high, respectively). Real-time size-dependent chemical composition of aerosol particles was measured by Aerodyne HR-TOF-AMS (High Resolution Time-Of-Flight Aerosol Mass Spectrometer) using 600°C vapourizer temperature.

Aerosol mass spectrometer found nitrate, chloride, sulphate, polycyclic aromatic hydrocarbons (PAH) and organics, which were divided into smaller subgroups by positive matrix factorization (PMF) (Ulbrich, 2009). Organics were split into formerly reported factors HOA (Hydrocarbon-like Organic Aerosol) and OOA (Oxygenated Organic Aerosol) and new factors named "Aromatics" and "Benzene". The proportion of each chemical compounds are presented in table 1.

Table 1. Relative abundance of the chemical compounds for combustion experiments.

Compound	Med. Combustion (%)	Poor combustion (%)
HOA	43	8
OOA	15	6
Aromatics	0	24
Benzene	12	26
PAH	0	31
SO_4	23	0
Chl	7	5

HOA had highest peaks C_2H_3O, C_4H_7, C_4H_9 and showed notable hydrocarbon series (i. e. $C_nH_{2n\pm1}$) with O/C ratio 0.1. OOA had high peaks of CO and CO2 and O/C ratio 0.75. Benzene had remarkably high contribution of C_6H_5 and $C_5H_3NO_4$ and O/C ratio 0.19. C_6H_5 was thought to be originating from the particles produced from the split of aromatic hydrocarbons contained aromatic ring retaining products. Aromatics had high contribution in hydrocarbon series of $C_{n+5}H_{n+1}$,n = 1,..,4 and O/C ratio 0.23. Aromatics had good correlation with PAH compounds in poor combustion as shown in figure 1.

Particles were not detectable in AMS at efficient combustion conditions due to their small size and low mass concentration. In medium combustion conditions main constituents were HOA, SO_4, OOA, Benzene and Chl whereas in poor combustion there were also PAH and Aromatics present simultaneously with constantly occuring CO/NO_X plumes. In the case of Poor combustion, no SO_4 was detected, but small amounts of nitrate (mainly NO fragment) were found. No ammonium was detected, hence we conclude that NO was originated mainly from organics.

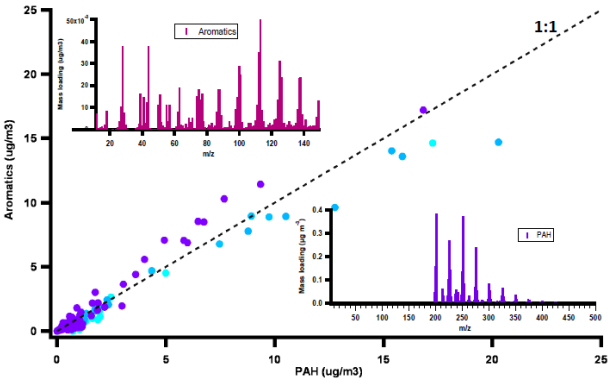

Figure 1. Aromatics vs. PAH, 1:1 line and mass spectra of the compounds.

Batch-wise fired appliances that use pellets as fuel may provide an option to significantly decrease emissions from small-scale combustion of wood. In these appliances a single batch of pellets is burned for heating the appliance. In this study a hybrid masonry heater was used where the grate used for combustion of wood logs could be replaced with a specially designed pellet burner.

Previously, measurements were made with a hybrid masonry heater, where air staging was used only in pellet combustion, and in wood log combustion air was lead only from below the grate. After that, some improvements were made. Additional wall material was applied to the combustion chamber. This material was used to reflect part of the thermal radiation, and keep the combustion chamber temperature higher. Secondary air inlets were placed to the back wall of the combustion chamber to be used in (advanced) wood log combustion. In pellet combustion the tertiary air inlets were more efficiently directed towards the flame in order to achieve better mixing.

Three different measurements were made with the improved heater. In conventional wood log combustion there was no air staging, but good operational practices were followed (i.a. amount of fuel, ignition from top). In advanced wood log combustion the secondary air was used. In addition the primary air was reduced so that the combustion was operated mainly with secondary air. The pellet combustion was operated similarly as before. The measurements were compared to those made before the improvements (wood log and pellet).

Comprehensive measurement equipment was used. Gaseous compounds CO, CO_2 and O_2 were measured straight from the stack with FTIR, and OGC with FID. The sample gas was diluted with porous tube diluter and ejector diluter for the collection of PM_1 and particle mass size distribution (DLPI) samples. PM_1 samples were collected separately from ignition, steady firing and burn out phases and the mass size distribution sample from the total combustion in the pellet combustions. In wood log combustions the samples were collected from 1 to 2 batches. The organic (OC) and elemental carbon (EC) contents were analyzed from PM_1. Time-weighted average values $PM_{1,ave}$, were calculated for total combustion from the samples of different combustion phases. The flue gas was further diluted with another ejector diluter for online measurement of particle number size distribution (ELPI and FMPS), total particle number (CPC) and mass (TEOM) concentrations. In addition, the combustion air flow rates were measured from air supply ducts separately for primary air and combined for secondary and tertiary air.

In pellet combustion the PM_1 emission in ignition phase was previously rather high. With the improvements the emission in ignition was 3.6-fold lower. In the whole combustion cycle the PM_1 emissions was 3-fold lower. CO emission was nearly 2-fold lower than before the improvements, but OGC emission had increased by ~40%, being still below 14 mg/MJ. The PM_1 emission was found to be as low as 2.3 mg/MJ during the steady firing of the combustion.

The improvements in wood log combustion without air staging lead to a decrease in CO emission (nearly 4-fold lower) and in OGC emission (6-fold lower) compared to the combustion before the improvements. However, the PM_1 emission during the whole combustion cycle was nearly the same. It was noticed that in the previous measurements the PM_1 emission in the 1st batch was lower than in the 2nd batch, whereas in the current measurements the PM_1 emission decreased towards the subsequent batches.

With the air staging in wood log combustion CO and OGC emissions were 3-fold and 2-fold lower, respectively, compared to measurements before the improvements. However, the PM_1 emission in the whole combustion cycle was actually about 30% larger. The gasification rate of the fuel was most likely too high for the combustion air flow capacity. The combustions improved towards the end of the cycle but the emissions were still larger than without the air staging.

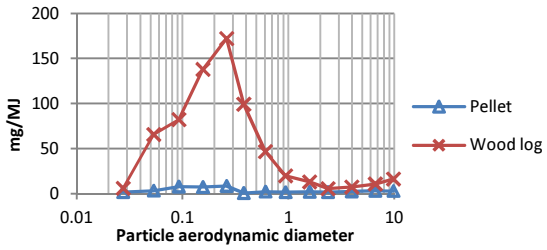

Figure 1. Mass size distributions in current study. Wood log combustion without air staging.

Effective density of particles emitted from different biomass combustion conditions

J. Leskinen[1], A. Virén[1], H. Lamberg[1], T. Kaivosoja[1], T. Kettunen[1], I. Nuutinen[1], T. Torvela[1], O. Sippula[1], J. Tissari[1], J. Jokiniemi[1,2]

Keywords: biomass burning, particle characterization, density measurement
Presenting author email: jani.leskinen@uef.fi

The properties of emitted particles from biomass combustion strongly depend on combustion conditions. When describing particle behaviour in human lungs (deposition), density is a key feature. Density is also a link between mobility size and aerodynamic size, and it is therefore important parameter for aerosol instruments.

In this study a novel fully logic operated and adjustable biomass combustion reactor (40 kW) was utilised to create different combustion conditions. These conditions were called efficient, erratic and poor combustion. They were achieved by adjusting fuel feeding and primary and secondary air flows. Fuel used was wood chips. The efficient case (~10 mg/MJ of CO) corresponds to optimal biomass combustion and the poor case (~2100 mg/MJ of CO) approaches conventional batch combustion. Whereas, the erratic case (~260 mg/MJ of CO) represents continuous biomass combustion with unideal burner settings.

The aerosol was diluted with porous tube diluter and two ejector diluters in series. Aerosol for collection samples was taken after the first ejector (DR ~ 25-50) and online instruments took sample after the second ejector (DR ~ 600-1000).

The effective density of (single) particles was measured using DMA (TSI), APM (Kanomax) and CPC (TSI) in series. According to demanded DMA (mobility size) and APM (single particle mass) operational parameters, only particles with certain effective density will penetrate them to CPC and will be counted. In order to cover the wanted range of particle densities and sizes, the parameters of the DMA (voltage) and APM (voltage and rotational speed) are varied [McMurry 2002].

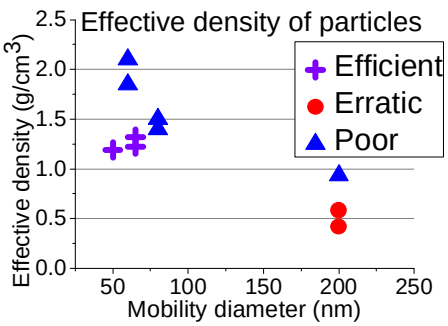

Figure 1. Preliminary results of the effective density of particles from different biomass combustion conditions.

Particle emissions from each combustion case were also characterised using ELPI (Dekati), SMPS (TSI) and TEOM (Thermo Scientific). In addition, OC, EC and ash contents of particle matter were analysed. Moreover gaseous emissions were measured using FTIR (Gasmet) and separate gas analysers (ABB).

Table 1. Typical averaged emission parameters.

Parameter	Efficient	Erratic	Poor
Mass Emission (mg/MJ)	10	180	300
GMD (ELPI, nm)	60	100	110
OGC (mg/MJ)	4	7	100
OC (mg/MJ)	0.2	41	49
EC (mg/MJ)	0.05	48	116
Ash (mg/MJ)	4	5	4

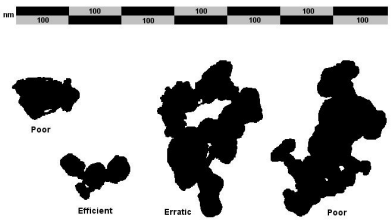

Figure 2. TEM-images (binary projection) of typical particles in each combustion cases from analysed size classes.

The effective density varied depending on the combustion conditions (Fig. 1). Generally speaking, density decreases as particle size increases. The small particles in the efficient case were mostly ash ($\rho_{bulk} \approx 2.7$ g/cm^3) which were quite loosely attached material (Fig 2). In the poor case the small particles (~ 60nm) seemed to be mainly elementary carbon (84 % of PM_1, $\rho_{bulk} \approx 2$ g/cm^3) and organic material and were more spherical in shape. Therefore these particles in the efficient case were less dense than in the poor case. With larger particles (~ 200 nm), poor conditions produced more organic matter than the erratic conditions. The organic matter is assumed to condense on the surface of the particles, which decreases the porosity of the particle and increases the effective density.

The link-up between chemical contents and morphology of particles formed in biomass combustion is an important issue yet still unclear. Description of single particle morphology types has been mostly qualitative, and the results can not usually be generalized. A semi-quantitative method using Energy Dispersive Spectroscopy (EDS) analysis with Transmission Electron Microscopy (TEM) analysis was evaluated. The applicability of the method in resolving chemical features of a certain morphology treated as group was of interest. The results suggest zinc enrichment in ultrafine particles of ash type morphology.

TEM-EDS analysis was carried out to interconnect chemical composition with typical soot and ash morphologies found in fine particles formed in biomass combustion. The combustion conditions were varied between efficient, erratic and poor, resulting in variation in organic carbon, elemental carbon and inorganic contents of PM_1. Chemical composition was determined with EDS both for 80-100 nm ultrafine size class (UFC) and for particles of non-classified sample (NCS). The UFC classification size was selected from the site where the number size distributions of the three setups overlapped. Analysis results were compared with ICP-MS analyses of PM_1 and SEM-EDS analyses on impactor samples having aerodynamic cut diameters in range of 30 nm to 10 µm.

TEM-EDS spectra were acquired in STEM mode using a spherical disk point selection tool. Constant emission current, magnification and signal collection times were used. Approximately 60-120 element spectra were acquired. Average of 8-10 background spectra were subtracted from the single particle spectra before the elemental mole fractions were quantified. The weighted averages of mole fractions were calculated for most abundant elements, K, S, O, C, Cl and Zn, using a parameter including disk area and acquisition parameters as weight. From previous studies it was known that large carbon content was indicative for soot morphology recognizable by eye from TEM samples. Therefore the results were recalculated using observed carbon mole fraction to make subclasses with soot and ash type morphologies, seen in TEM micrographs.

Table 1 shows average mole fractions of common elements showing differences both between the three combustion cases and between UFC and NCS.

From the results it can be concluded that there is a chemical link between morphological features seen in single particle TEM. The analyzed samples had high variation in carbon mole fraction. Subclasses of particle morphologies could therefore be described using carbon intensity as tool.

In addition it was concluded from the results that zinc was enriched in ultrafine particles, supporting previous studies. Moreover, efficient combustion of biomass seems to enrich zinc more than erratic and poor combustion as the particles of the same size class are compared. As shown in Fig. 1 this was observed in UFC particles. The feature was not observed in NCS, as well as was not in the bulk ICP-MS analysis. Instead the TEM analyses support the current findings.

As for conclusions more knowledge on particle characteristics was gained using this method on the side of bulk analyses. As for all quantitative analysis the more particles are analyzed the better would be the precision. However some qualitative selection has to be made to distinguish separate morphologies. With this condition the method can be utilized for describing variation in morphological features in biomass combustion origin fine particles.

Table 1. Average mole fractions of common elements before division to subclasses.

mol-%	Eff NCS	Err NCS	Poor NCS	Eff UFC	Err UFC	Poor UFC
Zn	4	8	0.4	34	10	2

Use of biomass materials and bio-waste in existing power and combined heat and power plants is widely recognized as an important means to meet internationally agreed green-house gas emissions reduction targets. According to CEN/TC 343 the input waste for SRF-production can be product specific waste, municipal solid waste, industrial waste, commercial waste, construction and demolition waste, sewage sludge etc. SRF can be used for electricity production and combined heat and power usage. Different technologies such as circulating and bubbling fluidised beds or continuous grate firings meeting best available techniques standards are used to demonstrate the highly efficient co-utilisation of low quality biomass together with SRF.

Present R&D activities at KIT are focused on studying combustion behaviour in continuous grate systems. In May 2011, a number of tests in the 500 kW pilot scale grate system, TAMARA, were performed to evaluate slagging, corrosion risk, forming of particles, emissions and assessment of ash utilization. Three fuels were fired: wood chips and two SRF's with high amounts of biomass (wood).

In this study, we report about our investigations on particle concentration, size distribution and chemical characterization of aerosol as a function of different solid fuel mixture. Particle samples were taken between the boiler and the bag filter. The particle concentrations were measured gravimetrically according to VDI 2066 with 50 mm plain filter. In addition to the gravimetric measurements, the size distribution was measured with a cascade impactor (Anderson Mark III impactor with 7 stages). The Anderson impactor was operated under isokinetic sampling conditions with a flow rate of 15 lpm. Under this operation conditions the size range of the impactor is from 0.4 to 20 µm.

From earlier investigation at TAMARA incineration plant, it is known that the unit has a good burnout and therefore the fly ash size distribution would be in the submicron range. The size distribution of the fly ash behind the boiler was measured with a scanning mobility analyser and an optical particle counter. Both of these online analyzers need a sample dilution if the particle concentration in the flue gas is too high.

Figure 1 shows the gravimetrically measured particle mass concentration in flue gas for different fuels. Wood chips, as reference material, has a mass concentration less than 100 mg/m³ and the solid recovered fuels having concentration 260 and 350 mg/m³, respectively.

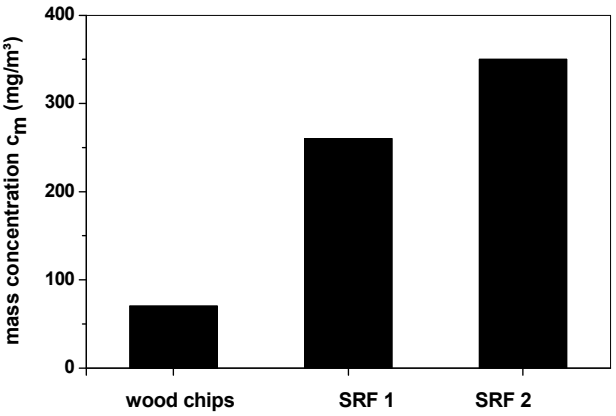

Figure 1. Particle mass concentration for different fuels

Figure 2 shows the size distribution of the fly ash from wood chips and the solid recovered fuels. The left part of the distributions is measured with the SMPS and the right part with the Anderson impactor. The impactor measures the mass distribution and the mobility analyser measures the number distribution. For data representation, the SMPS data were converted into the mass distribution (dm/dlog d_P). The size distribution of the fly ash for wood chips and solid recovered fuels showed nearly the same mean diameter in the range of 200 nm and therefore the burnout of all fuels was well.

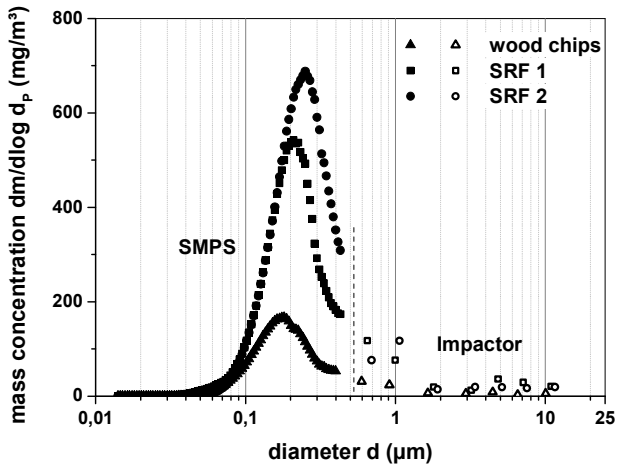

Figure 2. Particle size distribution of the fly ash

Particulate emissions from the co-combustion of forest biomass waste and sewage sludge in a bubbling fluidised bed

Nowadays, the development of technologies/strategies able to produce energy in an efficient and environmental friendly way constitutes an important challenge and an unquestionable necessity. The use of biomass is taken an increasing interest regarding industrial heat and power production. Valorisation of industrial wastes constitutes a sustainable alternative in terms of safely manage industry wastes. In this way, co-combustion, i.e. the simultaneous combustion of two or more fuels in the same plant for energy production, constitutes a promising choice. Among the different alternatives available for co-combustion, fluidised bed combustion is one of the most advantageous methods due to its flexibility and parameter control (Leckner et al., 2004).

Some industries, such as the pulp and paper industries, can valorise both, the sewage sludge produced and the forest biomass waste generated during the activity. Co-combustion of these two waste products in fluidised bed offers a feasible alternative to manage these residues and, at the same time, generate income through energy recovery. However, special attention must be paid to operating and environmental problems associated with this process. Thus, focusing on air quality, particles and gases emissions acquire an important relevance when sewage sludge is used as an additional fuel (Leckner et al., 2004; Shao et al., 2008).

In this study, particulate emissions from the co-combustion of forest biomass residues with sewage sludge from a pulp and paper mill industry were studied. The combustion experiments were conducted in a pilot-scale bubbling fluidised bed combustor (BFBC) (Tarelho et al., 2011). The bed was operated with silica sand. Forest biomass residues resulting from eucalyptus felling for the cellulose industry were air dried, chopped and sieved in order to obtain particles in the size range of 1-5 mm. Sewage sludge was air dried and also sieving for the same particle range size. The final fuel was constituted by 40% of sewage sludge and 60% of forest biomass residues The combustion flue gas from the BFBC passes through a cyclone separator in order to minimise particle emissions to the atmosphere.

Particle sampling was carried out at the exhaust duct, before and after the cyclone separator with the reactor operating at steady state conditions. Fine particles ($PM_{2.5}$) were collected onto quartz filters using a low volume sampler. Carbonate fraction was determined by sample acidification with phosphoric acid. Organic and elemental carbon were determined by a thermal-optical transmission technique after removing carbonate fraction by exposing the filters to HCl vapour and then removing the HCl excess from the sample with NaOH. Ion chromatography was used for determining water-soluble inorganic ions.

Furthermore, before the cyclone, particles were analysed by using a laser spectrometer in order to determine aerosol size distributions between 0.1 and 10 µm. Morphology and elemental composition of individual aerosol particles onto polycarbonate filters (0.2 µm pore size) were investigated by Field Emission Scanning Electron Microscopy (FE-SEM).

An important fraction of particulate matter emitted is constituted by carbonates. This fact was confirmed by FE-SEM that showed that filters were loaded of crystallised submicrometric mineral particles. The analyses revealed a dominance of calcium products, mainly carbonates and oxides containing less than 5 wt % Mg, and sodium/potassium chlorides, calcium sulphates, and silicates in a lesser extent. The presence of needle-fibre elongated crystals was remarkable since non biogenic micro-rods are rare and it might have direct implications on lung disease.

The role of a cyclone on decreasing particle emissions to the atmosphere was evaluated.

An appropriate understanding of the emissions from biomass waste and sewage sludge combustion in fluidised beds is needed in order to establish proper control of combustion conditions and minimise the operational problems and environmental impacts.

Ignition and combustion of coal dusts with different fuel mass concentrations

S.G. Orlovskaya, V.V. Kalinchak and O.N. Zuy
Department of Physics, Odessa National I.I. Mechnikov's University, Odessa, 65082, Ukraine
Keywords: heat and mass transfer, combustion particles, concentration, temperature.
Presenting author email: svetor@rambler.ru

Coal clean combustion remains a challenge. It is well known that reactions in pores affect significantly the combustion characteristics of coal particles, but this effect is not enough investigated in case of coal dusts.

The coal dusts ignition, burning and extinction processes are studied numerically with special attention to the reactions in pores. The effect of coal particles mass concentration on dust ignition characteristics is analyzed in details with account of porosity because the natural coals are usually porous (Pomerantsev, 1973).

The fuel mass concentration in dust depends on the particles countable concentration and mean particle diameter according to the next expression:

$$C_m = \frac{1}{6}\pi d^3 \rho C_N .$$

So the mass concentration (C_m) could be changed by varying the particles diameter (d) or particles concentration (C_N). The rate of heat transfer between the particle and surrounding medium as well as chemical heat release density depend strongly on the particle diameter (Kalinchak, 2005). In case of high concentration of small particles the total surface increases dramatically.

The simulation results of dust ignition delay time (t_{ind}) versus fuel mass concentration are presented in Figure. The curve 1 corresponds to specified value of the countable concentration C_N: the mass concentration increase is caused by the particle diameter growth. The curves 2 and 3 describe the ignition delay time dependence on the mass concentration $t_{ind}(C_m)$ for fixed particles diameters and increasing the particles concentrations.

It is shown that in the first case the dependence $t_{ind}(C_m)$ has a local minimum due to minimization of heat losses at some value of the particles diameter. Besides it is demonstrated that ignition delay times of coarse dusts are five times greater than those of fine dusts at the same values of fuel mass densities (when $C_m \geq 0.1$ kg/m^3).

The particles initial diameters range which corresponds to full fuel burnout is defined. It is shown that due to reactions in pores this range could be increased twofold.

In case of porous coal particles dusts the full burnout occurs in the range of air to fuel ratio is $3.5 < \eta < 1$, while for solid carbon particles dusts the corresponding range is $2 < \eta < 1.3$.

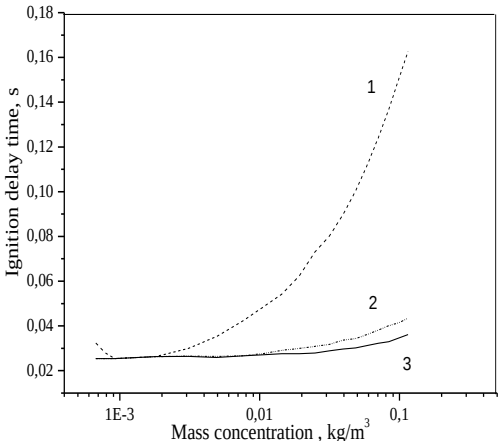

Figure 1. The ignition delay time of porous coal dusts versus mass fuel concentration at gas T_g =1300 K. 1 – C_N =1.9·10^{7}m^{-3}, 2 - d_b =50mcm, 3- d_b =40 mcm.

It is found that reactions in pores lead to significant decrease of ignition delay time and the critical diameter of particle ignition (when $d \leq d_{cr}$ the particle can't ignite).

It is determined that ignition delay time (t_{ind}) of porous particles is notably less then that of solid particles (Table 1), at the same time critical diameter of particles extinction (d_E) is twofold less.

Table 1. Combustion characteristics of porous (a) and solid (b) particles, d_b =100 mcm, T_g =1300 K, C_m =0.044 kg/m^3.

Characteristics	t_{ind}, msec	d_E, mcm	T_{bur}, K	t_{bur}, msec
a)	54	6	2282	244
b)	250	13	2265	264

The burning temperature (T_{bur}) and burning time (t_{bur}) are determined mainly by oxygen concentration at the particle surface, so depend slightly on particle porosity.

Reduction of particulate matters emitted from a diesel-generator fuelled by waste-edible-oil biodiesel with acetone and isopropyl alcohol addition

J.H. Tsai[1], S.J. Chen[1,*], K.L. Huang[1], C.C. Lin[1] and W.Y. Lin[2]

[1]Department of Environmental Science and Engineering, National Pingtung University of Science and Technology, Pingtung County, Nei Pu, 91201, Taiwan
[2]Institute of Environmental Engineering and Management, National Taipei University of Technology, Taipei City, 10608, Taiwan

Keywords: waste-edible-oil biodiesel, acetone, isopropyl alcohol, diesel-generator.
Presenting author email: chensj@mail.npust.edu.tw

Because of the concerns of high international oil price and crude oil reserve depletion, increasing interest has been paid to the research and development of alternative energies. Biodiesels have received increasing attention as alternative fuels for diesel engines and generators. Many studies have shown that the use of biodiesel as an alternative fuel in diesel engines may improve combustion efficiency and reduce the emissions of carbon monoxide (CO), hydrocarbons (HC), particulate matter (PM), and polycyclic aromatic hydrocarbons (PAHs) (Subramanian *et al.*, 2004; Lin *et al.*, 2006; Tsai et al., 2011).

Acetone and isopropyl alcohol, two major industrial waste solvents (Lin and Wang, 2004), are widely used as cleaning and washing agents in electric and precision machineries. For a new generation semiconductor plant, over one thousand tons of isopropyl alcohol and acetone per year are consumed and then treated as waste after use. Recycling waste-edible-oil, isopropyl alcohol, and acetone as an alternative diesel fuel would reduce such environmental burden.

In this study, new blended fuels were prepared by adding 1–3 vol% of dehydrated acetone (A) and 1, 2, 3, 5, and 10 vol% of waste-edible-oil biodiesel (W) into a regular diesel (86–97 vol%) and using 1 vol% of isopropyl alcohol (P) as stabilizers. An auto-detector flow sampling system equipped with quartz fiber filters (with diameters of 47 mm) was installed downstream of the diesel-engine generator exhaust to determine suspended particles.

The preliminary results showed that using the tested biodieselhols (blends of isopropyl alcohols, acetones, and esterificated waste-edible-oils) fuels could reduce the PM emission concentration (6.97–30.6% reduction, average = 19.5%), compared to D100 (Figure 1). In particular, using 3 vol% acetone as a biodieselhol fuel in the diesel-generator had the highest reduction of PM emission (by an average of 27.5%), regardless of the ratio of waste-edible-oil-based biodiesel to premium diesel fuel. This phenomenon is similar to those reported by several researches that adding oxygenated additives into diesel fuels, such as ethanol or acetone, increased fuel oxygen content resulting in the improvement of fuel combustion reaction, and thus reduced PM emissions (Lin *et al.*, 2010; Lin *et al.*, 2012).

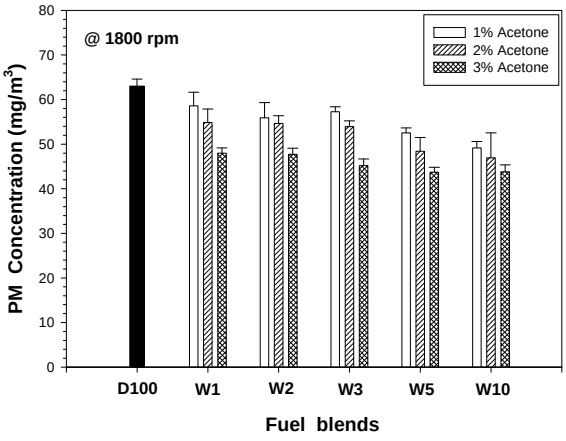

Figure 1. Concentrations of PM emitted from the diesel-engine generator fuelled by waste-edible-oil biodiesel with acetone and isopropyl alcohol addition.

Study of paraffin droplets evaporation and burning

S.G. Orlovskaya, M.S. Shkoropado, F.F. Karimova

Department of Physics, Odessa National I.I. Mechnikov's University, Odessa, 65082, Ukraine
Keywords: n-alkanes, droplets, vapour, diffusion.
Presenting author email: svetor@rambler.ru

Investigations of droplets combustion are of great concern due to promising prospects of hybrid paraffin (n-alkanes) based propellants. The ground testing at Stanford University demonstrated that such fuel exhibits high regression rate and provides sufficiently high specific impulse Santos *et al* (2006). In addition paraffin based propellants are eco-friendly and safe in exploitation. High efficiency of paraffin-based propellants is explained by peculiarities of heat and mass transfer in combustion chamber. The charge surface melts under heat flux from reaction zone. High speed oxidizer flow pulverized melted paraffin and entrains the droplets, which ignite and burn quickly. So to model combustion process we have to know burning characteristics of single droplet.

To study kinetics of droplet evaporation and burning we use video microscopy and digital image analysis techniques. A paraffin droplet (n-Docosane or n-Octadecane) is suspended on tungsten filament loop. The droplet evaporation and burning are recorded on personal computer via two cameras: diameter decrease is recorded through microscope (x16) and the flame height is registered by another camera.

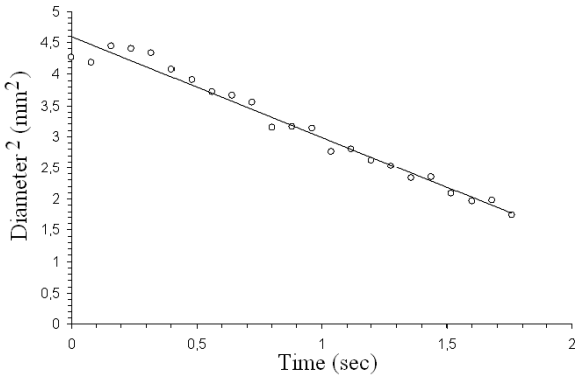

Figure 1. The history of n-Docosane droplet diameter squared.

At Figure 1 the square of the burning droplet diameter versus time (t_{bur}) is presented. The curve is close to linear one, so the d^2 law is true and the burning rate is limited by diffusion. The burning rate constant (K_{bur}) is calculated as tangent of the line inclination angle $d^2 = f(t)$ (Table 1).

Evaporation of n-Docosane and n-Octadecane droplets was studied in air at different temperatures.

Table 1. Burning characteristics of n-Docosane droplet.

Initial diameter (mm)	t_{bur}, s	K_{bur}, mm^2/s
1.87	1.36	0.013
1.99	1.52	0.016
2.04	1.84	0.016

The Sreznevsky law being applied, so the evaporation constants (K_{ev}) are defined as mentioned above. In Fig.2 the calculated values of K_{ev} versus air temperature (T) are presented.

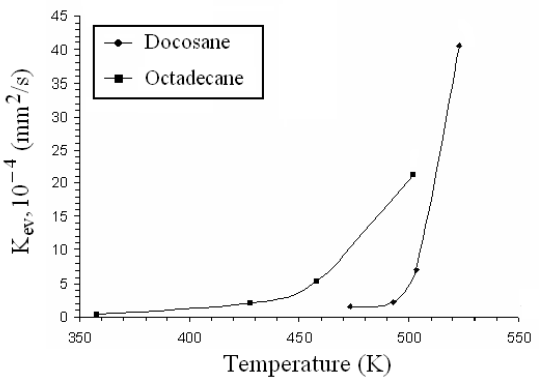

Figure 2. The temperature dependencies of the evaporation constants.

One can see that n-Octadecane evaporation coefficient increases significantly when the air temperature exceeds 450 K and in case of n-Docosane it rises abruptly above 500 K. These curves corresponds to Arrhenius dependence so we can estimate the evaporation heat by plotting $\ln(K_{ev})$ versus T^{-1}. In so way we obtain for n-Docosane value 91.7 kJ/mole, which is close to data of Chickos *et al* (1997) for the temperatures above 400 K.

The diffusion coefficient (D_c) of n-Docosane vapor in air at elevated temperature is estimated with account of natural convection (Table 2).

Table 2. Diffusion coefficients of n-Docosane vapor in air.

T, K	K_{ev}, 10^{-4} mm^2/s	D_c, 10^{-3} mm^2/s
493	2.23	1.4
523	40.56	8.1

Testing performance of fume hood in chemical laboratory

T. Jankowski
Department of Chemical, Aerosol and Biological Hazards, Central Institute for Labour Protection – National Research Institute, 00-701 Warsaw, Poland
Keywords: trace gases, fume hood, dust removal, ventilation system, ANSI/ASHRAE 110 test

The performance of a laboratory fume hood in providing protection for the worker at the face of the hood is strongly influenced by the aerodynamic design of the hood. It is important to study the effectiveness of the fume hood as specified in the ASHRAE 110-1995.

The CIOP-PIB studies are carried out flow visualization test, face velocity test and tracer gas containment test of the laboratory fume hoods. Smoke tubes and balls (Dräger, Germany) are used to map out the flow pattern which then enables us to improve on the flow dynamics generated by our fume hoods. Face velocity test was carried on using Testo 435-4 Transducer for measuring air velocity at the front of fume hood. The face velocity uniformity test evaluates the uniformity of the inflow velocity at various points across the sash opening while the final part, the SF_6 containment test, evaluates the containment efficiency. In tracer gas containment test, a manikin with clothing is used to simulate the actual human in front of the hood. A SF_6 particle detector - MIRAN SapphIRe 100E, capable of reading as low as 0.001ppm, is used in the detection of leaked SF_6 during the containment test. Detector probe is located at breathing zone of manikin to capture leakage of SF_6, simulating in actual operation the possibility of escaping fumes from the work chamber.

Figures 1, 2, 3 and 4 presents results of fume hood test in chemical laboratory.

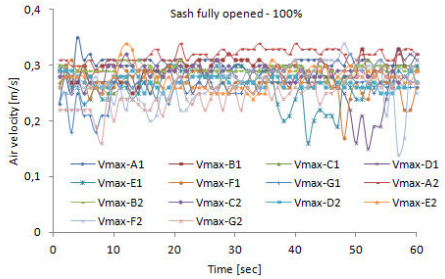

Figure 1. Air velocity distributions at sash full opening.

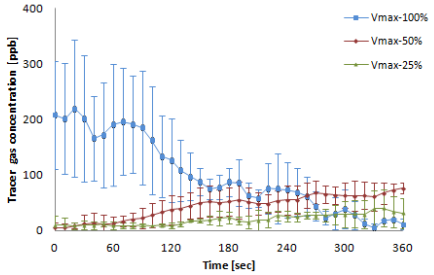

Figure 2. Distribution of SF_6 at tracer gas leak test.

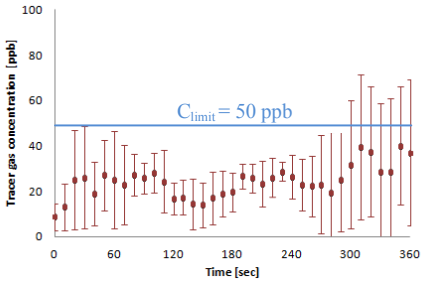

Figure 3. SF_6 distribution at face hood surface scan test.

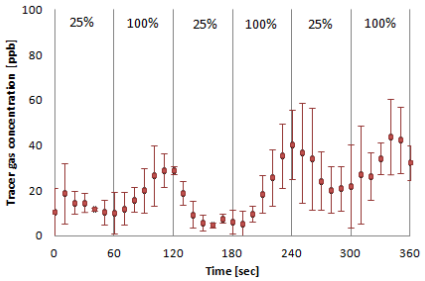

Figure 4. SF_6 distribution at sash movement effect test.

Figure 1 shows the variability of air velocity across the face of the fume hood in the range from 0.14 to 0.35 m/s. The study showed the value of air velocity dependence of the sash position, respectively: 0.28 m/s for 100%, 0.47 m/s for 50% and 0.69 m/s for 25% of the design hood opening.

According to the results shown in figure 2 only while the sash fully opened, SF_6 concentration exceed 50 ppb in the initial phase of the test (from 0 to 180 sec). As shown in figure 3 at any point during the face hood surface scan test, the SF_6 concentration does not exceed 50 ppb. In figure 4 can observe that SF_6 concentration decreased while the sash position was 25% and increased while the sash fully opened. Any surge in SF_6 levels outside the fume hood were not greater than 1000 ppb.

This paper has been prepared on the basis of the results of task 04.A.09 carried out within the National Programme “Improvement of safety and working conditions” partly supported in 2011-2013 within the scope of state services by the Ministry of Labour and Social Policy. The CIOP-PIB is the Programme's main co-ordinator.

Anthropogenic influence in bulk deposition fluxes in an urban-industrial area in the southwest of Spain

S. Castillo[1], J. de la Rosa[1], Y. González-Castanedo[1], A. Sánchez de la Campa[1], R. Fernández[1] and X. Querol[2]

[1]Unidad Asociada CSIC-Universidad de Huelva Contaminación Atmosférica, Universidad de Huelva, Spain
[2]Instituto de Diagnóstico Ambiental y estudios del Agua (IDAEA), CSIC, Barcelona, Spain
Keywords: deposition, insoluble particles, carbonaceous particles, trace elements, industrial aerosols
Presenting author email: sonia.castillo@dgeo.uhu.es

Areas close to industrial states are subject to an important influence of industrial emissions not only originating from the funnel emissions derived from the industrial processes, but also from other activities such as manipulation and transport of raw materials. The particulate matter originating from these anthropogenic activities may contribute notably in the levels and geochemistry of the deposition fluxes in these areas, and have influence on human health and in urban furniture. In 2006 was published the 151/2006 Spanish Decree to control the levels and methodology in air pollution in areas nearby to pollution zones (industrial and urban areas). This decree includes the control of the sedimentable particulate levels which establish limits of 300 mg/m^2.day.

Since 2006 a long time series of deposition sampling was performed in the city of Huelva. The sampling site (La Rábida) was located in the surrounding of the Ría de Huelva close to two important industrial states and near the harbour of the city. In 2008 were incorporated two more sampling sites, one with an urban influence in Huelva (Campus, 8km from La Rábida) and other one in Matalascañas close to the Doñana National Park with a rural influence (CIECEM, 45 km from La Rábida). The object of this sampling network was to evaluate the impact of the industrial activity in the deposition fluxes. In this work, we study and compare the deposition fluxes, both in the soluble and insoluble fractions for the bulk deposition sampled in three sites with an industrial influence in descending order.

The annual levels of bulk deposition show a decrease in the deposition levels as we move away from the industrial source. In La Rábida the deposition levels registered a mean of 21.4 g/m^2/yr, in Campus 18.6 g/m^2/yr, while in the rural area (CIECEM) registered only 10.7 g/m^2/yr (Table 1). The deposition levels registered in the urban and rural areas were normal in comparison with other sites with similar characteristic in Spain (Castillo, 2006).

Table 1. Annual deposition levels (g/m^2).

	La Rábida	Campus	CIECEM
	Industrial	Urban	Rural
Jun08-May09	25.8	22.4	9.5
Jun09-May10	18.8	15.8	8.7
Jun10-May11	19.8	17.6	14.0
mean	21.4	18.6	10.7

All the three locations present the same seasonal trend with the highest deposition levels during the summer period and lower in winter (Figure 1). In the summer, the high rate of soil resuspension due to the low precipitation levels registered during this period in the South of Europe and the most frequent African dust episodes above the Mediterranean basin caused this increase in the deposition levels in this period. Although this is the general trend, in La Rábida it was observed peaks along the year out of the general trend. These peaks show the local influence of the industrial and harbour emissions in this area.

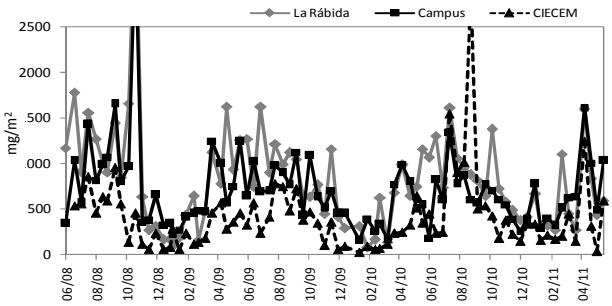

Figure 1. Seasonal trend of deposition levels (mg/m^2).

The high industrial influence was observed in the chemistry of the insoluble fraction. It´s observed that the carbonaceous species were the most elevated contributors to the total mass. This contribution was up to 15% of the total annual mass in La Rabida and less in Campus and CIECEM (11%). The levels of trace elements were notable also in La Rábida. Species such as Cu were the major contributors of trace elements (more than 50% in most cases) and minority Zn and Pb.

The meteorological analysis of the wind direction show a high correlation between the major amount of carbonaceous and trace species with three predominant wind directions, SW, NNE and minor NW, which favoured the transport of the anthropogenic emissions from the industrial states to the sampling stations.

The authors would like to express their gratitude to the Huelva Port Authority and the Environment Department of the Andalusia Government for their valuable collaboration.

Number size distribution of welding fumes

M. Manigrasso[1], C. Fanizza[1], P. Carrai[2], and P. Avino[1]
[1]INAIL ex- ISPESL, via Urbana 167, I-00184 Rome, Italy
[2]ASL2 Lucca, Dipartimento di Prevenzione, piazza Aldo Moro, I-55012, Lucca, Italy
Keywords: Combustion particles, Welding fumes, Nanoparticles, Number size distribution, FMPS.
Presenting author email: m.manigrasso@inail.it

Combustion derived nanoparticles are constantly inhaled in outdoor urban polluted atmosphere (Manigrasso and Avino, 2012) as well as in some workplace. Notably, exposure to welding fumes occurs in some occupational settings. The toxicity of welding fumes depends on both their chemical compositions and ability to penetrate and deposit deeply in the lungs. Fume chemical composition is determined by the composition of the base and of the filler metal. Its penetration and deposition in the regions of the respiratory system is mainly determined by their size. Therefore, the knowledge of the size distribution of welding fumes is a crucial information towards the estimate of the doses of toxic compounds delivered into the respiratory tract.

To this purpose particle number size distribution was continuously measured during Metal Inert Gas (MIG) welding of a mild carbon steel. Aerosol number size distributions were measured by means of a Fast Mobility Particle Sizer (model 3091, FMPS, TSI, Shoreview, MN, USA). FMPS counts and classifies particles, according to their electrical mobility, in 32 size-channels, in the range from 5.6 to 523 nm, with 1s time resolution.

Personal samples of the inhalable mass fraction of airborne particles were collected during welding with IOM personal sampler at flow rate of 2.0 L min^{-1}. Metal analysis was performed with an Inductively Couple Plasma Optical Emission Spectroscopy (ICP/OES). Metals detected in the breathing zone of the worker are reported in Table 1. It is worth noting the presence of Mn at concentration close to the ACGIH Threshold Limit Value-Time Weighted Average (TLV-TWA) of 200 µg m^{-3} (AIDII, 2011). The main target of the toxic effect of Mn and its compounds is the nervous system (Sińczuk-Walczak et al., 2001).

Figure 1 reports the temporal evolution of submicrometric particles (6-523 nm), nucleation mode particles (6-16 nm) and number Geometric Mean Diameter (GMD) before, during and after the welding operations performed without local exhaust ventilation. Before welding, nucleation mode particles represent about 7% of submicrometric particles and GMD is about 60 nm. After about 40 s from the welding start, the percent contribution of nucleation mode particles increases to 60% whereas GMD drops to about 18 nm. Total and nucleation mode particle concentrations increases from 2.1×10^4 to 2.0×10^6 and from 1.6×10^3 to 1.0×10^6, respectively. The contour plot in Figure 1 (in box) describes the temporal variation of the particle number size distribution across the peaks. It evidences the strong and fast-evolving contribution of nucleation mode particles: peak values are maintained for less than 10 s. The implication of such contribution on human health is linked to their high deposition efficiency in the alveolar interstitial region of the human respiratory system, where gas exchange occurs (ICRP, 1994).

Table 1. Heavy metal breathing zone concentrations (µg·m^{-3}) during MIG welding of a mild carbon steel.

Fe soluble	Cu	Mn	Cr total	Ni insoluble
18.8	18.1	148.4	3.7	2.0

Clogging of industrial High Efficiency Particulate Air (HEPA) filters in case of fire: extension of an empirical model to realistic fire conditions.

F.-X. Ouf[1], V.-M. Mocho[1], S. Pontreau[1] and Z. Wang[1]

[1]Institut de Radioprotection et de Sureté Nucléaire (IRSN), BP 68, 91192 Gif-Sur-Yvette Cedex, France.
Keywords: clogging, HEPA pleated filter, fire, soot particles.
Presenting author email: francois-xavier.ouf@irsn.fr

AREVA NC and IRSN are conducting research on the impact of a fire on the behaviour of containment devices for radioactive materials such as High Efficiency Particulate Air (HEPA) pleated filters. The aim of the present work is to produce experimental results of clogging of industrial HEPA filters in case of fire involving realistic materials used in nuclear facilities, from medium to large scale.

For this purpose, an experimental test rig has been developed (Mocho and Ouf, 2011). This facility is composed of a 1 m^3 furnace where several types of fuel (liquids and solids) are burnt. It is surmounted by an exhaust duct where the ventilation flow rate is imposed with the help of an extraction device and two calibrated orifice plates, associated to two separate exhaust ducts and HEPA filter-housings, corresponding to a range of air flow from 50 to 500 m^3/h (filtration velocity from 0.23 to 2.1 cm/s). The clogging of HEPA filter is monitored by measuring the pressure drop of filters and the filtered air temperature at a given filtration velocity. Upstream of HEPA filters, combustion aerosols are characterized in terms of size distribution, mass concentration, composition and particle morphology respectively using a DMS500 (Cambustion Ltd), glass (mass concentration) and quartz fiber (organic to total carbon ratio OC/TC) filter samplings and transmission electron microscope (TEM) analysis of particles deposited on TEM grids.

First results deal with physico-chemical properties of particles produced by thermal degradation of several types of fuels. In most cases these particles are submicronic fractal aggregates with primary particle diameters ranging from 31 to 53 nm. A significant contribution of organic carbon components has been also reported and could be observed on TEM micrographs as a coating around fractal aggregates. A summary of the properties determined for all these sources is proposed in the table 1; figure 1 presents typical TEM micrographs of particles emitted by each fuel.

Table 1. Properties of aerosol emitted by thermal degradation of studied fuels.

Fuel	Morphology	D_m (nm)	D_{pp} (nm)	OC/TC (%)	Composition
TBP/TPH	Coated Fractal Compact	230 – 240	31 - 34	5 – 13	C / O / P
LEXAN	Coated Fractal	220 – 260	51 - 53	12 – 16	C / O
OIL	Coated Fractal	250 – 340	41 – 45	10 – 12	C / O
Electrical Cable	Coated Fractal Compact	300	48	11	C / O / Cl
KIOWAGLASS	Coated Fractal Fractal	237 – 274	35 – 39	5 – 8	C / O / Pb
Trash can	Compact	180 - 320	32 - 34	4 – 10	C / O / Sb / Zn / Al

Typical clogging behaviours of HEPA filters are presented on figure 2 for a filtration velocity of 2.1 cm/s.

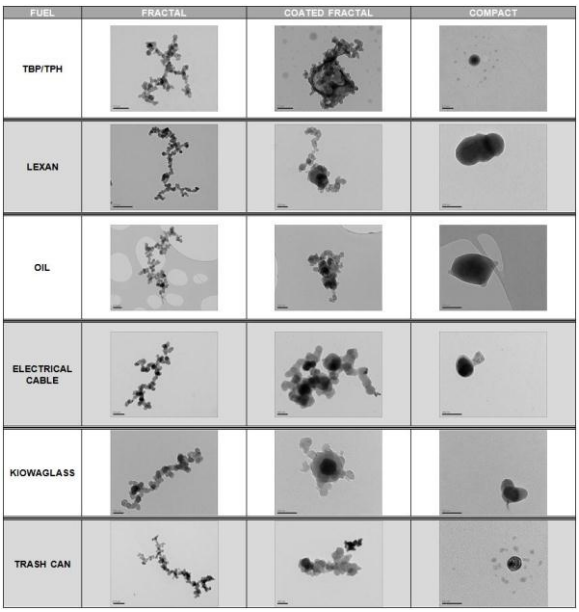

Figure 1. Typical TEM micrographs of particles emitted by thermal degradation of studied fuels.

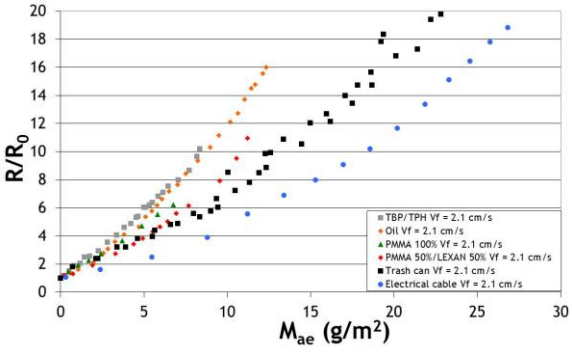

Figure 2. Evolution of non-dimensional airflow resistance (R/R_0) as a function of deposited mass of aerosol per filter surface area M_{ae}.

Results have confirmed the reliability of the empirical clogging model (Mocho and Ouf, 2011) for a large range of fuels, filtration velocities and fire conditions.

Finally, experiments have been performed on a large scale facility, for real scale scenarios (electrical cabinet, constant and variable filtration velocity). Once more, a fairly good agreement has been observed between experiments and the empirical model.

This work was supported by AREVA NC.

Elemental and morphological characterization of combustion by-products released from coal-fired thermal power plants in India

Rakesh Kumar[1] and Sudesh Yadav[2]
[1]Department of Environmental Sciences, University of Jammu, Jammu-18006, J&K, India
[2]School of Environmental Sciences, Jawaharlal Nehru University, New Delhi-110067, India
Keywords: coal combustion products, morphology, mineralogy, relative enrichment factor, elemental chemistry

Presenting Author: rakeshkumaratri@gmail.com

Utilization of coal for electricity generation produces large volumes of coal ash i.e. flyash and bottom ash as combustion waste along with flue gases. Particulate emissions from coal-fired thermal power plants have tendencies to accumulate higher amounts of toxic elements owing to their greater surface area (Vassilev and Vassileva, 1996; Xu et al, 2003). These potentially toxic elements are released into our immediate environments through resuspension triggered by winds and leached into surface and ground waters.

In this work feed coal (FC), bottom ash (BA) and flyash (FA) samples were collected from two thermal power plants in Northern India. FA samples were collected from different electrostatic precipitators (ESPs) field arranged in the series. These samples were then characterized for their morphological aspects and geochemistry (mineralogy, major and trace elements including rare earth elements-REE).

SEM micrographs revealed that the size of ash particles frequently decreased downstream towards the last end field of the electrostatic precipitators. Finer ash fractions are found to have homogeneous size range along with ideal spherical morphologies. However, coarser fraction FAs had irregular morphologies. Plerospheres which are the ash particles filled with microspheres (Goodarazi, 2006) are noticeable in FA samples. Plerospheres are suggested to exercise a morphological control on the emission of finer ash particles. Pleurospheres were present in large numbers in the ash collected from the ash ponds. Thus, under the extreme conditions of slurry transportation plerospheres remains relatively stable.

X-ray diffractograms of ash samples indicate the predominance of amorphous alumino-silicate glasses Quartz, mullite, sillmanite and magnetite and hematite are the dominant crystalline mineral phases in BA and FA. Among the FA samples the emergence of a strong mullite peaks is observed towards the finer fractions of FAs. However, a decrease in quartz peaks was also observed. The variations in the peak height indicates an increase in mullite content toward finer ash fraction whereas quartz proportion decreased. Emergence of hematite peak is also observed towards finer ash fractions.

Relative enrichment factors (Meij and Winkel, 2007) of FC, BA and FAs revealed that most of the trace elements present in the coal showed differential partitioning among different sized ash fraction.

$$REF = \frac{\text{Elemental concentration in ash}}{\text{Elemental concentration in fuel}} \times \frac{\text{\%age ash content in fuel}}{100}$$

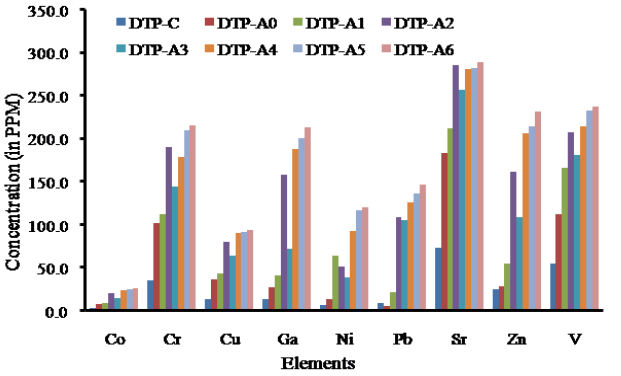

Figure 1. Showing enrichment of trace elements in the finer fraction of the flyash particle. (DTP-C is feed coal; DTP-A0 is bottom ash; DTP-A1 to DTP-A6 are flyash fraction (coarser to finer) collected from a series of electrostatic fields in power plant).

REF values indicates that Ba, Co, Cu and Mn remain relatively non-volatile during the combustion process and show uniform distribution on flyash fractions. Concentration of Ga, Pb, Tl, Ni, Zn and V were higher in FA than BA and increased with decreasing FA particle size. Finer particle at he latter ESP field accumulate greater amount of volatile trace metals due to their surface areas and being at high temperatures. However, REEs tends to remain non-volatile during the combustion process and observed no significant towards finer fractions.

Characterisation of particle number, nitrogen oxides and ozone concentrations in an urban background area located near a municipal waste incinerator

A.Donateo[1], D.Contini[1], F.Belosi[2], F. Prodi[2], F.M. Grasso[1]

[1]Institute of Atmospheric Science and Climate (ISAC-CNR), 73100, Lecce, Italy
[2] Institute of Atmospheric Science and Climate (ISAC-CNR), 40129, Bologna, Italy

Keywords: Industrial aerosol, NOx, Ozone, Particle concentration

In industrialized areas, the major contribution to the fine and ultrafine particles comes from anthropogenic activities, namely from emissions of industrial combustion processes and traffic-related emissions. In the waste treatment, incineration represents a favourable technique for reducing the volume of waste streams and recovering its energy content for the generation of electricity and district heating (Buonanno G. et al., 2009). The incineration sector has undergone rapid technological development over the last 10–15 years, due to specific legislation applied to industry that has obliged several European countries to reduce toxic emissions from municipal waste incinerators. However, the levels of environmental pollution linked with these activities and facilities are associated with a range of adverse health effects in humans. The principal contaminants include particles, nitrogen dioxide, sulphur dioxide, metals and heavy metals, (PAHs) and PCDD/Fs. Measurements have been taken in an urban background site nearby a municipal waste incinerator (Frullo) in the Emilia Romagna region (Italy) using a mobile laboratory.

Measurements were made between 6 June and 22 July 2008 (summer campaign) and from 20 January to 10 March 2009 (winter campaign). Particle number concentration has been measured using a CPC (Grimm model 5.403), coupled, for eddy correlation configuration, with a sonic anemometer (Gill, R3) at the top of a meteorological mast (10m) and a Rotronic (MP100A) thermo hygrometer. Mobile laboratory was also equipped with a nitrogen oxides detector (Teledyne T-API 200E) and an ozone detector (Teledyne T-API 400E). PM1 and PM2.5 measurements were also available at the site.

Measurements show a seasonal pattern with concentrations during winter larger than summer concentrations. A clear daily and weekly pattern was observed with weekdays concentrations larger than weekends concentrations, instead ozone concentration showed similar average values. Traffic-related emissions are the main causes of the observed concentration patterns.

All data were studied considering three principal wind direction sectors: wind direction directly from incinerator chimney at NW (292°-338°), from waste incinerator plant from W to N and from the city of Bologna at SW (200°-245°). In Fig.1 number particles concentration was reported as a function of wind direction. Different wind direction sectors were distinguished with three colours: cyan from the plant, yellow from the city of Bologna and green from chimney. A contribution from the plant is observed but the largest is coming from the urban area.

There is a limited correlation between NOx and particle hourly concentrations, especially in the summer campaigns due to the presence of particle number concentration peaks in the middle of the day. These were likely due to nucleation and/or growth of particles and their statistics will be discussed and compared with similar phenomena observed in urban background site in the area, where nucleation events frequency observed was high during spring and summer, in particular in July month (Hamed et al., 2007).

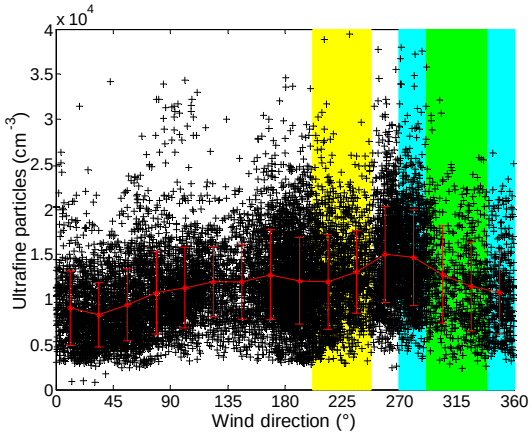

Figure 1. Number particle concentration against wind direction. In red the averages in bins of size direction (error bar represent a standard deviation).

The financial contribution of the project MONITER (Monitoraggio degli Inceneritori nel Territorio dell'Emilia Romagna) is acknowledged.
The authors wish to thank Mr. G. Trivellone (ISAC-CNR) for the technical help in preparing and implementing the campaign.

Analysis of Soot deposit for post fire investigation: comparison between full scale experiment and theoretical approach

A. Bellivier[1], M. Vigreux[1], F.X. Ouf[2] and H. Bazin[1]

[1]Department of Physical Measure and Fire Sciences , Laboratoire Central de la Préfecture de Police
39bis rue de Dantzig, 75015 Paris, France
[2]Institut de Radioprotection et de Sûreté Nucléaire (IRSN), BP 68, 91192 Gif sur Yvette Cedex, France
Keywords: aerosol, soot, thermophoresis, particle deposition, fire.
Presenting author email: axel.bellivier@interieur.gouv.fr

One of the "Laboratoire Central de la Préfecture de Police" missions is to investigate on the causes of a fire that occurred in Paris and its suburb. A part of the soot produced during the fire is deposed on walls. In this context, the phenomenon of soot deposit is studied in order to evaluate the information that could be used for fire investigators.

Several phenomena of deposit could occur: sedimentation, Brownian diffusion, impaction under the effect of the centrifugal force, electrophoresis, deposit by turbulent diffusion and deposit by thermophoresis. The thermophoresis corresponds to the migration from the zones of high temperature towards zones of lower temperature. At the scale of a building fire, it is the main phenomenon of deposition because smokes temperatures are much higher than those of the walls.

Before analyzing the soot deposit during post fire investigation, laboratory tests are needed. An experiment in real scale, as a first approach, was conducted to study the phenomenon of thermophoresis. The experimental device BANCO (Ouf & al., 2008) was used to compare measurements to a theoretical model of thermophoresis (Talbot & al., 1980).

Experimental set up

The soot is produced by an acetylene burner. The deposition targets are placed in a holding area of hot smoke (approx. 85°C). There are three different targets corresponding to three different temperatures conditions: a "cold" (nearly 10 ° C imposed by a heat exchanger), an "ambient temperature" and a "hot" one (nearly 185 ° C imposed by a heat plate). Targets are exposed in the furnace to the smoke during 30 minutes. Deposit mass are measured by the weighing of the targets prior and after the soot deposition.

Theoretical description of thermophoresis

The thermophoresis velocity is given by (Talbot & al., 1980):

$$v_{th} = \frac{-H\,\mu_f\,Cu}{2\,\rho_f}\,\frac{dT}{dy}$$

where H is characterising the particles' internal thermal gradient, μ_f the fluid viscosity, Cu the Cunningham factor, ρ_f the fluid density and $\frac{dT}{dy}$ the thermal gradient.

Then the mass per unit area of soot deposition could be obtained by:

$$D = \rho_s\, v_{th}\, dt$$

where ρ_s is the soot concentration in smoke and dt the duration of the exposition.

Results

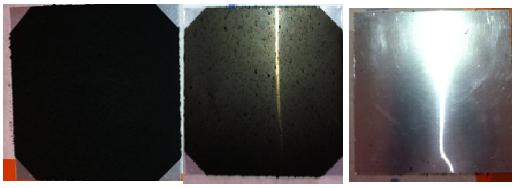

Figure 1. Visualisation of thermophoresis phenomenon on "cold" target (heavy deposition), "ambient temperature" target (medium deposition) and "hot" target (no deposition).

Qualitative observations of the thermophoresis deposition are shown in Figure 1.

Table 1 shows a comparison between experimental measurements and theoritical deposition based on the previously described approach.

Table 1. Comparison between experiment and theory.

Target	Measured soot deposition (g)	Theoretical soot deposition (g)
"Cold"	$1.6\cdot10^{-2}$	$1.9\cdot10^{-6}$
"Ambient"	$1.2\cdot10^{-2}$	$1.2\cdot10^{-6}$
"Hot"	< DL	Closed to 0

Conclusion

The experimental results are consistent: the deposition is more important on the coldest target. There is however a strong difference between measurements and predictions due to the assumptions made (spherical particles, steady state, etc.) to use the model. Nevertheless those firt results are encouraging for the investigation purpose. The next steps are to take into account the fractal morphology of soot particles and to compare these experimental results to a CFD simulation modeling of fire (customised FDS code).

Carbon particulate matter derived from combustion consists of a variety of organic compounds, which often present features similar to polymers and molecules used as photoactive layers in the most common organic solar cells (Zhu *et al*. 2009). This consideration has recently provided the inspiration to check out the possible applications of these products in the optoelectronic application such as the photovoltaic technology.

At the current state of knowledge the flame-formed carbon particulate matter mainly contain two different classes of materials: soot and nanoparticle of organic carbon (NOC) (D'Anna 2009). These two classes of particles present substantial differences on their sizes, optical properties and chemical features.

In this study, combustion-formed carbonaceous materials were collected from various fuel-rich laminar premixed flames of ethylene and air, in order to characterize both the optical and the electrical properties.

UV-visible absorption spectroscopy analysis has been used to measure the optical band-gaps of the materials by reporting the optical spectra in the Tauc plot (Tauc *et al*. 1966). The I-V characteristics, i.e. current vs. voltage plots, have been measured in order to estimate the electrical conductivity. Three different sampling procedures have been developed. A quartz substrate was rapidly inserted in flame, to collect by thermophoresis the carbon particulate matter, containing two main different classes of materials: soot and nanoparticles of organic carbon (NOC). The first class showed a band-gap ranging between 0.1 eV and 0.8 eV and a fair electrical conductivity, while the second class was characterized by a larger optical band-gap ranging between 1.9 eV and 3 eV and a low electrical conductivity.

The optical band-gap was investigated under a varying of flame conditions (C/O ratio and height above the burner) and residence time of the substrate in the flame.

A second particles collecting approach was realized by using a tube probe, positioned inside the flame, with a 0.8 mm orifice, followed by a particles impactor. This method was used to collect selected classis of particles.

A third method was a chemical procedure based on Soluble organic fraction (SOF) which was chemically extracted from the sampled particulate. In this later case the electrical characterization of the collected material showed an unusual presence of a hysteresis in the I quadrant of the I-V characteristic of SOF.

Finally by using the theoretical model proposed by Bruschi and Nannini 1991, the phenomenon of electrical conduction through a soot particles layer was simulated via tunnelling and percolative effect, which include both microscopic and macroscopic phenomena relative the charge transfer.

Presenting author email: natalia.ivleva@ch.tum.de

Aerosol particulate matter (PM) generated by combustion sources have a significant influence on atmospheric chemistry, Earth's climate and human health. Therefore, the detailed physicochemical characterization of combustion PM is crucial for understanding their impact on the environment. Moreover, the identification and quantification of anthropogenic and natural emission sources which govern global and regional aerosol abundances are essential for development of efficient emission reduction strategies. Besides engine exhaust particles, PM emitted by biomass burning (or, more specifically, wood combustion) is a seasonally important PM source in central Europe. It was shown that traffic and wood burning emission sources can be identified in ambient air by means of aerosol mass spectrometry (AMS), which allows for determination of organic and inorganic aerosol (Lanz *et al*, 2010). However elemental carbon (EC) cannot be detected by AMS. On the other hand, EC and inorganic species in combustion aerosols can be characterized by Raman microspectroscopy (RM). This non-destructive technique provides fingerprint spectra with the spatial resolution of an optical microscope and allows the identification and semi-quantitative analysis of soot, humic-like substances, nitrates, sulfates, and carbonates in size resolved samples of air particulate matter (Ivleva *et al*, 2007).

In order to demonstrate the feasibility of RM for discrimination between particle emission from wood/biomass combustion and road traffic, we firstly analyzed different reference compounds. Wheat (*Triticum aestivum*) straw as well as Norway spruce (*Picea abies*) branches, needles, roots and wood were dried, milled and heated at 450°C in ambient air for 2.5, 5 or 10 min. The Monarch 44 and Euro IV soot were used as examples for industrial soot (carbon black) and traffic particulate emission, respectively.

The RM analysis (λ_0 = 514 nm) of heated biomass samples revealed changes in their spectral features with the heating time, viz., the increase in the intensity of D (defect) peak around 1350 cm^{-1} compared to G (graphite) peak around 1600 cm^{-1}. This observation, which is in agreement with the Raman study on wood and bark of Japanese cedar pyrolyzed at increased temperature (Yamauchi, Kurimoto, 2003), indicates the ordering of amorphous carbon and increase of sixfold ring clusters area. Unlike all spruce samples, no differences were found in the spectra of wheat straw heated for 2.5, 5 or 10 min, indicating that pyrolysis was completed in less than 2.5 min of heating. Spectra of all analyzed biomass samples pyrolyzed for 10 min are very similar, with the exception of spruce wood sample, where slightly lower width of G and D peaks was found. The later suggests a slightly higher structural order of graphite-like carbon.

The comparison of spectra from pyrolyzed biomass, carbon black and diesel soot indicates significant differences in the width und relative intensity of D peak, which can be used for discrimination between combustion particles of different origin (Fig. 1).

The next step in our study will be the analysis of biomass burning aerosols of different origin, to extend our data base. Moreover, we plan to analyze the aerosol samples from various combustion sources, to prove the potential of RM for the discrimination between particle emission from wood/biomass combustion and road traffic.

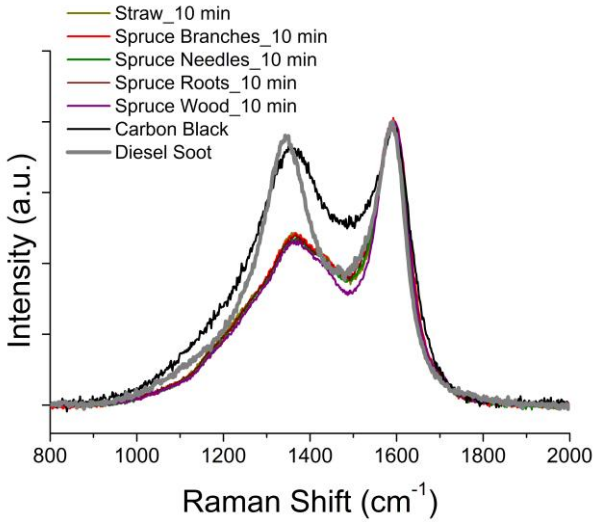

Figure 1. Spectra of wheat straw powder, and Norway spruce branches, needles, roots, wood powder heated at 450°C in air for 10 min., as well as carbon black (Monarch 44) and diesel soot (Euro IV).

Field scale evaluation of ultrafine particles emissions from stationary combustion and industrial sources

S.Cernuschi[1], G. Lonati[1], M. Giugliano[1], S. Ozgen[1], G. Ripamonti[1]

[1]Department of Hydraulics, Environmental, Infrastructure and Surveying Engineering, Politecnico di Milano, Milan, 20133, Italy

Keywords: emissions, ultrafine particles, nanoparticles, combustion sources, emission factors

Presenting author email: stefano.cernuschi@polimi.it

Despite all recent attentions addressed to their presence in ambient air, ultrafine and nanoparticle emissions are still poorly characterized, particularly within stationary combustion and industrial activity sectors. Source effects related to process configurations and operating conditions, together with all technical issues associated with sampling and measurement procedures, result in limited and rather comparable informations, with a general lack of base data required for evaluating any intervention policy that should be eventually adopted for preserving air quality.

The paper reports on a broad research programme addressed to stack field testing at real scale operating conditions on several stationary combustion and industrial processes, conducted for evaluating total number concentrations and size distributions in a size range extended towards the evaluation of ultrafine and nanoparticles. The investigations interested municipal and industrial waste-to-energy (WTE) plants, a biomass power plant, residential scale boilers fed with different fuels (i.e., wood pellets, light oil, natural gas), a closed fired place burning wood logs and a thermal oxidizer treating emissions from thermal desorption for soil remediation. Field measurements were dedicated to the determination of primary particle concentrations at stack gas conditions and to the investigation of the contribution of any material of condensable origin, arising from cooling and dilution effects immediately following flue gas release into the atmosphere. For this purpose, measurements were performed using a specifically designed sampling line, equipped with a dilution system and a particle counting device.

Average concentration range detected as a whole is included between four orders of magnitude (10^{-3} cm^{-3} – 10^{-7} cm^{-3}; under all sampling conditions, ultrafine fractions largely prevail in number size distributions, with average diameters almost constantly located in the nanoparticle size range. Source and fuel type for residential heating units result in variations in concentration levels, with different effects arising from dilution sampling. For waste incineration, concentrations and emission factors are included in the lower range of all measured sources: some process and design configuration effects are observed, with stack concentrations influenced by the presence of wet scrubbing units and the baghouse operating temperature of dry removal processes.

This work, jointly conducted by Politecnico di Milano and LEAP consortium (Laboratory of Energy and Environment of Piacenza), was partially supported with a research fund from Italian Federation of Environmental Utilities (FederAmbiente).

Characterization of aerosols produced by a commercial combustion aerosol generator MiniCAST™ 5201: EC/TC, size distribution, morphology and optical properties.

Since the last decades, the question of the global impact of combustion generated aerosols is of raising concern. Many researches have been conducted on the toxicological and global warming influences of particles emitted by wood combustion and aircraft engines or fire. Due to their complex composition and morphology, their reactivity and physical behaviour are not understood. Subsequently, the need of reference materials is growing over the years and recent developments allow to produce in a stable and repeatable way carbon particles assumed to be representative of combustion aerosol. Recently, Jing Ltd (*www.sootgenerator.com*) has proposed a combustion aerosol standard, called MiniCast, based on a propane diffusion burner, to be a candidate as a reference source of combustion generated particles. Since its beginning, this new device has been involved in many researches but few of those have proposed an overview of the physico-chemical properties of the particles produced by the MiniCast™ 5201.

The aim of this technical paper is to characterize the size distribution, morphology, elemental composition (EDX), microstructure (HRTEM), EC/TC (ratio of elemental carbon to total carbon) and optical properties of some selected set-points of the MiniCast™ burner. The corresponding set-points have been considered in order to produce a large range of EC to TC ratio ranging from 4 to 95 % of elemental carbon and are summarized in table 1.

Table 1. Experimental conditions of the MiniCAST™.

Propane (mL/min)	Nitrogen (mL/min)	Oxidation air (L/min)	Dilution air (L/min)
50	**0**	1.2	20
50	**50**	1.2	20
50	**100**	1.2	20
50	**150**	1.2	20
50	**200**	1.2	20
60	0	**0.8**	20
60	0	**1.0**	20
60	0	**1.1**	20
60	0	**1.2**	20
60	0	**1.5**	20

At the outlet of the MiniCAST™, a PALAS VKL10 ejector-type dilution device has been used to sample and dilute particles. The size distribution has been measured by a Scanning Mobility Particle Sizer (TSI SMPS 3936) and the morphology has been characterized by analysis of Transmission Electronic Microscopy micrographs of particles deposited on TEM grids (Ouf et al., 2010). In addition, the elemental to organic carbon ratio has been determined with the help of a thermo-optical method (Sunset Lab Inc.) using the "Improve" protocol, and the specific extinction coefficient has been retrieved with a turbidimetry optical bench described in Yon et al. (2011).

Figure 1 presents the evolution of elemental to total carbon ratio as a function of electrical mobility diameter.

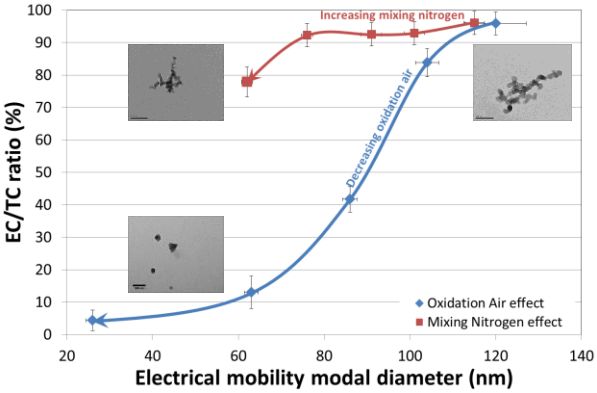

Figure 1. Evolution of EC/TC ratio as a function of electrical mobility diameter.

Considering an increase of mixing nitrogen flow rate, the EC/TC ratio does not change significantly while the mobility diameter significantly decreases. In this case, the evolution of size of particle is mainly due to coagulation inside the flame which does not modify the particles composition. On the other hand, as the oxidation air flow rate decreases, both the EC/TC and mobility diameter strongly decrease. In the most extreme case, the MiniCAST™ produces compact particles with a modal diameter of 25 nm and composed of nearly 4 % of EC. For this second case, a strong oxidation of combustion particles inside the flame could be suspected by incompletely burned gases. Despite the evolution of size, the change of EC/TC ratio as a function of oxidation air has been also reported to be linked with an evolution of morphology and optical extinction coefficient of these particles. Further analyses of TEM, HRTEM and EDX data are in progress and will bring more information on the nature and properties of such particles.

Presenting author email: hungcm1031@gmail.com

Nowadays, catalytic oxidation has been established to increase the effectiveness of AOP (Advanced Oxidation Processes) technology using dedicated catalysts, which potentially shorten the reaction times of oxidation, and allow it to proceed under milder operating conditions. The selective catalytic oxidation (SCO) of NH_3 in a stream to molecular nitrogen and water is one method for solving problems of NH_3 pollution. This work considers the oxidation of NH_3 from gasified biomasses fuels by selective catalytic oxidation (SCO) over binary rare-earth oxides (Cu-La nanomaterials) at temperatures between 150 and 400℃. To further understand the properties of the binary CuO/La_2O_3 composite catalyst, Figure 1 compares the FTIR spectra at various Cu-La molar ratios, and also confirms the presence of the CuO-like phase and the La_2O_3 phase on the surface of the CuO/La_2O_3 composite catalyst. Figure 1 reveals that the peaks associated with the CuO-like phase on the framework are associated with a peak at around 1384 cm^{-1}. Figure 1 also shows that the La^{3+} cations and the La_2CuO_4 phase adsorbed onto copper oxide clusters are at 1524 cm^{-1} and 520 cm^{-1} of the catalyst, respectively. Therefore, we suggest here that the catalytic activity of the binary $CuO\text{-}La_2O_3$ composite oxide catalyst system in oxidizing ammonia may be explained by the reversible redox behavior of $CuO\text{-}La_2O_3$ couples in promoting the functional mechanism. Figure 2 presents the X-ray diffraction (XRD) patterns at various Cu-La molar ratios, verifying the presence of CuO and La_2O_3 phases of the Cu-La composite metal catalyst. The dominant CuO diffraction peaks appeared near 2θ=35.4926 and 38.7593° for a CuO/La_2O_3 composite metal catalyst. La_2O_3 in a copper catalyst may be assumed promote the formation of the active phase of CuO under the conditions of ammonia oxidation, because La_2O_3 is well known that can be increased further thermal stability and oxygen storage capacity. Thus, the X-ray powder diffraction method confirmed the formation of copper (II) and lanthanum (III) oxide active sites on the binary CuO/La_2O_3 composite catalyst.

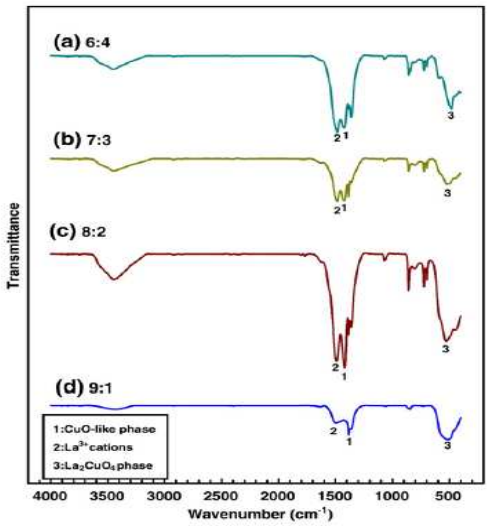

Figure 1. FTIR pattern of various metal content on the CuO/La_2O_3 catalyst for the conversion of NH_3. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, GHSV = 92000 ml/h-g.

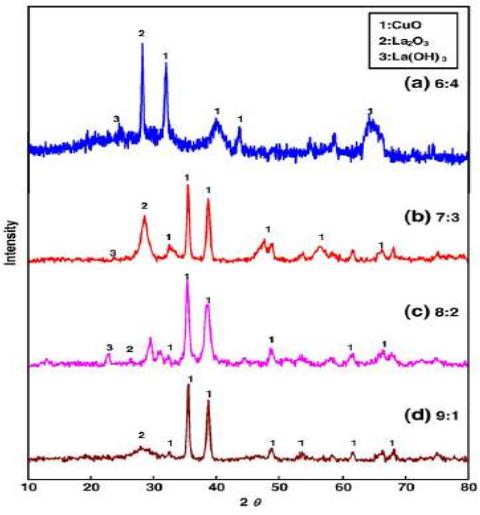

Figure 2. XRD pattern of various metal content on the CuO/La_2O_3 catalyst for the conversion of NH_3. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, GHSV=92000 ml/h-g.

Selective catalytic NH_3 using rare-earth oxides of gasified biomasses fuels. Part 2. Catalytic activity and mechanism study

Presenting author email: hungcm1031@gmail.com

NH_3 is a toxic inorganic gas with a pungent odor under ambient conditions, and is potentially harmful to public health reported in the literature. The selective catalytic oxidation (SCO) of NH_3 in a stream to molecular nitrogen and water is one method for solving problems of NH_3 pollution. This work considers the oxidation of NH_3 from gasified biomasses fuels by selective catalytic oxidation (SCO) over binary rare-earth oxides (Cu-La nanomaterials) at temperatures between 150 and 400℃. Figure 1 plots the measured catalytic activities over the binary CuO/La_2O_3 samples of interest as a function of temperature. NH_3 is converted even at 150℃, and more NH_3 was converted over the Cu-La (8:2) composite catalyst as the temperature increased, approaching 93% at 400℃. The extent of NH_3 conversion increased with temperature and approached 90%, 80% and 79% at 400℃ over Cu/La (9:1), Cu/La (7:3) and Cu/La (6:4) catalysts, respectively. Notably, more lanthanum corresponded to higher NH_3 conversion only at low temperatures. Conclusively, this work shows that the SCO process has the potential to treat highly concentrated streams of NH_3, helping industrial plants to meet discharge regulations. The overall selectivity of N_2 production varied from 12 to 53% and that of NO production varied from 0 to 45% over the range of 3-93% NH_3 conversion at NH_3 concentrations of 1000 ppm (Fig. 2). Nitrogen gas thought to be formed primarily by the dissociation of NO produced by oxidation of adsorbed NH_3. Therefore, according to the experimental results, we hypothesis that NH_3 and oxygen may be adsorbed onto specific sites on the binary CuO/La_2O_3 (8:2) composite catalyst, promoting the rapid conversion of NH_3 to nitrogen and water. Nitrogen was the dominant gaseous, and a small amount of NO was detected in the resultant stream.

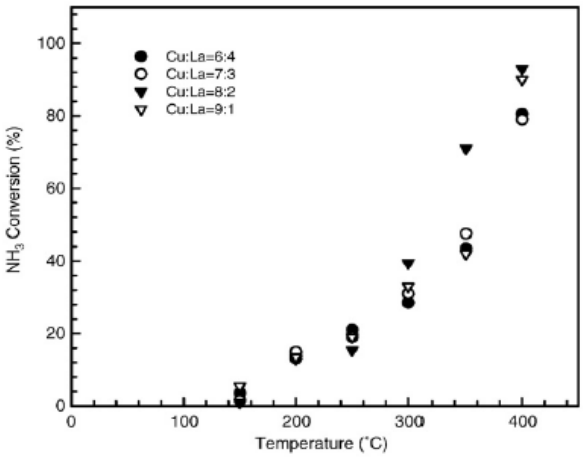

Figure 1. Dependence of the NH_3 content on the conversion, as function of temperature of the CuO/La_2O_3 catalyst. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, GHSV = 92000 ml/h-g.

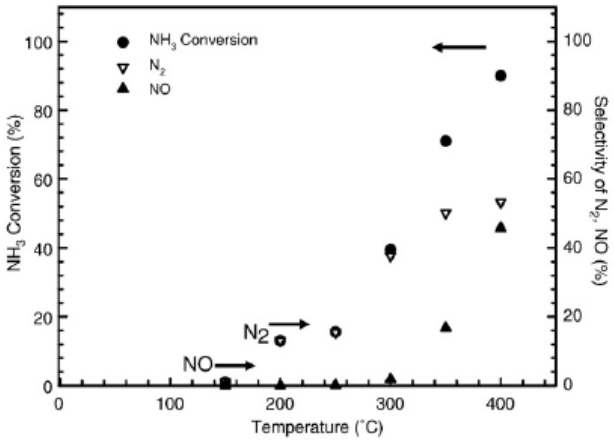

Figure 2. Relationship among NH_3 conversion, N_2 yield, and NO yield at various temperatures over the CuO/La_2O_3 (8:2) catalyst. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, Temperature = 150-400℃, GHSV = 92000 ml/h-g.

Selective catalytic NH_3 using rare-earth oxides of gasified biomasses fuels. Part 3. Reaction kinetic behavior study

Chang-Mao Hung[1], Shui-Jen Chen[2], Wei-Bang Lin[3] and Wen-Liang Lai[4]

Keywords: ammonia, binary CuO/La_2O_3 composite catalyst, kinetic model.
Presenting author email: hungcm1031@gmail.com

Ammonia (NH_3) is widely found in industrial processes and it is a valuable chemical product for using with a variety of purposes and its can be eliminated in several ways, including ammonium nitrate production industry, livestock feedlots, urea manufacture plants, nitrogen fertilizer application industry, biomass combustion or petroleum refineries, and refrigeration industry, which are either toxic inorganic gaseous and its pungent malodorous component under ambient conditions or have the potential harmful effects on the public. Moreover, the kinetic behavior of NH_3 oxidation with catalysis can be accounted by using the rate expression of the kinetic model. Kinetic parameters are also developed on the basis of the differential reactor data in this study. The adsorptive and catalytic behavior of a catalyst is strongly influenced by the capacity and texture of its exterior surface. Figure 1 summarizes the properties of test catalysts determined by BET (Brunauer-Emmett-Teller method) analysis, including specific surface area. The specific surface area was 72 m^2/g with molar ratios of 8:2. For the molar ratios of 6:4 on a CuO/La_2O_3 composite metal catalysts, the surface areas slightly decreased (4 m^2/g). This test showed that the catalysts were associated with a larger lattice surface of copper or lanthanum, and that higher loadings caused metal sintering, perhaps reducing catalytic activity. The change in the sizes of particles of the catalyst was determined using the laser light-scattering method, as depicted in Fig. 2. The mean particle size converged to approximately 12.3, 13.6, 9.3, and 8.7 μm, for fresh CuO/La_2O_3 composite catalysts with the four molar ratios, 8:2, 9:1, 7:3 and 6:4. However, the diameters of the catalyst decreased as the copper content declined, indicating that co-precipitation aggregates the low metal molar ratio. Moreover, a kinetic rate expression was developed to describe the data over the range of conditions investigated. Furthermore, correlation equations in the form of Arrhenius's law are derived from experimental data to predict the destruction efficiencies of ammonia from the temperatures and residence period in a catalytic process. A Langmuir-Hinshelwood model incorporating a first-order reaction appears to adequately represent the NH_3 oxidation, which shows fairly good agreements with experimental data. This kinetic model is appropriate for oxygen presence and high concentrations of NH_3.

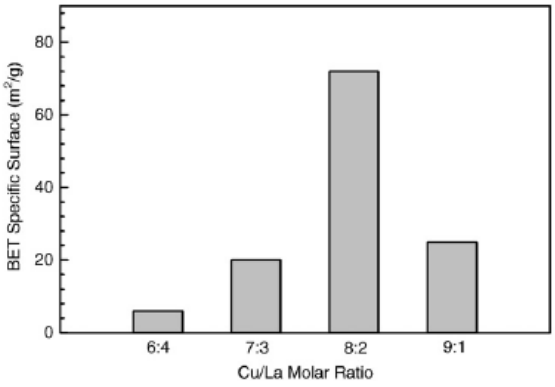

Figure 1. Effect of specific surface area on the CuO/La_2O_3 catalyst for the conversion of NH_3. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, GHSV = 92000 ml/h-g.

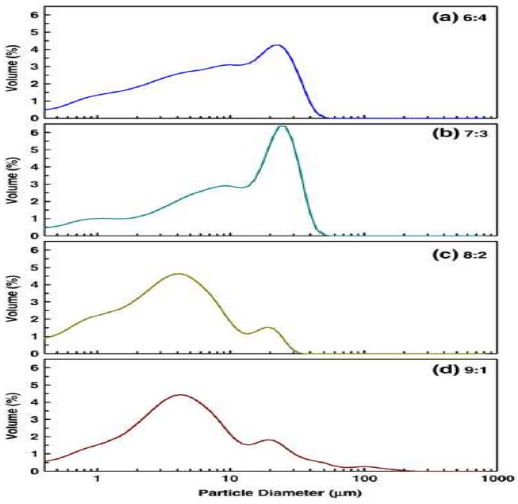

Figure 2. Changes in particle sizes distribution with various calcinations temperature on the CuO/La_2O_3 catalysts. Test conditions: 1000 ppm NH_3 in He, O_2 = 4%, RH = 12%, GHSV = 92000 ml/h-g.

Results and experience of long-term study of reduction of fine particle emissions from wood combustion boiler by a compact electrostatic precipitator

A. Bologa, H.-R. Paur and K. Woletz

Institute for Technical Chemistry, Karlsruhe Institute of Technology
Hermann-von-Helmholtz-Platz 1, Eggenstein-Leopoldshafen, 76344, Germany
Keywords: biomass combustion, fine particles, emission control, electrostatic precipitator.
Presenting author email: andrei.bologa@kit.edu

In the Europe the combustion of wood is widely used for domestic heating. The power generation is mostly done by means of combustion of wood-logs, chips or pellets in small scale combustion appliances, e.g. stove and boilers.

Wood combustion it is responsible for emissions of fine particles which are associated with various diseases. Usually particles are composed of ash, elemental carbon and organic matter and particle chemical composition, particle size distribution, number and mass concentration vary greatly depending on the design of the boiler, fuel quality, mixing of air and fuel, combustion temperature, etc.

Last time various filter systems were developed for reduction of fine particle emissions from small scale biomass combustion. These devices include cyclones, wet scrubbers, condensers, bag filters, cartridge filters, electrostatic precipitators (ESPs'), etc. The electrostatic precipitators are the most attractive devices as they ensure high mass collection efficiency and are operated at low power consumption and low pressure drop in comparison with other gas cleaning equipment. The design of the ESPs' range from conventional to space charge ESPs', from dry to wet units, from precipitators integrated into the combustion appliances up to the ESPs' installed downstream the combustion units, inside of the gas duct and/or chimney and at the exit of the chimney.

By biomass combustion in the boilers with integrated hear exchangers, the electrostatic precipitators are operated at gas temperatures of 100-200°C and for wood-log stoves up to 300-400°C.

The purpose of the current work is to present the results of the study of reduction of fine particle emissions from a 100 kW wood-combustion boiler by use of the CAROLA electrostatic precipitators.

The CAROLA electrostatic precipitators are developed in the Karlsruhe Institute of Technology in the Institute of Technical Chemistry. In the ESPs' the gas cleaning technology is based on the particle charging in a corona ionizer and charged particles precipitation in the grounded, external electric field free collector. The DC negative corona discharge is used for particle charging in the precipitators (Bologa *et al*, 2010).

For effective reduction of fine particle emissions from the exhaust gas, the compact CAROLA-precipitators are designed for boilers with capacity of 10 kW, 25 kW and 50 kW. For the long-term tests, several electrostatic precipitators were manufactured and installed in parallel downstream the 100 kW wood-chips combustion boiler. The purpose was to study the long-term operation stability of the ESPs', power consumption and the mass and fractional collection efficiency of the precipitators.

The particle mass concentration in the gas flow upstream and downstream of the ESPs' was measured by gravimetric method according to the German norm VDI 2066. For the measurements of particle number concentrations in the gas flow, the Scanning Mobility Particle Sizer (SMPS, Fa. Grimm) was applied.

The stability of the operation of the precipitator was ensured by the protection of the high voltage insulator with a screen electrode from the direct particle loaded gas flow. The ESPs' were operated without any additional air input for the high voltage insulators protection from loading with fine particles (Bologa *et al*, 2011).

The CAROLA-precipitators were operated with relatively small electrode gaps in the ionizer at maximum operation voltage of 20 kV and corona current of 1,5 mA. Thus the designed precipitators were characterized by the low power consumption.

The designed CAROLA-electrostatic precipitators are the space-charge ESPs' in which particles are precipitated on the surface of the grounded brush electrodes installed in the collector stage of the unit (Bologa *et al*, 2012). A single brush electrode is currently used in the ESP modules up to 25 kW boiler and double brush electrodes are used in the ESPs' for the boilers with capacity of 50 kW. In the designed modules, the automatic cleaning of the collector stage is realised by the periodical rotation of the brush electrode(s).

Among the control of fine particle emissions, in the current work it is planned to discuss the results of the measurements of the gaseous emissions from the wood combustion boiler and the possibilities for their reduction.

Comparison of Methods for On-Line Measurement of Diesel Particulate Matter

Z. Liu, J. Swanson, D.B. Kittelson and D.Y.H. Pui

Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, 55455, USA
Keywords: Diesel emissions, Aggregates, Mass concentration, Soot size distribution.
Presenting author email: jswanson@me.umn.edu

Gravimetric analysis is the regulatory method for diesel particulate mass measurement. Due to inherent problems such as adsorption/volatilization artifacts, it faces obstacles in measuring ultra low level emissions from modern diesel engines. Alternative methods of suspended particle mass measurement have been developed that showed significant improvements in time resolution, sensitivity, and accuracy. Three size-resolved methods were considered here. Two methods rely on inverting number size distributions obtained using a scanning mobility particle sizer (SMPS). Inversion techniques were based on effective density measurements (Park *et al*., 2003) and the Lall-Friedlander (2006) aggregate model. The third method employed the Universal Nanoparticle Analyzer (UNPA) (Wang *et al*., 2010) to measure the aggregate size distribution, from which mass is calculated.

We compared the results with gravimetric analysis (Figure 1) and found correlations ranging from high (R^2 >0.99) to modest (R^2 =0.61), depending on the method. The ratio of alterative method to filter mass concentration was calculated to be 0.99 ± 0.04, 0.47 ± 0.03 and 0.45 ± 0.19 for the effective density method, the Lall-Friedlander inversion, and the UNPA, respectively over a wide range of engine operating conditions. A catalytic stripper (CS) was used to evaluate the impact of semi-volatile particles and hydrocarbons on mass measurement. Results obtained by comparing "CS and "no CS" results suggested there were no sampling artifacts due to adsorption of gaseous hydrocarbons on the filter.

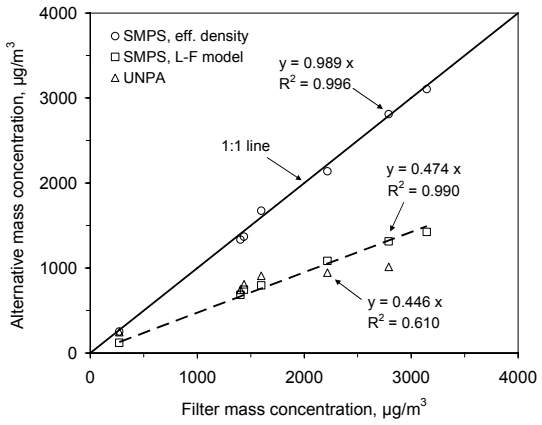

Figure 1. DPM mass concentrations by alternative methods in comparison to gravimetric analysis.

We also compared the diesel aerosol mass distributions obtained by the on-line methods. Figure 2 shows agreement to 15% - 20% in terms of mass mode measured by the different methods. As with the total mass concentration, the lower differential concentrations in reference to the effective density measurements are thought to arise from the fact that the diesel soot structure does not satisfy the loose aggregate assumption in the Lall-Friedlander model. Calculations based on particle counting uncertainty indicated that these on-line methods have a measurement sensitivity that is several orders of magnitude higher than that of the gravimetric analysis.

This study further demonstrated the robustness and value of the effective density measurement. Other results suggest that mass concentrations calculated using available aggregate models are limited in accuracy. Further work is needed to better understand the extent to which diesel particles can be modelled as loose aggregates. This will require better characterization of the charging and drag properties of particles found in diesel exhaust.

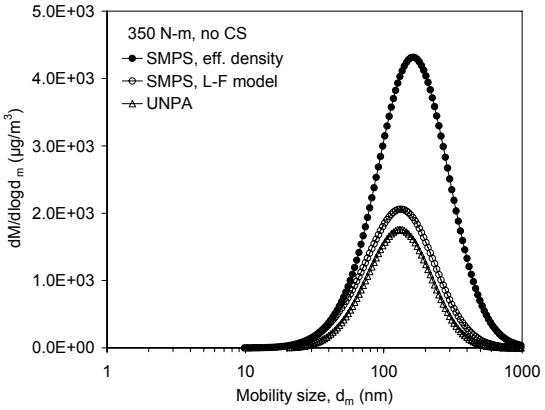

Figure 2. Comparison of DPM mass distributions measured by different on-line methods.

This work was supported by the Center for Filtration Research at University of Minnesota. Experiments were carried out in facilities of Center for Diesel Research at the same institution.

Laboratory investigation of PAH transformation during NO_2-based DPF regeneration

J. C. Wolf and R. Niessner

Chair for Analytical Chemistry, Technical University of Munich, Marchioninistr. 17, 81377, Munich, Germany

Keywords: PAH, oxygenated PAH, NO_2, Diesel exhaust, Filter.
Presenting author email: jan.wolf@mytum.de

In the meantime Diesel Particle filters (DPF) are an inherent part of our present automotives. These filters drastically reduce the emitted mass of soot particles. Because soot is a known carcinogen, this technology seems to be very beneficial to human health. But the carcinogenic potential of soot is mainly attributed to the adsorbed pollutants on the soot surface. Especially polycyclic aromatic hydrocarbons (PAH) are considered responsible for the mutagenic potential. To prevent DPF plugging and engine damage in consequence, these filters have to be regenerated. In many cases this is achieved by increasing the amount of NO_2 in the exhaust stream to alleviate the soot oxidation. During this regeneration the PAH are affected as well and will most likely follow one of two possible reaction pathways. During reaction with NO_2 they can be either oxidized or nitrated. Both reactions would lead to more toxic PAH derivates as oxygenated PAH (OPAH) or nitrated PAH (NPAH).

Our research tries to identify whether PAH nitration or oxidation is the most predominant transformation reaction during DPF regeneration. Therefore a laboratory simulation system for diesel exhaust gas mimic was constructed. In this setup spark-discharge soot, which is PAH-free, is coated with a submonolayer of benzo[a]pyrene (B[a]P) and directed to a miniaturized DPF (PM-Kat®-like) structure, where it gets trapped. The regeneration of the filter structure can be controlled by temperature as well as the amount of NO_2 or oxygen passing through. Even different regeneration cycles can be simulated with this system, with the advantage, that only one PAH (here B[a]P) and its reaction products are monitored.

To ensure artifact free sampling a highly efficient NO_2 denuding system was placed in line after the DPF structure prior to sampling. Right after the NO_2 denuding system the gaseous reaction products were sampled by use of a XAD4 coated annular denuder. The particle phase was collected downstream on a quartz fiber filter. The NO_2 denuding system is limited to a sampling gas temperature of <200°C. So we investigate the temperature range of 25°C up to 200°C.

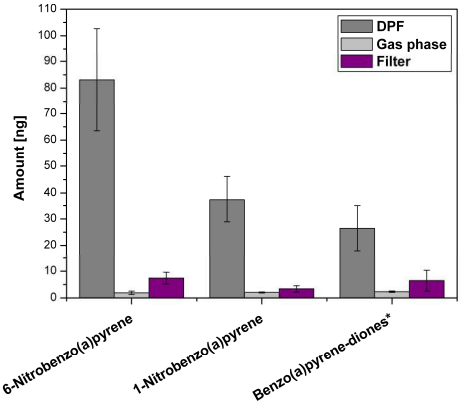

Figure 1.: Nitro- and oxy-B[a]P formation in the PM-Kat® like simulation system at 100°C and 50 ppm NO_2.(*sum of 1,6-, 3,6- and 6,12-B[a]P-dione)

Analysis was carried out by means of HPLC coupled to a high resolution mass spectrometer (*Thermo Fisher Exactive Orbitrap*). Ionization was performed by atmospheric pressure chemical ionization (APCI). This method is very sensitive for NPAH as well as for OPAH (LOD in the range of 0.05 – 0.50 Pg/µl; 10 µl injection Volume). Additionally the high resolution full mass scan (100-800 m/z) enables screening and identification of unknown reaction products.

Our experiments show that B[a]P is transformed into 1-,3- and 6-nitro-B[a]P as well as into B[a]P-diones. This transformation takes place exclusively in the DPF structure and is dependent on the NO_2 concentration passing the DPF. Our results find nitration is the preferred reaction mechanism at temperatures up to 100°C (see. figure 1). Nevertheless, our findings indicate oxidation might become the more important pathway with further temperature increase.

In summary, our results prove the transformation of B[a]P to nitrated and oxygenated derivates inside a DPF, continuously regenerated with NO_2.

Presenting author email: jtopinka@biomed.cas.cz

Introduction

Last decades are characterized by massive use of alternative fuels, including biofuels. Since the reports on the toxic effects of exhaust from engines powered by biofuels are often contradictory, it might be of great interest to compare genotoxicity of standard diesel particulate emissions with that of the most frequently used biofuels. For this purpose we performed the pilot study with the aim to identify possible genotoxicity induced by organic extracts from the samples of exhaust of engines running on diesel fuel, biodiesel (neat methylester of rapeseed oil) and neat heated, fuel-grade rapeseed oil. The engines were tested in a laboratory using engine dynamometers.

Methods and Results

In one set of tests, a Zetor tractor engine with an inline mechanical injection pump and no exhaust gas aftertreatment device was tested using the NRSC cycle (also the ISO-8178 test with C-1 weighing, normally used for certification of non-road engines) and the ISO-8178 test with C-2 weighings, representing low-load operation. A sample of undiluted exhaust was drawn through a cartridge with a fluorocarbon-coated filter and two polyurethane foam plugs, with 2.0-3.5 m^3 of exhaust sampled. As a marker of the genotoxic potential, DNA adduct levels induced by extractable organic matter (EOMs) in an acellular assay of calf thymus DNA coupled with ^{32}P-postlabeling in the presence and absence of microsomal S9 fraction (contains enzymes for metabolic activation of genotoxic compounds such as PAHs) were employed. Simultaneously, chemical analysis of 16 priority PAHs in EOMs, including 7 carcinogenic PAHs (US EPA) was performed. The results suggest that on ISO-8178 non-road engine test cycle, C-2 schedule, representing low engine loads, the organic extract from standard diesel particulate emissions induces highest DNA adduct levels (53 adducts/10^5 nucleotides/ kWh), while rapeseed oil and methyl esters of rapeseed oil induce 5.8 and 2.4 adducts/10^5 nucleotides/ kWh, respectively. These results correlate with the content of carcinogenic PAHs (c-PAHs) and B[a]P in the corresponding EOMs.

In a second set of tests, the exhaust was routed to the laboratory main exhaust duct, which has served as an improvised full-flow dilution tunnel, with dilution ratio of approximately 1:100 at idle to 1:15 at full load. From this duct, diluted exhaust was sampled with high-volume samplers (Digitel) on the Teflon coated filters (Pallflex) normally used for ambient air quality measurements, at rates 500-1000 litres per minute, with a target accumulation on the order of 10 mg of particulate mass. Two engines were tested. One was a Cummins ISBe4 engine with a Common Rail fuel injection system and no exhaust gas aftertreatment device, tested using the World Harmonized Stationary Cycle (WHSC) and modified Engine Stationary Cycle (ESC). The ESC cycle was modified by altering the length of each of the 13 modes and including transitions between modes to facilitate continuous sampling. The other engine was the Zetor engine described above, which was tested using the NRSC cycle. Filters were extracted by dichlormethane and genotoxicity of extracts was analyzed by ^{32}P-postlabelling of DNA adducts by test described in the previous paragraph. Major results are described in Table 1.

Table1. Genotoxicity of the organic extracts from particulate emissions of selected fuels

Engine fuel injection	Fuel /cycle	PM mg/kWh	7c-PAH µg/kWh*	DNA add. /10^8 n./kWh**	
				+S9	-S9
Cummins ISBe4 Common Rail	D[1]/WHSC	6.9	0.59	271	119
	R[2]/WHSC	7.2	0.77	198	16
	D[1]/ESC	14.1	2.05	648	175
	R[2]/ESC	23.8	1.76	473	182
	B[3]/ESC	20.2	1.63	542	182
Zetor 1505	D[1]/NRSC	185	18.33	3678	1038
	R[2]/NRSC	202	11.39	2950	1096

*7 carcinogenic PAHs: benzo(a)anthracene, chrysene, benzo(b) fluoran-thene, benzo(k)fluoranthene, benzo(a)pyrene, indeno(1,2,3-cd)pyrene, dibenzo(a,h)anthracene; **DNA adducts/10^8 nucleotides/kWh; [1]D-diesel; [2]R-rapeseed oil; [3]B-biodiesel B-100

Conclusions

1. The emissions of classic diesel contain more of total PAHs, but much less B[a]P and other carcinogenic PAHs.
2. Genotoxicity of particulate emissions of selected biofuels is comparable with a classic diesel.
3. Metabolic activation (+S9) resulted in several fold higher genotoxicity suggesting major contribution of PAHs to the DNA adduct levels. However, directly acting genotoxicants (-S9) are also significant.
4. Genotoxicity is highly dependent on the test cycle (ESC vs. WHSC).
5. Genotoxicity of the emissions is dose dependent.

These results should be taken as preliminary and more detailed study is going on to verify these preliminary findings.

Experimental Investigations of Sensitivity of Lichens to Diesel Exhaust under Lab Conditions

U. Langmann[1], P. Madl[2], W. Hofmann[2], G. Brunauer[1], R. Türk[1]

[1]Department of Organismic Biology, University of Salzburg, A-5020 Salzburg, Hellbrunnerstr. 34, Austria

Keywords:, Diesel exhaust, air pollution, laboratory experiments
Presenting author email: ulrike.langmann@stud.sbg.ac.at

The lichen vegetation reacts very sensitively to increased nitrogen-concentrations as well as to traffic exhaust and other pollutants in the air. Therefore, lichens are reliable indicators for air pollution. Recent environmental studies have shown that the loss of acidophytic lichen species and the increase of nitrophytic lichens can be explained by the increasing input of atmospheric generated nitrogen-compounds related to nanoparticles (Heinzelmann, 2007; Madl et al., 2010). This observed decreasing diversity of lichens due to increasing air pollution is followed and accompanied by a decrease in diversity of higher plants and animals and is therefore regarded as an optimal biomonitor for air pollution.

By the investigations presented here the effects of Diesel exhaust on the symbionts of six lichen species with different pollutant sensitivities are analysed. In a sealed stainless steel-chamber the pollution with Diesel exhaust was simulated for three weeks, which corresponds to the rhythmic rush hours cycles of a local highway. The closed chamber guarantees, that influences other than Diesel exhausts are excluded. Diesel Aerosols were fed into the chamber using a Tedlar-bag. Appropriate humidity levels were provided using an impiger powered with Hepa-filtered air. As a light source a HQ-400W lamp was used. A water-cooled system kept the tank temperature at physiologically optimal levels. Nanoparticles were quantified with an SMPS-system and the photosynthetic activity of lichens was measured with both a chlorophyll-fluorescence - Imaging-PAM as well as Mini-PAM devices. Vitality of lichens was determined by CO_2 gas exchange measurements.

The investigations provide explicit data, which show the negative effect on the photosynthesis of the lichens‘ photobionts. The measurements of treated lichens with Mini-PAM reveal that the electron-transport-rate ETR does not differ significantly from lichens, which are not exposed to Diesel exhaust.

The distinct quenching-rates qP and qN of fluorescence trends are evidence of the negative impact of Diesel pollutants (see Fig. 1 and Fig. 2). Therefore, we conclude: Diesel exhaust does not interfere directly with the photosystem II but affects the proton-gradient at the membrane between photosystem II and ATP-Synthase. Hence, ATP- and NADPH-yields along with the associated carbohydrate-synthesis of the Calvin-cycle of the photobiont are impaired. In effect the photobiont dies. The mycobiont is starved as it is dependent on the carbohydrate-synthesis of the photobiont.

Another remarkable result of this preliminary study is that the lichens are showing signs of regeneration when they are not exposed to Diesel-exhaust over week-ends as they regain nearly the same PAM-values as at the beginning of the investigations.

During these experiments we could also assess the optimal light, moisture and temperature conditions for the following long-term studies in order to eliminate light- and heat-stress.

To our knowledge this is the first study testing the impact of Diesel exhausts on lichens under laboratory conditions eliminating other interfering factors like in other environmental studies.

Nanoparticle emissions from ships calling the port of Gothenburg

J. Westerlund[1], M. Hallquist[1] and Å.M. Jonsson[2]

[1]Atmospheric Science, Department of Chemistry and Molecular Biology, University of Gothenburg, 412 96, Gothenburg, Sweden
[2]IVL Swedish Environmental Research Institute Ltd, Box 5302, 400 15, Gothenburg, Sweden
Keywords: shipping emissions, emission factor, coastal area, number size distribution
Presenting author email: jonathan.westerlund@chem.gu.se

Shipping is an important contributor to global emissions of air pollutants affecting both climate and health. Emissions from shipping are poorly regulated in legislation and 70 % of ship emissions occur within 400 km off land (Corbett et al., 1999). Ultrafine particles (UFP) are recognized to be one of the key elements in urban air pollution and particle number is believed to be a better measure for health effects than currently regulated mass standards (Kumar et al., 2010). In this study both number, mass and size of volatile and non-volatile particles are addressed.

Stationary ship plume measurements were conducted according to previous studies on shipping and road side measurements (Hak et al., 2009; Jonsson et al., 2011). The site was located in the entrance to the port of Gothenburg, the largest port of Scandinavia, which is an emission control area (ECA) with a newly introduced regulation limiting the fuel sulphur content to 1 % by weight. Particles were characterized using CO_2 as a tracer for fuel combustion and EFs (Emission Factors) were calculated using Eq.1:

$$\mathrm{EF_{part}} = \frac{\Delta \mathrm{part}}{\Delta \mathrm{gas}} \times \mathrm{EF_{gas}} \qquad (1)$$

where $\Delta part$ and Δgas are changes in particle number /mass and CO_2 during ship passages and EF_{gas} is the EF for CO_2.

The measurements were performed for real world dilution and for plume age time scales relevant to a harbour city (30-500 s), allowing plumes to travel several kilometres inland. Ship particle number EFs on individual basis are currently scarce and number emission factors cause the biggest uncertainty in dispersion modelling (Holmes and Morawska 2006).

In a previous study 734 EFs for particle number and mass were determined (Jonsson et al., 2011) and they have now been further extensively analysed. 613 ship passages were coupled to identifiable ships using AIS-data (Automatic Identification System) and were found to originate from 154 different ships. They were divided into 3 ship classes, as presented in Table 1. Significant differences were found between the ship classes both regarding particle number, mass, size and volatility. Engine load was found to be an important factor and was indirectly studied by comparing ship speed and acceleration differences between the ship passages. Age also seemed to have an effect on the EFs with a few older ships emitting more particles. An SCR-equipped passenger ship was analysed specifically. This ship had a remarkably high non-volatile number EF when leaving the harbour (2.3 times higher than the other departing ships).

In a typical harbour a number of supporting ships are in addition to the main cargo and passenger ship also active. It was demonstrated that for example tug and pilot ships had distinctly different particle emission characteristics. The differences between the individual ships and classes are important features and are discussed in relation to other studies and the air quality in harbour cities.

Table 1. Three ship classes with EFs for number and mass together with the log-normal distribution fit parameters CMD (count median diameter) and GSD (geometric standard deviation).

		Total particles (Non-volatile particles)			
Ship class	Speed ($m\ s^{-1}$)	EF_{PN} # $(kg\ fuel)^{-1}$ $\times 10^{16}$	EF_{PM} mg $(kg\ fuel)^{-1}$ $\times 10^{16}$	CMD (nm)	GSD
Cargo	8.49± 0.29	2.86±0.21 (1.39 ± 0.33)	2590±196 (521±110)	38.8 (13.3)	1.56 (1.57)
Non-cargo	10.4± 0.29	2.37±0.20 (1.33 ± 0.43)	2230±687 (432±92.2)	40.3 (13.7)	1.54/ 1.54
Tug/ Pilot	15.2± 1.68	1.67±0.27 (0.52±0.22)	1190±868 (404±251)	29.7[a], 10.3[a] (10.3)	1.73[a], 1.20[a] (1.35)

[a]Tugs and pilots had for the total particles a bimodal size distribution

Detailed chemical characterization of PM and COV, and source apportionment near a French highway

Contact email: polo@lgge.obs.ujf-grenoble.fr

The relation between exposure to ambient fine particulate matter (PM) and human mortality is now well established, particularly in the roadway proximity. Further, Hoffman et al (2009) showed the link between long-term residential exposure to high level of PM and coronary atherosclerosis. Improving air quality for reducing morbidity and premature death has become an urgent need. In spite of the evolution of vehicle motorization, the PM_{10} level has not been decreasing proportionnally in urban environments during the last decade (Harrison, 2008). The characterization and quantification of traffic emissions are still poorly known for the French motor vehicle fleet. These emissions involved exhaust and non-exhaust emissions (i.e. road-traffic like re-suspension of road dusts, from brake, tyre and road-surface-wear, from the corrosion of vehicle components…). The PM_{10} emissions related to traffic can represent up to 60% non-exhaust emission (Bukowiecki, 2010). A detailed chemical characterization of exhaust and non-exhaust traffic related emissions is still needed.

In order to characterize the chemical composition of traffic sources, detailed measurements were performed in the vicinity a suburban highway characterized by regular traffic congestions in Grenoble-Echirolles (France). Measurements were simultaneously conducted at an urban background site (Grenoble-Les Frênes), 2.5km away. This two weeks campaign took place in September 2011 within the MOCOPO and PM-Drive programs. PM_{10} and Volatile Organic Compounds (VOCs) were sampled on a 4h basis at the two different locations. In addition, high time resolved measurements (HR-ToF-AMS, PTR-ToF-MS, MAAP, SMPS…) were performed at Grenoble-Echirolles. At the same time, the traffic on the highway was recorded with a high temporal resolution (loops and systems allowing vehicles identification).

HR-Tof-AMS has been used to measure the concentration and chemical composition of the non-refractory submicron aerosol. Figure 1 presents the temporal evolution of two well-known fragments derived from AMS measurements: mz 57 (mostly $C_4H_9^+$) and m/z 44 (mostly CO_2^+), considered as markers of HOA associated with fuel derivatives emissions and OOA associated with secondary organic aerosol respectively. The mz 57 fragment follows clear daily cycles highly correlated with traffic and BC (MAAP). The evolution of mz 44 is completely different, and is well related with that of ions from secondary origins like sulfate, nitrate, and ammonium. A strong link also exists with the weather pattern during this two-week campaign. These first results allow already a distinction between the traffic emissions and others sources, which is a good foundation for this study.

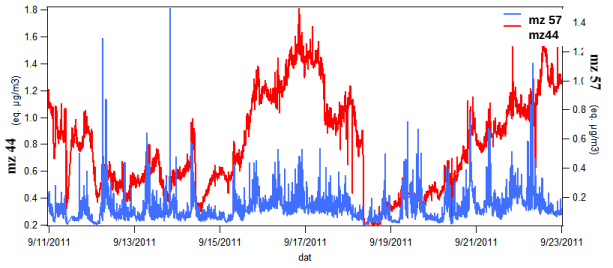

Figure 1: Temporal evolution of the fraction m/z 57 and m/z 44 at Echirolles (France)

Off-line sampling allows the detailed chemical characterization of aerosols notably the organic speciation with the aim of research of source tracers and determination of chemical fingerprints of large chemical families (hydrocarbons, PAH, saccharides…). About eighty compounds have been quantified. Further, a large array of trace metals was also measured on these filters. From these results, both the Chemical Mass Balance (CMB) and Positive Matrix Factorization (PMF) models will be used in order to apportion the contribution of influential sources including non-exhaust traffic emissions. These results will be presented and compared with on-line data and with traffic.

Time-resolved NO_2 analysis in the presence of soot

J. C. Wolf, K. Thaler, R. Niessner, and C. Haisch

Chair for Analytical Chemistry, Technische Universität München, Marchioninistr. 17, 81377, Munich, Germany

Keywords: NO_2, soot, transient analysis, Diesel exhaust, sampling artefact.
Presenting author email: Christoph.Haisch@ch.tum.de

Nitrogen dioxide plays a major role in Diesel exhaust aftertreatment technology as well as in atmospheric transformations. NO_2 is routinely monitored, either by FT/IR spectrometers or by chemiluminescence detectors. Both are commonly used in automotive exhaust measurements at test bench experiments, where a time resolution in the range of a second is required. Since soot particles cause contamination and artefacts in both measurement techniques, the soot particles are filtered in front of the measurement devices. Several authors did report about the heterogeneous reaction of NO_2 and soot. However, there are hardly any systematic investigations devoted to the consequence of these interactions on the precision of NO_2 measurement, and particularly to transient analyses. Over an instrument service period, the pre-filter of these instruments can acquire significant loads of soot, which can influence the NO_2 measurements to varying amounts. Even more severe, we observed this effect not only on filters, but also in the tubings and gas handling system, transferring the gas from the emission source to the analysis instrument.

Our investigations focus on the artefacts induced by soot-loaded filters and contaminated tubings on the total NO_2 concentration, and particularly to the influence on the temporal dynamics of the instrumentation. A propane burner (in-house made) and a spark discharge generator (Palas, GFG1000) were employed to systematically load tubings and filters with soot. In this investigation, PVC, Tygon®, Teflon®, stainless steel tubings, and quartz fiber filters were investigated. After weighting, the soot loaded tubings and filters were exposed for 3 minutes to high concentrations of NO_2 (~100 ppm). The transmitted NO_2 concentrations were measured using a newly developed photoacoustic sensor, which allows for the simultaneous detection of soot and NO_2 sensor with a response time below 1 s. Filter experiments were performed at different reaction temperatures between 20°C to 75 °C, while the tubing experiments were carried out at 20°C only.

Our first results show a significant influence of the soot load in tubings and filters on the rise time of the NO_2 and, depending on the experimental conditions, also on the absolute concentrations (see Fig. 1). These effects are more pronounced for spark discharge soot than for flame soot, which can be attributed to the higher reactivity of the former. This observation suggests the reaction mechanism proposed by Tabor et al., where NO_2 is adsorbed to the reactive sites in a first reaction. In a second step, the adsorbed molecules oxidize this active site and are released as NO, which results in a passivation of the soot surface. As it can be seen in Fig. 1, a second exposure period of the same filter to NO_2 was less affected by artefacts, which again favours the passivation of the surface during the first NO_2 exposure.

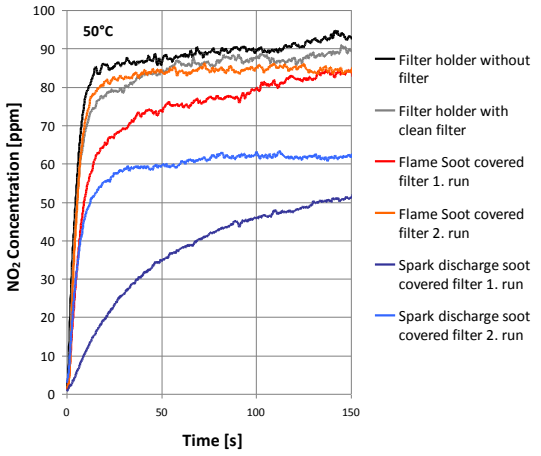

Figure 1.: NO_2 concentration (at 50 °C) downstream a filter holder: (black) without filter; (grey) with a clean quartz fiber filter; (red/orange) with a propane soot loaded filter; (dark blue/blue) with a spark discharge soot loaded filter.

Similar effects were observed for soot loaded tubings, where the tubing material influences the effects quantitatively. In contrast to the filter analyses, full transmission is reached for any material after a certain time (seconds to minutes).

In summary, our results suggest a significant risk of artefacts during NO_2 measurement in the presence of soot aerosol. This effect might be minimized by increasing the sampling gas flow and using PVC or Tygon® tubings.

Particle size and number distribution of particles emitted by a modern diesel engine using mineral diesel and Biodiesel from Soybean

C. C. Barrios S, A. Domínguez-Sáez, C. Martín Jiménez
Environmental Department, CIEMAT, Avda. Complutense, 22. 28040, Madrid, Spain

Keywords: Biofuels, nanoparticles, particle size distribution and vehicles emissions.
Presenting author email: carmen.barrios@ciemat.es

For several decades, studies have shown the biodiesel of vegetal origin as a good substitute for mineral diesel in its application as a fuel for diesel engines because of its energy efficiency and emissions with less environmental impact (Chung *et al.*, 2008). However, the knowledge of the direct relationship between human health problems and the emission of nanoparticles from internal combustion engine has generated the necessity to know the physical characteristics of these particles when they come from the biodiesel blends combustion in different proportions and their differences with the particles from mineral diesel combustion (Avinash *et al.*, 2011). So far, studies on exhaust emissions from diesel engines have shown that particulate emissions from these engines are one of their biggest problems (Tzamkiozis *et al.*, 2012). The aim of this study is to make a comparative study of the distribution in size and number of particles emitted by a modern diesel engine (EURO 4, TDI) working with mineral diesel versus a blend of mineral diesel-biodiesel of vegetal origin (soybean) in a proportion of 30% by volume (B30). The choice of this blend proportion is because this is the maximum proportion of biodiesel which does not affect significantly the operating conditions of the inlet system elements of the motor and the ignition delay (Buyukkaya., 2010).

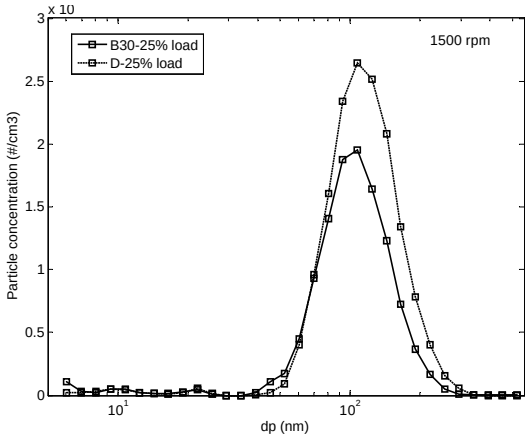

Figure 1- Particle size and number distribution at 25% rated engine load for 1500 rpm using mineral Diesel and Biodiesel (B30).

For load operating conditions tested (25%) at 1500 rpm, it have been observed a decrease in number of total particles of about 25% and an increase in particle sizes below 50 nm emitted by the motor operating with B30, in comparison to mineral diesel. Figure 1 shows the particle size and number distribution emitted during operation at 25% load with mineral Diesel and Biodiesel (B30) and it is important the differences in emission sizes lower than 50 nm from the B30 at same speed and engine load. In Figure 2 the same behaviour observed at 2500 rpm with 25% load, and a displacement of maximum of the curve toward smaller sizes.

The experience of this work has been very helpful, bringing us closer to understanding the physical characteristics of particles emitted by a diesel engine operating with Biodiesel from Soybean and the difference from the particle emitted by the same engine operating with mineral diesel. All experiments that provide results in an increase of the nanoparticles are an important source of information to evaluate the impact (over human health) of widespread use of biofuels in vehicle fleet, especially in urban areas.

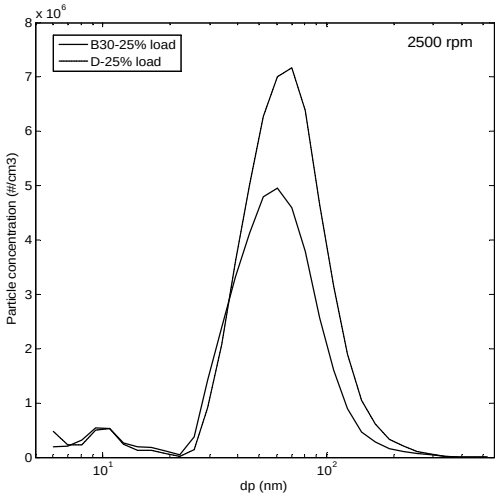

Figure 2- Particle size and number distribution at 25% rated engine load for 2500 rpm using mineral Diesel and Biodiesel (B30).

Measuring black carbon emission factors of cars in real driving conditions

I. Ježek[1], G. Močnik[1]

[1]Aerosol d.o.o., Ljubljana, SI-1000, Slovenia
Keywords: emission factors, cars, diesel emissions.
Presenting author email: irena.jezek@aerosol.si

Describing the influence of traffic on air pollution is complex. The amount of emitted pollutants depends on the vehicle engine, its maintenance, quality and consumption of fuel, filtering or processing of fuel, fluency of traffic, driving regime, topography, and weather conditions. For evaluation of the amount of pollutants emitted, several different tests can be used. Efficiency of combustion is given as an emission factor expressed as either mass of pollutant per fuel consumed or per driven kilometer. Tests for individual vehicles are usually performed in laboratories with dynamometers. With these tests we can get information about influence of used fuel, fuel additives, accelerations, engine type, temperature, dilution etc. These tests are expensive, time consuming and describe emissions of only few vehicles which are supposed to represent the fleet average. As shown in before, Kirchstteter et. al. (1999) and Wang et al. (2011), few individual vehicles (super emitters) can contribute significantly to the fleet emissions, much more than the average vehicle in the fleet.

In previously mentioned studies there have been two different approaches to measuring emissions of individual heavy duty vehicles. The first, performed by Kirchstetter et. al. (1999), measured transient increases of different pollutant concentrations emitted by individual vehicles passing a stationary measuring site. The second, performed by Wang et al. (2011), measured plumes of individual vehicles by chasing them on the road with a mobile station. Because the number of diesel cars is significant in Europe and therefore information on super emitters in the car fleet important, we wanted to test how these two methods work on cars, where the different pollutant emissions are much lower.

We have tested both methods on 4 different diesel cars. The first method was performed with the car passing the measuring site at two different speeds and while accelerating. We have measured concentrations of black carbon (prototype Aethalometer AE33), particle number concentration (FMPS, ELPI+) and CO_2 (Vaisala Carbocap343) on a safety training track field, where there were no other vehicles present at that time.

We have found that measured emission factors can be very versatile for one vehicle. One of the cars tested was a Euro 5 diesel. It emitted so little emissions that most plumes have not been detected by the stationary method. In Table 1 we report emission factors for three Euro 3 diesel cars while driving at two different speeds and while accelerating.

Table 1 Black carbon emission factors (average, std deviation) for three Euro 3 cars measured on two stationary sampling spots with different road slopes. Site 1 was on flat road, site 2 was on a slope.

Black carbon emission factors [g/kg]		Site 1			Site 2		
		car1	car2	car3	car1	car2	car3
50 km/h	average	0.08	0.03	/	0.03	0.09	0.41
	std	0.02	0.02	/	0.01	0.03	0.14
90 km/h	average	0.06	0.10	0.11	0.03	0.06	0.15
	std	0.02	0.03	0.01	0.02	0.03	0.10
acceleration	average	0.22	0.20	0.32	0.18	0.16	0.51
	std	0.15	0.07	0.21	0.12	0.15	0.23

First results show that black carbon emission factors for these three vehicles vary within each group and that measuring on slope did not increase the emission factor. We will show similar variation for particle numbers.

Table 2 Chasing emission factors for black carbon.

BC emission factor [g/kg]	car 1	car 2	car 3
EF	0.16	0.14	0.33
std	0.03	0.04	0.10

Chasing experiment showed slightly different results with higher EF values (Table 2). These are interpreted as being due to varying speed and acceleration during driving on the test circuit. We will show the importance of setting the right parameters for data processing, such as setting the baseline and errors that can be produced during data evaluation.

Operation is in part financed by the European Union, European Social Fund. We would also like to thank AMZS d.d., PE Center varne vožnje, for letting us use their safety training track to conduct our experiments.

Nowadays, particulate emissions of aircraft engines are a main concern for regulatory agencies because of their influence on the air quality decrease and also on the modification of the atmosphere composition. These particulate emissions are mainly constituted by soot aggregates, which are made of primary nanoparticles. Characterizing their size and their quasi-fractal morphology is required to monitor them through on-line measurement techniques or to evaluate their impact as a pollutant.

Since years, the European Aviation Safety Agency (EASA) funds scientific projects aiming to define a new certification requirement of aircraft engine exhausts, through several "SAMPLE" projects (Petzold et al., 2008, Marsh et al., 2009, Crayford et al., 2010). Part of these projects is devoted to characterize the size and morphology of soot aggregates emitted by a combustion chamber that is coupled to a hot end simulator (Wilson *et al.*, 2004). Eight different engine settings have been investigated, representing a range of running conditions that covers different Carbon/Oxygen ratios, namely the low smoke/low organic (LS/LO), low smoke/high organic (LS/HO) and high smoke/low organic (HS/LO) combustion conditions.

For each condition, soot aggregates have been sampled by impaction on Transmission Electron Microscopy (TEM) grids. We have determined the distributions of the primary particles size and the aggregates gyration diameter from TEM pictures (figure 1). Our results show that whatever the combustion conditions the geometric mean diameter of the primary particles is smaller than 10 nm and the geometric mean gyration diameter of the aggregates is below 100 nm. Moreover, the morphology of soot aggregates has also been investigated for each combustion condition in order to study a potential correlation between the aggregates morphology and the engine combustion settings.

Firstly, the aggregates mass fractal dimension has been determined using classical 2D-3D transposition relationships (Baron and Willeke, 2001) but no significant impact of the combustion settings on the mass fractal dimension has been revealed. Secondly, we used three shape factors, namely the roundness, the aspect ratio and the form factor (Chakrabarty *et al.*, 2006, Hentschel and Page, 2003) to characterize the morphology of soot aggregates according to the engine combustion settings. It appears that there is an impact especially on the ramification of the aggregates. Lower the Carbon/Oxygen ratio is, more ramified the aggregates are.

As a conclusion this work investigates relationship between engine setting and soot morphology. This new approach to characterize the real shape of combustion chamber soot is a more sensible methodology than the only quasi-fractal one. To a further extend it may be a complementary tool to distinguish combustion sources

Exhaust emissions and particle hygroscopicity with a diesel engine run with HVO fuel-oxygenate blend

The need to reduce greenhouse gas emissions as well as regulated emissions drives the need to study alternatives for fossil fuels.

Hydrogenated vegetable oil (HVO) is the newest commercially available bio-based diesel fuel. It is composed of paraffinic hydrocarbons and includes essentially no aromatics or sulphur. HVO fuel is reported to lower regulated emissions (Aatola *et al.*, 2008). Compounds containing oxygen (i.e. oxygenates) can be blended to the fuel to further reduce the particle emissions. Oxygen content in biodiesel (i.e. FAME) has been reported to increase the oxygen content in the emitted soot as well as alter the oxidation behaviour of the emitted soot (Song *et al*., 2006). Increased oxygen content in particles could also have an effect on particle hygroscopicity.

In this study (Happonen *et al*., 2012), we investigated how the addition of oxygenate (Di-n-pentyl ether, DNPE) to HVO fuel alters particulate emissions and particle hygroscopicity. Oxygen content in the DNPE-HVO blend was 2 wt-%. The effect on NO_x-emissions was also studied.

The measurements were performed on an engine dynamometer with single-cylinder test engine modified from a commercial six-cylinder off-road common rail diesel engine.

Particle size distributions were measured using a Scanning Mobility Particle Sizer (SMPS) and the total number concentration with a Condensation Particle Counter (CPC). Particulate mass (PM) was measured according to the ISO 8178-1:2006 standard. Particle hygroscopicity was studied using a hygroscopic tandem differential mobility analyzer (HTDMA). We also performed organic/elemental carbon (OC/EC) analysis on collected particle filter samples.

Particulate matter (PM) emission was reduced 26-32% with all measured loads while particle number reduced 10-17%. With 75% and 100% loads NO_x-emission was slightly higher with oxygenate blended fuel, unlike with 50% load where NO_x – emission was 2-3% lower.

Growth factors are all within error limits (one standard deviation), as shown in figure 2. However, the growth factors measured with HVO were measured at approximately 2%RH higher humidity than HVO-DNPE growth factors and still the growth factors with HVO-DNPE are slightly higher than with pure HVO. The differences would be clearer if measured at the same RH. Thus, fuel seems to slightly affect the hygroscopic properties of emitted particles.

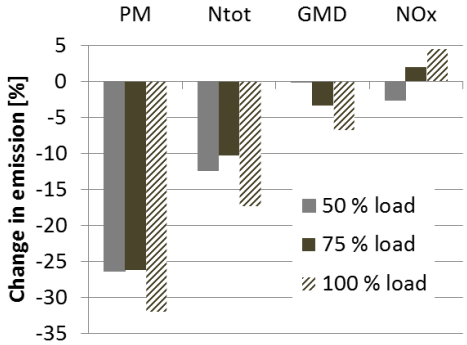

Figure 1. Relative changes in emissions caused by oxygenate blending with HVO fuel.

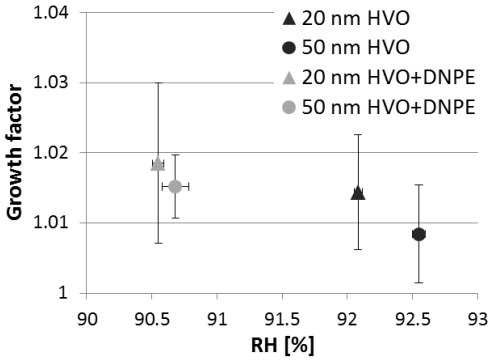

Figure 2. Growth factors of chosen particle sizes with and without oxygenate blending.

This study was funded by Tekes (Finnish Funding Agency for Technology and Innovation).

Effective Density and Fractal–like Dimension of Diesel Soot Aggregates as a Function of Mobility Diameter

P. Baltzopoulou[1], E. Papaioannou[1,2] , M. Kostoglou[3], A.G. Konstandopoulos[1,2]

[3] Div. of Chemical Technology, Dept. of Chemistry, Aristotle University, Thessaloniki, 54124, Greece
Keywords: soot aggregates, effective density, fractal-like dimension, oxidative fragmentation.
Presenting author email: pbaltzop@cperi.certh.gr

In the current study a simultaneous measurement of electrical-mobility-based (measured by SMPS, Scanning Mobility Particle Sizer, TSI) and aerodynamic-diameter-based (measured by ELPI, Electrical Low Pressure Impactor, Dekati) distributions is employed in order to study the morphology of soot aggregates produced by diesel engines at different operational conditions. This general approach has been used in the past to calculate an average fractal dimension for the entire aggregate size distribution (Virtanen *et al*, 2004).

A set of integral equations is constructed relating the output of each stage of ELPI to a weighted integral of the mobility diameter distribution. In the case of describing the entire aggregate population with just one fractal dimension the mathematical problem is a typical minimization problem with one unknown, that can be readily solved. In the present work it is assumed that the fractal dimension is in general a function of the aggregate size (i.e. mobility diameter). The reason behind this assumption is the existence of the oxidative fragmentation mechanism (Echavarria *et al*, 2011). The oxidative fragmentation of soot particles limits further aggregate growth while the resulting soot fragments may re-collide with the soot aggregates, leading to the establishment of a steady state at which point coagulation balances oxidative fragmentation and therefore the emergence of a size distribution with a "constant shape". The simultaneous action of these two processes, in general may lead to a distribution of soot aggregate morphologies (hence fractal dimensions), since both cluster-cluster and monomer-cluster aggregation events will be occurring within the same population.

The resulting mathematical problem that must be solved can take the form of a non-linear Fredholm integral equation of first kind which is well known to be ill-posed. Especially in the present case with the limited amount of experimental information (stemming from the few discrete ELPI stages) and considering that no knowledge exists for the shape of the unknown fractal dimension vs mobility diameter distribution an inversion approach seems hopeless. Instead, a reasonable approximation of the kernel functions with Dirac delta functions allows deconvolution of the data leading to the stabilization of the inverse problem and allowing the estimation of a different fractal dimension for each aggregate particle and corresponding mobility diameter.

The above approach leads to an effective density distribution from 2.5 to 0.3 g/cm^3 (Figure 1). Effective density values for the smaller soot aggregates (smaller than 100 nm) are very close to the density of carbon, slightly augmented, most likely due to existing inclusions from metal oxides.

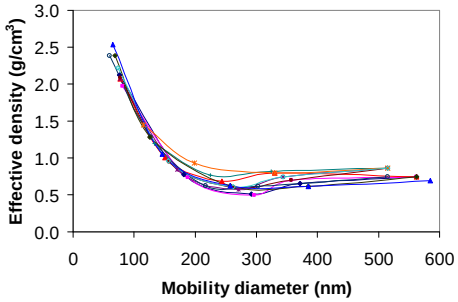

Figure 1. Effective density of soot aggregates for different operational conditions

Based on the work of Naumann (2003) we apply the following relation to calculate the fractal dimension, D_f from the effective density, ρ_{eff} and the mobility diameter, d_{me} :

$$\frac{\rho_{eff}}{\rho_o} = \frac{1}{f \cdot h_{KR}^{\,Df}} \left[\frac{d_{me}}{d_o} \right]^{Df-3} \qquad (1)$$

where, h_{KR} is the Kirkwood – Riseman ratio accounting for shielding effects and hydrodynamic interactions itself a function of D_f, f is the volume filling factor, d_o is the primary particle of the soot aggregates, while their density is, ρ_o, taken to be that of carbon. The results for D_f range between 3 and 1.75 and for the large soot aggregates tend to reach a value of 2.4 (Figure 2).

PM10 is responsible for a greater IL-6 secretion after "in vitro" incubation with synoviocytes from patients with Rheumatoid Arthritis than in those with osteoarthrosis

V. Guercio[1], F. Cetta[1], F. Laghi Pasini[1], , E. Selvi[1], E. Balistreri[1]I. Santi[2], M. Monti [2], L. Cantarini[1], E. Bolzacchini [3] and M. Galeazzi[1]

[2]Geriatric Institute "Pio Albergo Trivulzio" (PAT), Milan, 20146, Italy
[3]Dept. of Environmental Sciences, University of Milan, Milan, 20126, Italy
keyword: Rheumatoid Arthritis, osteoarthrosis, human fibroblast-like synoviocytes, IL-6
Presenting author email: guerciovalentina@libero.it

Autoimmunity and, in particular increased IL-6 secretion, play a crucial role in the occurrence of Rheumatoid Arthritis (RA). Genetic factors are thought to be responsible for about 50% of RA risk, suggesting that environmental factors could contribute to the development of RA in the genetically predisposed. In particular, pollution from traffic in adulthood has been considered as a newly identified environment factor for RA.

Aim of the study: to assess the "in vitro" effects of variable concentration of various types of PM when incubated with human Fibroblast-like synoviocytes (FSC), to evaluate the occurrence of proinflammatory effects.

Methods: daily levels of PM10 and PM2.5 and PM1 (diameter < 10 μm, 2.5 μm, 1 μm, respectively) were measured by PM detection units, both outside and inside 2 schools for children and 2 nursing homes for retired people, either in summer and in winter time in Milan, Italy. Both OPC detectors and low volume gravimetric detectors were used. Samples from Teflon filters were used after sonication in sterile phosphate buffer saline (PBS). Aliquots of these samples at various concentration of PM10 (10 μg/ml, 50 μg/ml, 70 μg/ml) were incubated at 37°C for 24, 48, 72 hours with human type B synoviocytes obtained from 5 patients with RA, and 5 with osteoarthrosis (OA) during hip replacement surgery.

Results: -Engulfment of particulate material within synoviocytes was observed even at lower concentrations and after 24 h incubation; -the penetration of PM into the cell was associated with an increased cytokine production. In particular, there was a considerable increase of IL6 concentration, namely after incubation with winter PM, up to 9-folds the basal values, already after 24 h (867,36 vs 100) in FSC obtained from RA patients ($p<0,001$), whereas summer PM determined a significant increase of IL6 (637,39) only after incubation for 72 h . This effect was likely due to the greater content of PAH rich OC in winter PM. In addition, after incubation for 24 h of the same type and the same concentration (10 μg/cm2) of PM10, collected during Summer and Winter, with alveolar type cells (A549 cell line), i.e. cells from front-line respiratory district (**Fig 1b**), the previous increase of IL6 observed in subjects with RA (**Fig 1a**) was not found (**Fig1**).

Conclusion: The inflammatory response elicited by PM is greater in RA-FLS, than in OA-FLS and other inflammatory or autoimmune diseases. Even if affected tissues are distant from the initial site of exposure, they are likely to be part of the health side-effects produced or facilitated by environment pollutants.

In particular, being RA a disease in which genetic predisposition plays a basic pathogenetic role, it could also be an interesting " new model" to evaluate host-particle interaction, and to try to weight the relative role of intrinsic toxicity of xenobiotics, including composition, structure, surface reactivity vs that of individual susceptibility, in the occurrence of clinical outcomes in humans. In particular, PM-related health effects seem to be not only determined by intrinsic toxicity of pollutants, mediated by oxidative stress, but are likely due to more complex responses, namely those typical of autoinflammatory and/or autoimmune diseases, which occur only or mainly in susceptible individuals.

In particular, if autoimmunity is crucial for RA occurrence and RA is part of the "pollution related syndrome", even low local concentration of PM could be sufficient to trigger pathological events in predisposed subjects.

Damage to newborns, in terms of risks for diseases occurring even decades after exposure to PM, as a crucial item in the global effects of air pollution to a given population

B. Lorenzi[1], F. Cetta[1], V. Guercio[1], P. Paladini [1], F. Granato[1], R. Zangari[1], M. Monti[2] , M. Giovannini[3], E. D'Auria[3], M. Mandelli[3] and M. Sala[3]

[1]Dept. of Surgery and Thoracic Surgery, University of Siena, Siena, 53100, Italy
[2]Geriatric Institute "Pio Albergo Trivulzio" (PAT), Milan, 20146, Italy
[3]Dept. of Pediatrics, University of Milan, Milan, 20122, Italy
Keywords: Particle concentration, health effects of aerosols, susceptibility window, newborn damage.
Presenting author email: lorenzi7@unisi.it

Aim of the study: Between 2007 and 2010, a comprehensive approach to health effects of air pollution was performed in Milan, Italy (Prolife Project): 1) measurement of PM concentration; 2) comparison between daily concentration of PM and other pollutants and hospital admission; 3) longitudinal studies in frail subpopulations, such as children attending primary school and elderly people living in nursing homes; 4) "*in vitro"* and "*in vivo"* experiments concerning host particle interactions.

The lack of adequate metrics of exposure, effect and susceptibility in epidemiological studies evaluating PM concentration and health effects is one of the main responsible for the conflicting results of these studies (Clark, 2010). In particular, the question of damage to human health by environmental pollutants has never been addressed exhaustively.

The current paradigm of environmental pollution included acute damage, usually measured as hospital admission for various diagnosis during "pollution peaks" - and chronic damage, i.e. the risk of developing cancer and/or chronic diseases as long -term effects. A dose and effect linearity, due to the intrinsic toxicity of pollutants has been presumed, but never proved, whereas the role of individual susceptibility in the occurrence of the final outcome has never been properly considered.

Results: The following results were obtained: 1) In a prospective study involving 118 children (63 males and 55 females) attending primary school, close to a park far from vehicular traffic, in 3 consecutive days very high peaks of indoor PM were detected for about one hour (8:15-9:15 in the morning), up to 1000 μg/m^3 indoor for PM10. There was no evident clinical outcome (increase of asthmatic bronchitis, upper or lower respiratory diseases) or different prevalence of spirometric or FeNO values in any of the 118 children who were evaluated during those days. 2) Functional alterations of human cells incubated in vitro with different types of PM10 and PM2,5 (10, 50, 75 μg/ml) and concentration greatly depended on individual susceptibility and on the pre-existing disease of the host. In particular, semiquantitative functional analysis showed that individual susceptibility of the host was responsible for more than 50% of the final outcome as compared with intrinsic toxicity of pollutants. 3) Comparison of the rate of asthmatic children in 2009 with historical series of 3 decades before, showed an evident increase of susceptible children, likely due to the effects of early life exposure to air pollution, during the critical "susceptibility window" involving the first months of life of newborns (Clark, 2010).

Conclusion: The question concerning the determinants of final outcomes and the measure of each component responsible for damage, - involving both toxic and harmful processes, but also repair mechanisms,- requires a multidisciplinary approach, involving clinicians and pathologists. In particular, the relative power of the damage due to intrinsic toxicity of pollutants, which can be without clinical evidence even at PM concentration of 1000 μg/m^3 - and that of individual susceptibility deserves further evaluation.

In the overall analysis of exposed population, the damage to newborns by pollutants usually escapes current evaluation of PM concentration and health effects, which is able to capture only damage expressed as "hospital admission, morbidity and mortality" measured within a 2- day lag.

A proper estimation of this damage, i.e. of the increased proportion of newborns - children of non susceptible parents - who will become susceptible to "pollution disease", because of exposure to pollutants in early life, is mandatory. Even if it will be measured some decades later, as a burden of diseases related to PM pollution, this damage actually is a major component of the total damage from environmental pollution, at a given time, which could also be transmitted to future generations.

Aim of the study to detect new tools, which could be useful for a better risk assessment in humans of effects of air pollutants, on the basis of *"in vitro"* studies of host-particle interactions.

Methods and results: the A549 (human alveolar epithelial cell) and the BEAS-2B (human bronchial epithelial cell-line), together with sperm cells and synoviocytes from humans with rheumatoid arthritis (RA) and osteoarthrosis (OA), were treated after 24-48h with both summer and winter PM_{10} and $PM_{2.5}$ sampled in Milan, Italy. Therefore, both human beings and cell-lines were exposed to the same pollutants. In addition, a cross comparison was performed between clinical and *in vitro* effects.

A549 cell viability wasn't significantly reduced after summer and winter PM exposure, and summer PM had no significant effects on BEAS-2B viability. Winter PM treatment induced a decrease in cell viability, at the dose of 25 and 50 mcg/cm^2. Moreover, winter PM_{10} induced a 5-fold increase in IL-8 release in treated cells, and summer PM_{10} induced a 20-fold increase in IL-8 expression. BEAS-2B resulted more responsive to PM treatment than A549. Short- term clinical effects in Milan were not related to PM daily concentration.

Discussion: "*In vitro*" studies confirmed potential toxicity of PM, but these studies cannot be used for clear-cut inferences to humans. In fact, in terms of health or biological effects, one cannot compare the effects of inhalation by breathing of diluted particles in a concentration equivalent to the one that can be introduced with a single breath in 1 sec with the effects of incubation, with a cell line of alveolar cells of particles deposited on filters, which contain aggregated and concentrated particles, that correspond to 60sec x 60min x 24h, i.e. 8640 folds the portion inhaled by a single breath. In particular, in humans each quantity can be partly cleared, and partly can rich the alveolar area. In addition, the final response includes not only the cellular and molecular response, but also includes the response of the "entire organism". Two main differences can be found between *"in vitro"* and in humans studies: 1)the human being gives not only biological, but also chemical and mechanical responses, which are able to clear completely inhaled particles; 2)the model used in analyzing host-particle interactions postulates a dose and effect linearity, whereas observed outcomes in humans show a "no threshold" behaviour. Therefore, in humans the prevalent causative mechanism cannot be the intrinsic toxicity of the pollutants with a linear progression (the greater the dose, the greater the health effect), but a different one. "*In vitro*" models, even if not immediately extensible to humans, may represent a surrogate for the experimental animal, in order to evaluate quantitatively parameters such as: inflammogenicity, mutagenicity, cell cycle alterations. The use of different cell lines and human samples, with different responses, has shown the great importance, not only of the intrinsic toxicity of the toxic agent, but also of the different type of targeted cell in triggering a different response. These differences- related to host response and individual susceptibility- can be one of the possible explanation for the "no threshold phenomenon" and for the inadequacy of the "pure" toxic model, characterized by dose and effect linearity, to capture the complexity of host-particle interactions. An adequate model of risk evaluation- applicable to human health- isn't available, mainly because of the persistent lack of knowledge, concerning pathogenetic and pathophysiological mechanisms, which are responsible for clinical outcomes in humans. In an ideal model, 2 different components should be distinguished: the particle-related component and the host-related one. However, at the moment we don't know yet the relative weight of each component.

Source-specific mutagenicity and carcinogenicity of $PM_{2.5}$-bound polycyclic aromatic hydrocarbons in a large city of North-eastern Italy

M. Masiol[1], S. Squizzato[1], A. Hofer[1], F. Benetello[1], G. Rampazzo[1], B. Pavoni[1]

Presenting author email: masiol@unive.it

Epidemiological studies directly correlated the exposure to airborne particulate matter with some adverse health effects (Pope et al., 2009), which are further enhanced by some chemical, physical and biological properties of the particles. Airborne particles can be composed of, or absorb on their surface, some substances having carcinogenic and/or mutagenic effects on humans. Among these compounds, Polycyclic Aromatic Hydrocarbons (PAHs) have been largely studied because of their known or suspected carcinogenic properties and their wide distribution in the urban atmospheres.

Up today, several approaches have been developed to assess the potential risk of exposure to complex mixtures of PAHs using equivalency factors based on Benzo(*a*)pyrene (BaP), which is recognized as class 1 carcinogen by IARC. Toxic Equivalency Factors (TEF) and Mutagenic Equivalency Factors (MEF) have been used in combination with measured concentrations of PAHs mixtures to compute the Carcinogenic (TEQ) and mutagenic equivalents (MEQ).

Unfortunately, most of conventional risk assessment studies are limited to estimating the carcinogenic potential of PAHs mixtures without providing information about the role of specific sources. This fact represents a great limitation, because equivalency factors can vary by some orders of magnitude amongst congeners and different emission sources potentially emit specific congeners.

In this study, 11 particle-phase PAHs, listed as carcinogenic and mutagenic agents by the IARC, were quantified in three sites of Venice-Mestre, Northern Italy. This large city was recently recognized as an ideal place to study the effects of the atmospheric circulation and long–range transports in the Po Valley. It is located between the eastern border of a wide continental plain and the Adriatic Sea and presents emissive scenarios common to other large European cities: high density residential areas, heavy traffic roads and motorways, coal and gas thermoelectric power plants, many industrial installations (Rampazzo et al., 2008; Masiol et al., 2010; Squizzato et al., 2012). These sites have been selected because of their different emissive scenarios and relative location with respect to the major winds. Analyses were carried out by Gas Chromatography-Mass Spectroscopy after solvent extraction of collected filters.

Some diagnostic ratios were calculated and a factor analysis was performed to detect the most probable emission sources. Three main sources were identified: traffic, domestic heating and heavy oils. A multi linear regression analysis was performed on the sum of analyzed congeners showing that domestic heating is the main source of PAHs in winter, whereas traffic mainly accounts for the carcinogenic and mutagenic risk during the whole year. In the same way, the source-specific mutagenicity and carcinogenicity have been computed (Figure 1).

In a second step, a chemometric approach using wind data was applied to group days with similar atmospheric circulation patterns. The study of the wind roses and their associated changes in PAH profiles, total carcinogenicity and mutagenicity discriminated the sources of particle-phase PAHs and their role in determining a serious hazard for human health.

Results, interpreted on the basis of seasonal variations and atmospheric conditions, have shown that even though domestic heating is the main source of total PAHs in winter, a background pollution including traffic mainly accounts for the carcinogenic and mutagenic risk during the whole year.

The proposed procedure has quantitatively pointed out the prevailing sources of organic air pollutants and particularly the very hazardous ones for human health.

It can be easily applied to other anthropized environments as a useful tool to design local and regional air pollution control strategies, including the use of better prevention technologies and traffic restrictions.

Quantitative and qualitative relationship between AOD obtained by AERONET and $PM_{2.5}$ from in situ measurements in Brazilian Amazonia over several years

M. Paixão[1], D. Mourao[2], A. Correia[1], S. Hacon[2], P. Artaxo[1]

Exposure to elevated levels of inhalable particulate matter has been associated to serious health threat such as cardiopulmonary and lung cancer mortality (Pope et al, 2002). The relationship between particulate matter measured on the surface and column averaged aerosol optical depth provided by remote sensing such as satellite sensors and ground-based measurements has been studied by several authors over the last years.

The Brazilian Amazonia, specifically the so-called Arc of Deforestation region, is heavily impacted by biomass burning aerosol particles with aerosol optical depth (AOD) reaching values as high as 5.0. Epidemiologic and health studies about the impact of inhalable particulate matter suffer from lack of surface measurements, especially in remote areas. Remote sensing data can improve monitoring air quality; in this sense the AERONET program provides reliable long-term measurements of AOD in key Amazonian sites.

In the present study it's explored the relationship between aerosol optical depth and *in situ* $PM_{2.5}$ concentrations measurements obtained by several campaigns from 1995 to 2006.

We noticed a change in the load of $PM_{2.5}$ in Alta Floresta about the year 2000, when PM concentrations dropped by half, but surprisingly the aerosol optical properties didn't follow the same trend. The hypothesis is that the site itself changed due to land use, and as the city grew the biomass burning spots went far from the measurement location. However, the columnar AOD measured by AERONET has an estimated area of representativity of more than 150 x 150 km according to (Hoelzemann et al., 2009), and might not be susceptible to such regional scale changes.

We found a significant correlation between AERONET AOD and $PM_{2.5}$ varying from 0.77 in Santarém, a pristine site, to 0.86 in biomass burning affected sites. Figure 1 shows the linear regression in Alta Floresta. It's proposed a linear relationship of $PM_{2.5}$ = (40±2)*AOD500 + (5±2) in µg/m³, evaluated from 2001-2006 for biomass burning sites. The method was validated using MODIS aerosol optical depth to estimate PM2.5 with the proposed regression, and compared with TEOM measurements in Ji Paraná, 2002, and Alta Floresta, 2006 (see Figure 2), with good agreement.

Although the Brazilian National Council for Environment doesn't contemplate a standard for $PM_{2.5}$, it's clear that the high loads in Brazil might affect the population and further policy discussions are needed.

Statistics of PM10 concentrations in Mazovia, central Poland (2007 – 2011)

A. Pietruczuk, J. Jarosławski and I. Pawlak

Institute of Geophysics Polish Academy of Sciences, Warsaw, Poland
Keywords: PM10, size distribution, statistical analysis.
Presenting author email: alek@igf.edu.pl

Results of PM10 concentrations measurements performed at four stations in central Poland (2007-2011) were analyzed in terms of levels, distributions of occurring concentrations, the number of exceedances of the limit values and the potential sources of aerosols.
Analyzed PM10 levels were similar at suburban and rural stations, except the station located in downtown of the cities or next to the busy street. The largest PM10 concentration was observed at Warsaw Kerb station, they were about 30% higher than in other stations.
Increase of PM10 concentration from year to year is observed during reported period. The number of days with exceeded daily limit value of PM10 is also rising. The number of exceedances is the highest at Warsaw Kerb station and decreases with the decrease of population density and road traffic in the vicinity of the measurement point.

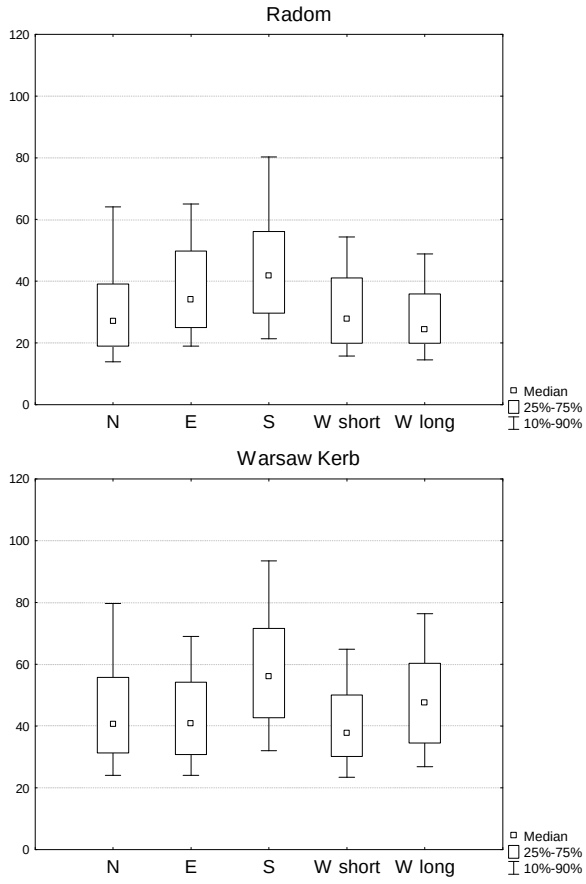

Figure 1. PM10 concentrations urban stations for different airmass origin.

Seasonal variability analysis of PM10 revealed additional maximum beyond the usual autumn-winter one. This maximum occurred in April at all stations corresponds to seasonal fires activity in Eastern Europe. Similar spring maximum is also seen at annual pattern of aerosol optical thickness (Jaroslawski and Pietruczuk, 2010). Elevated concentrations during cold part of the year could be associated to coal combustion, the main source of heat in Poland.
Cluster analysis of back-trajectories calculated by HYSPLIT model revealed that PM10 concentrations in the Mazovia region strongly depends on the origin of airmass. The highest values are registered for the air of the regional and Southern origin, while the lowest for the air-masses originating from the North and North-West direction. Air-mass advected from South direction could be polluted by industry in southern Poland (e.g. Silesia region) and industry in Czech Republic (e.g. Ostrava. PM10 concentrations related to air-mass advection from Western and Easter Europe are similar at all stations. This is rather surprising because one can expect that continental airmass from mostly rural areas of Belarus and Ukraine are cleaner than the airmass which could be polluted by European urban and industrial regions. However, regions east of Poland are the source of seasonal fires taking place mainly during spring (Barnaba et al., 2011).

It is well known that the problem of waste disposal is critical in advanced societies, characterized by increasing consumption of goods, and one of the technologies used to manage this problem is waste incineration. In Italy there is a high perception of health risk related to the presence of incinerating plants. For this reason, local communities are very interested in their air quality and in the possible presence of health-risk pollutants, related to the activity of these plants. The aim of this study is to characterize the inorganic ions and carbonaceous compositions in PM1 and PM2.5 samples collected in the surroundings of an incinerator.

To reach this goal two extensive monitoring campaigns were performed: the first one was held in summer 2008 and the second one in winter 2009. The plant under study is located in a suburban-farming area, less than 10 km away from northeast of Bologna (Italy), in the southeast of Po Valley, which is a well known atmospheric polluted critical area.

Seven out of eight monitoring stations were installed in a domain of 8x9 km^2 around the plant. The eighth station was placed far away, inside the urban area of Bologna, in a site used for urban background measurements by Arpa Environmental Agency.

A preliminary study with ADMS-Urban (Cerc, Cambridge, UK) dispersion model was performed in order to select coordinates of four monitoring stations, using PM10 emissions as a pollutant tracer (Bonafè and Rossi, 2011). Two stations representative of maxima deposition of plant emissions and two stations, used as "control" were chosen. The other stations were placed as to represent different air conditions in the domain: high traffic, rural and suburban area Inorganic ions (NH_4^+, K^+, Cl^-, NO_2^-, NO_3^-, SO_4^{2-} and Oxalate), total carbon (TC) and the associated water soluble organic fraction (WSOC) were determined in bi-daily aerosol samples. Extensive statistical analyses were performed, using both univariate and multivariate methods. In addiction some seasonal comparison were made.

Results

Principal Component Analysis was applied to the concentration data of the studied compounds. The data were normalized to the mass of PM. The compositions of PM2.5 were found significantly different from those of PM1 with respect inorganic ions in both the summer and the winter campaign.
The compositions of PM2.5 and PM1 were found to be different in both seasons.

PM2.5 samples collected in the first maximum were more rich in TC when compared to its control.

Seasonal variation were also observed in the composition of the inorganic fraction as reported in Figures 1 and 2, confirming results published by other authors. Nitrate and sulphate were found to be correlated to the ammonium in winter and summer respectively.

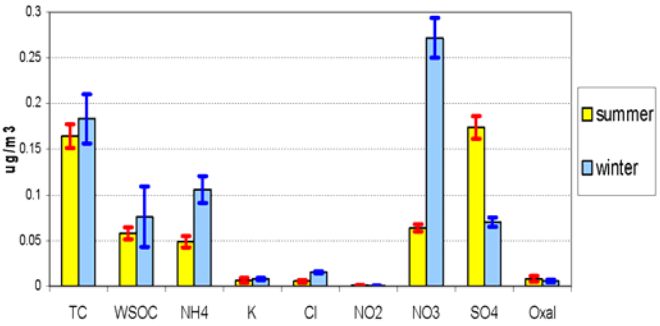

Figure 1. PM-normalized average concentrations of analytes, with standard deviations.

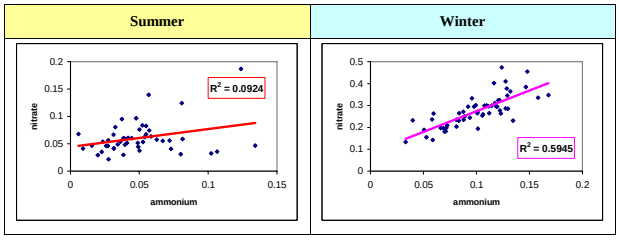

Figure 2. Correlation of nitrate and ammonium concentration in PM2.5 measured at the maximum of deposition of the incinerator

It is well known that the problem of waste disposal is critical in advanced societies, characterized by increasing consumption of goods, and one of the technologies used to manage this problem is waste incineration. In Italy there is a high perception of health risk related to the presence of incinerating plants. For this reason, local communities are very interested in their air quality and in the possible presence of health-risk pollutants, related to the activity of these plants. The aim of this study is to characterize the metal fraction in PM1 and PM2.5 samples collected in the surroundings of an incinerator. The samples were previously extracted in pure water to focus on the metals more biologically available.

To reach this goal two extensive monitoring campaigns were performed: the first one was held in summer 2008 and the second one in winter 2009. The plant under study is located in a suburban-farming area, less than 10 km away from northeast of Bologna (Italy), in the southeast of Po Valley, which is a well known atmospheric polluted critical area.

Seven out of eight monitoring stations were installed in a domain of 8x9 km^2 around the plant. The eighth station (MGA) was placed far away, inside the urban area of Bologna, in a site used for urban background measurements by Arpa Environmental Agency.

A preliminary study with ADMS-Urban (Cerc, Cambridge, UK) dispersion model was performed to select monitoring station coordinates, using PM10 emissions as pollutant tracer. A first station (MXW) representative of maximum falling out of plant emissions was placed in the east side, not too far from the incinerator, along the wind main-direction axis. A second station (CTW), used as a "control" of the first one, was chosen in a position representing both the minimum falling out of plant emission and whole extra-incinerator immission, according to the PM10 simulation (Bonafè and Rossi, 2011). A second maximum (MXS) was placed on the west side of the plant on the same wind axis, and a second control (CTS) was chosen. The other stations were placed as to represent different air conditions in the domain: high traffic (MXD), rural (MND) and suburban area (CAS).

Thirteen different metals were analyzed through atomic absorption spectroscopy GF-AAS with Zeeman background correction. Extensive statistical analyses were performed, using both univariate and multivariate methods. Furthermore some seasonal comparison were made.

Results

The ambient measurements showed that the metal compositions of PM2.5 and PM1 were not significatively different in the summer season. This was not true for the winter season, in which PM1 metal composition was found different from that of PM2.5 fraction and also variable among the monitoring stations. In both seasons aluminum, iron and zinc were the prevailing and most widespread elements. Summer PM2.5 or PM1 metals in both maxima were not different from their controls. The same behaviour was found in the winter season for PM2.5 particulate fraction only. On the contrary the PM1-metal composition was found different between the first maximum and its control samples.

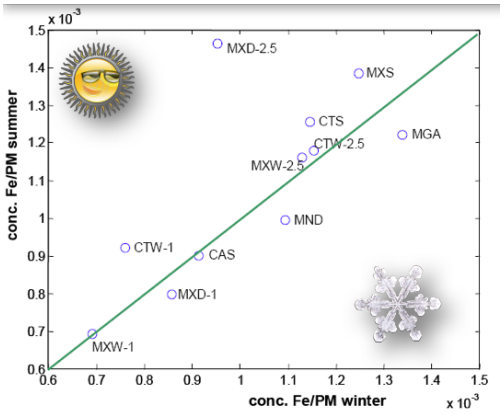

Figure 1. Average iron concentrations for both seasons and every monitoring station. The green line has slope one and intercept zero.

The typically crustal metals were widespread through the different stations samples in both seasons, while the other metals were found more seasonal influenced.

It is well known that the problem of waste disposal is critical in advanced societies, characterized by increasing consumption of goods, and one of the technologies used to manage this problem is waste incineration. In Italy there is a high perception of health risk related to the presence of incinerating plants. For this reason, local communities are very interested in their air quality and in the possible presence of health-risk pollutants, related to the activity of these plants. The aim of this study is to characterize polycyclic aromatic hydrocarbons and some of their nitro-derivatives in PM1 and PM2.5 samples collected in the surroundings of an incinerator. Furthermore the plant accountability was also investigated.

To reach this goal two extensive monitoring campaigns were performed: the first one was held in summer 2008 and the second one in winter 2009. The plant under study is located in a suburban-farming area, less than 10 km away from northeast of Bologna (Italy), in the southeast of Po Valley, which is a well known atmospheric polluted critical area.

Seven out of eight monitoring stations were installed in a domain of 8x9 km^2 around the plant. The eighth station (MGA) was placed far away, inside the urban area of Bologna, in a site used for urban background measurements by Arpa Environmental Agency.

A preliminary study with ADMS-Urban (Cerc, Cambridge, UK) dispersion model was performed to select monitoring station coordinates, using PM10 emissions as pollutant tracer. A first station (MXW) representative of maximum deposition of plant emissions was placed in the east side, not too far from the incinerator, along the wind main-direction axis. A second station (CTW), used as a "control" of the first one, was chosen in a position representing both the minimum falling out of plant emission and whole extra-incinerator immission, according to the PM10 simulation (Bonafè and Rossi, 2011). A second maximum (MXS) was placed on the west side of the plant on the same wind axis, and a second control (CTS) was chosen. The other stations were placed to represent different air conditions in the domain:

- MXD as high traffic; it is also the highest polluted site in the preliminary simulation;
- MND as rural; it is also the lowest polluted site in the preliminary simulation;
- CAS as suburban area.

Twenty-three different PAHs and eleven nitro-derivatives PAHs (N-PAHs) were analyzed through GC-MS in PM1 and PM2.5. Extensive statistical analyses were performed, using both univariate and multivariate methods. Furthermore, markers and diagnostic ratios methods were used to complete the data interpretation.

ADMS-Urban dispersion model was eventually used to assess the plant accountability towards the ambient PAHs amounts, using direct emission measurements performed simultaneously at the smokestack.

The ambient measurements showed that there were different compositions between PM1 and PM2.5 PAHs, expecially during the winter season. Summer PM2.5-PAHs in the first max were not different from its control, but this cannot be retained true for N-PAHs, since they were more concentrated in the max station. In winter PM2.5-PAHs, on the contrary, were more concentrated in the control particulate.

The evaluation carried out by ADMS-Urban appears to ascribe to the incinerator a very small account, nearly about 2 ‰.

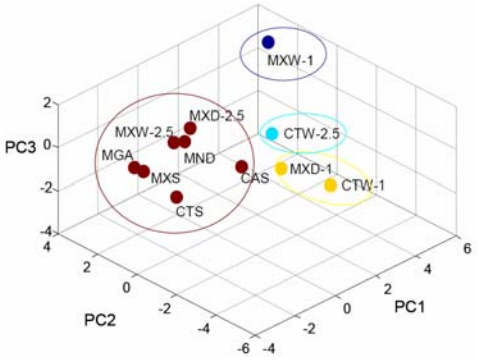

Figure 1. *K-means* clustering in the PC space able to describe more than 80% of the winter data variance.

Other complementary considerations lead us to think that the most of PAHs found in PM2.5 and PM1 aerosol are to be related to other sources, i.e. mainly to urban traffic.

Keywords: PM2.5, PM1, Air Quality, Monitoring, Modelling (microscale), Waste Incineration Impact.
Presenting author email: marossi@arpa.emr.it

It is well known that the problem of waste disposal is critical in advanced societies, characterized by increasing consumption of goods, and one of the technologies used to manage this problem is waste incineration. In Italy, there is a high perception of health risk related to the presence of incineration plants. Nowadays, in Emilia-Romagna there are eight incinerators and a new one is under construction, so investigating the possible presence of pollution related to these plants activities is crucial.

The Emilia-Romagna Region promoted an applied researching project called MONITER (http://www.moniter.it). One of the aims of the project was acquiring new knowledge about the air quality in the proximity of an incinerator (also seeking pollutants not covered by current regulations), in order to understand if these plants should be considered a risk for the local communities' health.

To reach this goal two extensive monitoring campaigns were performed near a plant having these main features: 600 tons/day of incinerating capacity, two 80-meters-high stacks and BAT purification devices. The first monitoring campaign was carried out in summer 2008 and the second one in winter 2009. The plant under study is located in a suburban-farming area, less than 10 km away from northeast of Bologna (Italy), in the southeast of the Po Valley, which is unfortunately a well known atmospheric polluted critical area.

Seven out of eight monitoring stations were installed in a domain of 8x9 km^2 around the plant. The eighth station (GMA) was placed far away, inside the urban area of Bologna, in a site used for urban background measurements by Arpa Environmental Agency.

A preliminary study with ADMS-Urban (Cerc, Cambridge, UK) dispersion model was performed to select monitoring station coordinates, using PM10 emissions as pollutant tracer. A first station (MXW) representative of maximum deposition of plant emissions was placed in the east side, not too far from the incinerator, along the wind main-direction axis. A second station (CTW), used as a "control" of the first one, was chosen in a position representing both the minimum deposition of plant emission and whole extra-incinerator immission, according to the PM10 simulation (Bonafè, G. and Rossi, M., 2011). A second maximum (MXS) was placed on the west side of the plant on the same wind axis, and a second control (CTS) was chosen. The other stations were placed to represent different air conditions in the domain:
- MXD as high traffic; it is also the highest polluted site in the preliminary simulation;
- MND as rural; it is also the lowest polluted site in the preliminary simulation;
- CAS as suburban area.

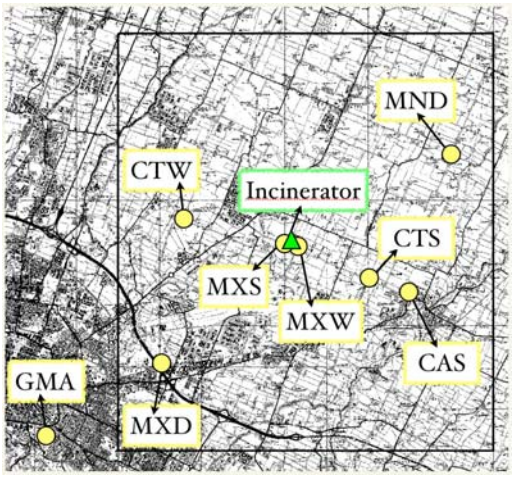

Figure 1. Location of the MONITER Project Campaigns. In the southwest corner is possible to see a part of the city of Bologna (I).

The MONITER Campaigns took into account various species of pollutants, for a total of more than 130 different chemical species sought into particulate. The data obtained were processed by extensive statistical analysis and the overall evaluation of results are the subject of this presentation.

A more detailed view of specific pollutants found in the particulate were presented in other specific communications of this same Conference.

Concentrations of PM_x, NO_2 and NH_3 in the metropolitan area of Barcelona: APICE long monitoring campaign

J. Pey[1], N. Pérez[1], A. Alastuey[1], X. Querol[1], J. Cortés[2]

[1]Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Barcelona, E-08034, Spain
[2]Autoritat Portuaria de Barcelona
Keywords: air quality, gaseous precursors, emission sources
Presenting author email: jorge.pey@idaea.csic.es

Concentrations of particulate matter (PM_{10} and $PM_{2.5}$) and NO_x are exceeding regularly the European standards in the Barcelona metropolitan area. As it's well known, NO_x concentrations recorded in urban areas are mostly anthropogenic in origin. Also PM_x levels are highly dependent of anthropogenic sources although natural contributions may be dominant in specific cases. The Barcelona region has a number of peculiarities that makes tricky the study of atmospheric pollutants, mainly concerning particulate matter. Thus, factors such as topography of the region, inputs of mineral dust particles from North Africa, local-regional meteorology, numerous anthropogenic emission sources, have to be taken into account. Previous studies revealed that around 1/4 of the PM_{10} concentration is mineral matter, mainly anthropogenic; 1/3 secondary inorganic aerosols; and the rest carbonaceous material and unaccounted mass (Pérez *et al.* 2008). A recent study revealed that formation of secondary inorganic aerosols in the Barcelona region occurs mainly inside the city (Pey *et al.* 2010). Accordingly, abatement plans for particulate matter need to consider both primary emissions but also gaseous precursors of secondary aerosols (such as NO_x, SO_x and NH_3) in order to be effective (Harrison *et al.* 2008).

In Barcelona, one of the major sources of atmospheric pollutants is road traffic, although other sources such as industry, power generation, construction-demolition, and harbour activities are relevant. Owing to the location of the harbour with respect to the city area and the wind regime (with high frequency of sea breezes), harbour pollution is affecting the city nearly half of the time.

The APICE (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions) project pretends to reduce harbour emissions to the atmosphere by adopting mitigation strategies, that will be taken at two different scales: local (specific abatement measures for the harbour of Barcelona) and trans-national (common strategies to be applied in the five cities involved in the project). To fulfil the objectives of the project, a long monitoring campaign (one year study, 2011) was intended, mostly in the harbour area but also covering (for a number of atmospheric pollutants) the whole metropolis.

In this work we show the results of PM_{10}-$PM_{2.5}$, NO_2 and NH_3 concentrations obtained during the campaign. A first evaluation of the results indicates that the highest levels of PM_{10} are recorded in the harbour area (40-50 µg m^{-3}), whereas those of $PM_{2.5}$ are more elevated in the city centre, at traffic hotspots (22-25 µg m^{-3}). Out of the harbour area, PM_{10} levels are relatively homogeneous (25-33 µg m^{-3}), slightly higher at traffic sites. Regarding NO_2 concentrations, only shown for the harbour area, these are clearly parallel to traffic influence. Thus, the highest levels are observed in specific areas in the harbour. As far as we are away from road traffic lines, NO_2 levels decrease drastically. A different pattern is observed for NH_3, clearly higher in two specific sectors inside the harbour: where dusty materials are handled, and close to the water waste treatment plant..

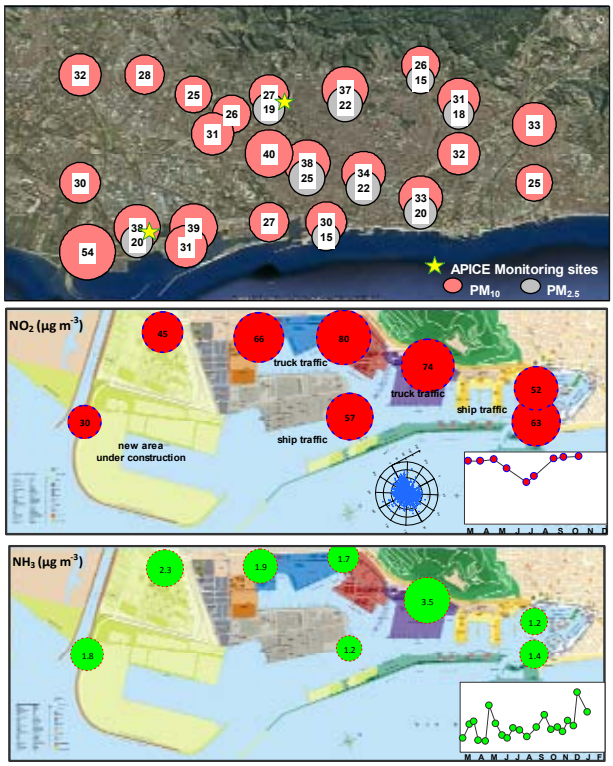

Figure 1. PM_{10}, $PM_{2.5}$, NO_2 and NH_3 (µgm^{-3}) spatial concentrations during APICE project.

It has been widely recognized the important role of the atmospheric aerosol on different aspect such as climate, ecosystems, biogeochemical cycles or human health. In-situ measurements of atmospheric particles, carried out near the ground, constitute the most direct way to obtain information about the particulate matter (PM). However, surface monitors miss important information as often aerosol plumes are injected over higher atmosphere layer. At this point, it is important to pay attention to satellite observations, which can play an important role on supplementing the surface monitors (Guo et al., 2009).

In the last years, satellite remote sensing has been identified as a potential valuable tool for estimating ground-level PM concentration. Among the main advantages offered by satellite sensors, the extensive spatial resolution along with the cost effectiveness are highlighted. Several authors have studied the relationship between aerosol optical depth (AOD) retrieved from satellite data and the mass fraction PM_{10} or $PM_{2.5}$ at ground level. The AOD is retrieved as a measure of light extinction by columnar aerosol loading of the atmosphere during the satellite overpass.

Furthermore, the variation in this relationship across space and time has been investigated (e.g. Gupta et al., 2006; Tian and Cheng, 2010). However, it is not an easy task as different factors such as meteorological conditions, mixing layer height or site location, influence this relationship (Pelletier et al., 2007, Boyouk et al., 2010). As a consequence, different results have been reported by several authors at different study areas (Boyouk et al, 2010 and references therein).

Sensors such as MODIS (Moderate Resolution Imaging Spectroradiometer) are able to well retrieved AOD, an aerosol optical property that is also measured from ground-based sunphotometers in the frame of AERONET (Aerosol Robotic Network) network. Several authors have used MODIS data, as it has the unique ability to retrieve AOD with greater accuracy.

Ground-level particulate matter concentration (PM_{10}) at Granada (Spain), were analyzed: at a remote regional background EMEP station (EMEP: Cooperative Programme for the Monitoring and Assessment of Long Range Transport of Air Pollutants in Europe) installed in Víznar (37º 14' N, 03º 28' W and 1260 m a.s.l.) and at the urban place (four different locations included in the Air Quality Monitoring and Control Network of Andalusia). Víznar lies 12.5 km from Granada and is a rural area in a natural basin surrounded by mountains with the highest mountain range located to the southeast. Granada (37.16º N 3.58º W, and 680 m a.s.l.) is a city with 300 000 inhabitants, that increases up to 600 000 if the whole metropolitan area is considered.

For this study, the daily data set of AODs at 550 nm was obtained by MODIS Terra and Aqua (collection 5.1). Data used in this work are daily Level 2 data at the spatial resolution of 10x10 km (at nadir), including information from Terra (MOD04_L2) and Aqua (MYD04_L2) platforms. Only cloud-free pixels were considered.

In this study, several years of data were analysed aiming to compare the relationship between satellite retrieved AOD and surface-measured PM_{10}. The importance of mixing layer height will be highlighted.

Improving knowledge on this PM-AOD relationship constitutes an important challenge. The use of satellite AOD retrievals data for PM estimation will enable to obtain reliable PM information at global scale. Therefore, it is important to continue studying in depth this relationship as it constitutes a very useful tool for mapping PM distribution over large spatial domains and, hence, for monitoring air particulate pollution (Péré et al., 2009).

Origin of $PM_{2.5}$ and Secondary Inorganic Aerosol (SIA) and relationship with gaseous pollutants in the Venice area

S. Squizzato, M. Masiol, E. Innocente, E. Pecorari, G. Rampazzo, B. Pavoni[1]

[1] Dipartimento di Scienze Ambientali, Informatica e Statistica, Università Ca' Foscari Venezia, Venice, 30123, Italy

Keywords:PM2.5, Secondary Inorganic Aerosol, local contribution, gaseous pollutants.

Presenting author email: stefania.squizzato@unive.it

Fine particles (AD ≤ 2.5 μm) mainly derive from industrial and residential combustion processes, motor-vehicle emissions and conversion of gaseous compounds to particulate phase. The particle mass deriving from gas-to-particle conversion is defined as secondary aerosol (SIA – secondary inorganic aerosol, SOA-secondary organic aerosol).

In the Venice area, $PM_{2.5}$ and NO_x emission are mainly related to road transport and combustion processes (combustion in energy and transformation industries and non industrial combustion plants) whereas SO_2 emission mostly derive from combustion in energy and transformation industries (ISPRA, 2012).

In this work, PM and major inorganic ions (NH_4^+, NO_3^-, SO_4^{2-}) are studied in relation to environmental conditions and gaseous precursors (SO_2 and NO_x) to highlight SIA formation patterns and origin.

One-year PM sampling campaign has been carried out from January 2009 to January 2010 in three sites, representing different emission scenarios and environmental conditions: (i) SRC, semi-rural-background costal site; (ii) UBG, urban background site; (iii) IND, industrial site. PM was collected simultaneously on 47 mm quartz fiber filters (Whatman QMA) using low volume automatic samplers equipped with $PM_{2.5}$ cut-off inlets and set according to EN 14907 standard.

Four sampling periods were selected to represent the four seasons and ultrasonic method was used to extract all filters for determination of major inorganic ions (NH_4^+, NO_3^-, SO_4^{2-}) by ion chromatography as proposed by Squizzato *et al.* (2012).

The concentrations of gaseous pollutants (SO_2, NO_x, NO, NO_2) in UBG and IND site were provided by local Environmental Protection Agency (ARPAV). Meteorological conditions (temperature, relative humidity, wind speed and direction) were recorded by Ente della Zona Industriale di Porto Marghera and ARPAV-Centro Meteorologico di Teolo.

The relationship between SIA and gaseous pollutant have been evaluated using SOR (Sulfur Oxidation Ratio) and NOR (Nitrogen Oxidation Ratio). SOR and NOR have been used to express the degree of atmospheric conversion of SO_2 to SO_4^{2-} and of NO_2 to NO_3^-. Then, wind speed and direction and back-trajectories have been combined with chemical data to point out the influence of local and external sources of PM and SIA and the Lenshow approach (Lenshow *et al.*, 2001) was used to estimate local contribution as described by Squizzato *et al.* (2012).

The $PM_{2.5}$ annual mean was 33 μg m^{-3} for the two mainland sites (UBG and IND) and 26 μg m^{-3} for SRC. $PM_{2.5}$ concentrations were inversely correlated with air temperature, with higher levels during the cold period. On a yearly basis, SIA accounts for 9.5 μg m^{-3} (27% of $PM_{2.5}$ mass) in UBG, 9.6 μg m^{-3} (28%) in IND and 9.5 μg m^{-3} (36%) in SRC.

Strong correlations were observed between NO_3^-, NO_2, NOR, NH_4^+, temperature and relative humidity (Table 1). This suggests a local origin for ammonium nitrate related to an increase in NO_x levels and particular environmental conditions (low temperature and high relative humidity). Heavy pollution events occur in days characterized by low atmospheric dispersion and air masses coming from Po' Valley. During these events the local contribution on PM and SIA increases. Nevertheless, considering the mass percentage, no significant variations were observed for all periods and samples. In conclusion, heavy SIA events are mainly due to a regional contribution and are enhanced by scarce atmospheric dispersion that traps pollutants.

Table 1. Correlation matrix between NO_3^-, NO_2, NOR, NH_4^+ temperature and relative humidity.

UBG	NO_3^-	NO_2	NOR	NH_4^+	T (°C)	R.H
NO_3^-	1.00					
NO_2	0.59	1.00				
NOR	0.96	0.48	1.00			
NH_4^+	0.89	0.59	0.87	1.00		
T (°C)	-0.44	-0.35	-0.51	-0.33	1.00	
R.H	0.35	0.04	0.43	0.33	-0.25	1.00

Analysis of the episodes of high PM10 concentrations from January to April and October to November 2011 in Central and Western Europe with focus on North-Rhine Westphalia

S. Wurzler, H. Hebbinghaus, P. Bruckmann, A. Baltruschat, U. Romberg, J. Friesel, U. Pfeffer, W. Straub, J. Geiger

North Rhine Westphalia State Agency for Nature, Environment and Consumer Protection (LANUV), P.O. Box 101052, D-45610 Recklinghausen, Germany

Keywords: PM10, air quality.

Presenting author email: sabine.wurzler@lanuv.nrw.de

The year 2011 was an exceptional year, with a long period of cold weather in January and persistent sunny and dry weather conditions in October and November.

The year 2011 was also special with regard to the PM10 concentrations in Germany and NRW. Most of the exceedance days occurred in the time span from end of January to April and during an episode mainly in November. Especially in November very high particle concentrations occurred. These particle episodes led to a multitude of exceedance days. An exceedance day is a day with a daily average PM10 concentration of more than 50 µg/m³. The European air quality directive 2008/50/EC specifies a limit value of 35 allowed PM10 exceedance days. This situation reminded in the northern Ruhr area of the smog episodes in the eighties in NRW, leading to an increased mortality and as political consequence to traffic bans and restrictions for industrial facilities. Fortunately, the PM10 concentrations in 2011 did not reach this level.

In North-Rhine Westphalia (NRW) for example, we observed in 2011 limit value exceedances at more than 20 measurement sites (Fig. 1). For comparison: in 2008, 2009, and 2010 we had PM10 limit value exceedances on average at 5 measurement sites in NRW. Another novelty was that we had to report limit value exceedances for several urban background sites. The highest daily averages were found in NRW in the northern part of the Ruhr area with values up to 140 µg/m³.

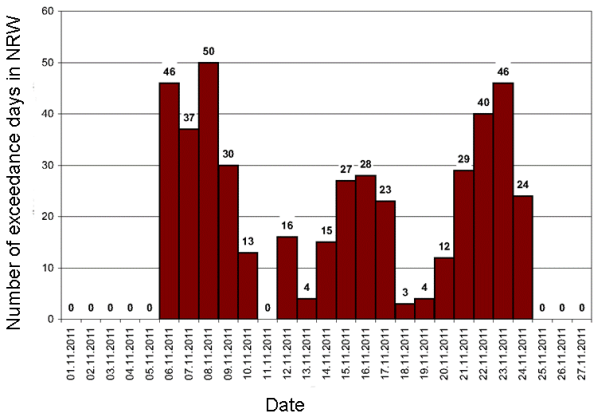

Figure 1: Number of exceedance days found at measurement stations in NRW during November 2011.

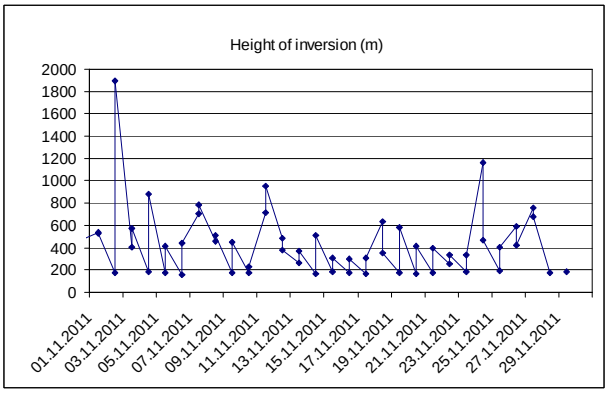

Figure 2: Height of inversion at Essen, NRW, Germany, during November 2011

Other parts of Germany showed high concentrations as well. In November, a first analysis showed exceedances on 18 days at rural background measurement sites in Germany (UBA, 2012). Over the whole year 2011, 11 rural background sites showed limit value exceedances (compared to 6 on average over the years 2005 to 2010), 19 urban background sites (13 over 2005 to 2010), and 33 traffic related sites (29 over 2005 to 2010).

EURAD simulations showed, at least for the November episode, that the high PM10 concentrations affected not only Germany but also large parts of Central Europe. The high PM10 concentrations covered Central Europe like a belt from west to east, sparing only the Scandinavian and Mediterranean countries.

Scope of the paper is to give an overview of the exceedance situation including the meteorological conditions. Additionally the origin of the particle burden will be investigated with focus on the questions whether the high particle loads were mainly home made or caused by long range transport. Figure 2 shows the height of inversion during November 2011 at the radiosounding station of the German Weather Service at Essen. It is clearly visible that during the whole month low heights of inversion persisted. This is certainly one of the causes leading to the high PM10 concentrations. Further investigations are currently under way.

Health relevant organic compounds on particulate matter ($PM_{2.5}$) at two urban sites in Munich: Critical data evaluation

J. Lintelmann, K. Fischer, R. Zimmermann

Cooperation Group "Comprehensive Molecular Analytics"
Helmholtz Zentrum Muenchen,
Ingolstädter Landstr.1, D-85764 Neuherberg

Keywords: PAH-derivatives, HPLC, LC-MS/MS, particulate matter, source apportionment

Recent studies underline the importance of the organic fraction of particulate matter for human health (Urch et al., 2004, Mauderly et al., 2008). Beside physical properties the chemical constitution of the particles determines their potency to cause severe health impairments.

During two consecutive years particulate matter ($PM_{2.5}$) was collected at two urban sites: In the Munich city center (2006) and at the Munich city border (2005) to aim for the characterization of representative, health relevant organic substances on $PM_{2.5}$ on the one hand, and for comparing concentrations, their time courses as well as information on respective sources on the other hand. Regularly sampling (every 3rd day for 24 hours) with a high volume sampler was performed. Particle-laden quartz-fibre filters were extracted and used for the determination of polycyclic aromatic hydrocarbons (PAH), nitro-PAH, and PAH-diones The HPLC-based methods applied were developed, validated and established in our laboratory (Lintelmann et al., 2006).

Data evaluation was performed applying different data analysis tools (e.g. multiple linear regression, principal component analysis (PCA) positive matrix factorization (PMF, Environmental Protection Agency, USA)). Additional information like temperature, wind speed, radiation, ozone-, CO- and PM-concentration was of course incorporated as far as available. Data analysis is a dynamic process meaning that not a *right* or *true* model/structure is found, but rather a reasonable, useful interpretation Stahel (2008). Some outlooks of this interpretation are:

Temperature and wind speed in contrast to radiation and ozone significantly influence concentrations of the organic compounds considered. As expected analyte concentrations are season dependent with higher and extreme values in autumn and winter.

PMF for the Munich city center samples leads to reasonable results concerning interpretation and regression diagnostics assessing four factors. One factor is assigned to diesel emissions due to a high load of 1-nitropyrene, which is regarded as a diesel marker, and coronene, 3- and 4-ring PAH as well (factor 1). A second factor is referred to residential heating emissions with high contributions in the cold seasons, dominated by PAH loadings (factor 2). A further factor probably is a mixture from combustion/heating emissions which have partly undergone atmospheric transformation processes. It is characterized by high loading of PAH-diones (factor 3). The last factor is ascribed to traffic (gasoline) emissions influenced by atmospheric transformation and transport processes (factor 4). It is dominated by nitro-PAH and low PAH-contributions.

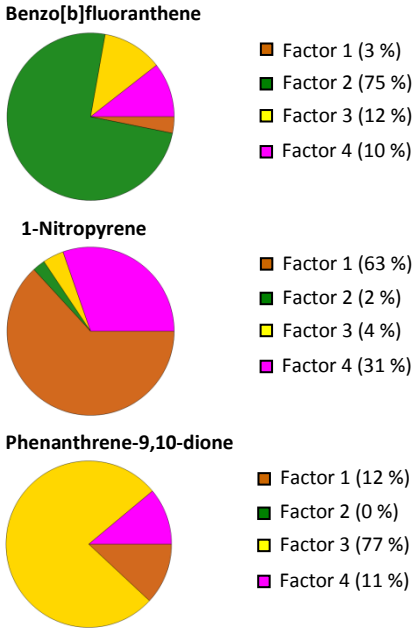

Figure 1: PMF-Factor pie charts for selected, representative health relevant organic compounds in $PM_{2.5}$, Munich, Germany.

VARIATIONS OF PM-10 AND ITS RELATIONSHIP WITH BE-7 MEASUREMENTS USING A HIGH-VOLUME AIR SAMPLER AT MÁLAGA

C. Dueñas*[1], M.C. Fernández*[1], E. Gordo[1], S. Cañete[1] and M. Pérez[2]

[1]Department of Applied Physics I, Faculty of Science, University of Málaga, 29071 Málaga ,Spain
[2]Department of Radiology and Health Physics, Ophthalmology and OTL, Faculty of Medicine, University of Málaga, 29071 Málaga, Spain.
Keywords: Berylium-7, Atmospheric Aerosols, Gamma Spectrometry, Particulate Matter (PM10).

Presenting author email: mafeji@uma.es

Levels of particulate matter fraction PM10 were monitored between 2009 and 20011 in Málaga (Spain).

The station "Carranque" (4º 28' 4" W; 36º 43' 40"N), belongs to the Atmospheric Pollution Monitoring network managed by the Environmental Health Service of the Andalusian Government. PM10 concentrations were measured at "Carranque" station by the beta attenuation method. The ^{7}Be concentrations in air was weekly continuously monitored which a high-volume air sampler (ASS-500C). This sampler uses polypropylene square filters (44 x 44 cm^2) and collection efficiency 93-99%, at a flow rate of 90000 l/min. Measurements by gamma-spectrometry were performed to determine the ^{7}Be activities of the samples using an intrinsic REGe detector.

Long-term measurements of cosmogenic radionuclides such as ^{7}Be provide an important data in studying global atmospheric processes and comparing environmental impact of radioactivity from man-made sources to natural ones. The period of measurements was performed from 2009 to 2011. The variation of the data with time was studied by time series analyses and seasonal patterns were identified.

Table 1 provides arithmetic mean (AM) and related statistical information such as geometric mean (GM), standard deviation (SD), variation coefficient (CVDF), maximum (MAX) and minimum (MIN) value.

	AM	GM	SD	CV(%)	MAX	MIN
^{7}Be (mBq/m^3)	5.1	4.8	1.7	34.7	10.2	2.1
PM_{10} (µg/m^3)	40.3	37.8	14.3	35.5	86.3	17.4

Table 1. Statistical parameters of the different measurements.

Plots of the frequency distribution of ^{7}Be activities and PM10 show the histogram highly skewed (flat on the right) and a symmetric distribution. The concentration data of ^{7}Be and PM_{10} with meteorological variables were correlated to understand the week variation of these radionuclides in air. This study has shown that ^{7}Be and PM_{10} are associated with different source in Malaga, they may reach high concentration simultaneously. The reason for this is the concurrent occurrence of subsidence processes over North Africa (resulting in the downward transport of ^{7}Be from the mid-troposphere) and the suspension of mineral dust over desert region with a subsequent transport to Malaga. In other hand, in order to simplify the analysis, the events have been grouped into: (a) Low ^{7}Be and high PM_{10}; (b) high ^{7}Be and high PM_{10} (c) High ^{7}Be and low PM_{10}.

Several events of high ^{7}Be concentrations are mainly caused by downward transport of ^{7}Be from the mid-troposphere at mid-latitudes. The meteorological situation was characterised by an Atlantic anticyclone system with a low-pressure area over central European North Atlantic. Also found high ^{7}Be concentrations associated with low aerosol mass concentrations. These values were attributed to downward transport from mid-to-upper troposphere over the North Atlantic.

The meteorological situation was characterised by a south Europe anticyclone located in the South Atlantic Ocean that favoured the development of a blocking system with a low-pressure area over north Europe. Under these conditions, a slanting stratospheric air mass can penetrate into the troposphere (Hernandez et al., 2008)

Figure 1 shows the back-trajectories and map of atmospheric dust loads during a typical example of this type of events.

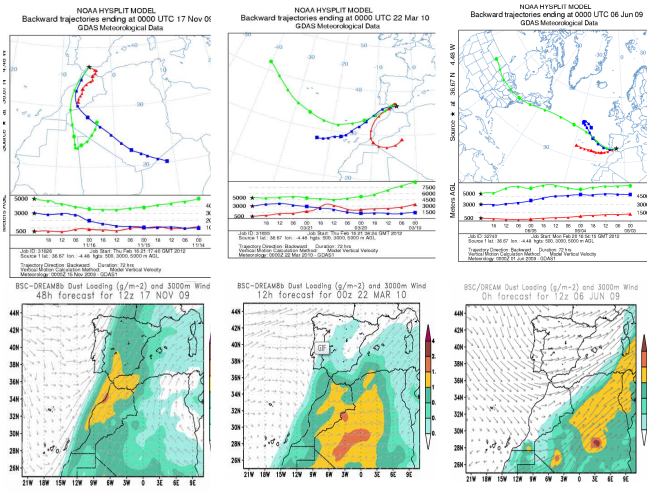

Figure 1. Map of atmospheric dust loads and back-trajectories

EDXRF analysis of elemental composition of $PM_{2.5}$ particles sampled in Taif, Saudi Arabia

A. A. Shaltout[1,2], D. R. Almallway[1], Z. F. Shehadeh[1], J. Boman[3]

[1]Physics Department, Faculty of Science, Taif University, 21974 Taif, P.O. Box 888, Saudi Arabia

[3]Department of chemistry and molecular biology, Atmospheric Science, University of Gothenburg, SE-412 96 Göteborg, Sweden
Keywords: XRF, urban pollution, $PM_{2.5}$
Presenting author email: johan.boman@chem.gu.se

The present work is the first part of an initiative to evaluate the trace element composition of atmospheric aerosol particles smaller than 2.5 μm in aerodynamic diameter ($PM_{2.5}$) in two different areas of Taif city, Saudi Arabia. The selected industrial measurement site was situated at the largest industrial area in Taif whereas the residential measurement site was situated at the most crowded street in central Taif, namely on Television Street. $PM_{2.5}$ samples were collected during June and August 2011 on polycarbonate filters in a cyclonic sampler. The duration of the collection was 24 hours.

The knowledge of the chemical composition of air particulate matter is very important because it has an essential relation to health problems (Renwick et al., 2001). In addition, it gives important information on their origin and may also reveal whether they were emitted as primary or secondary particles. The smaller the particle, the more harm it may cause, as it penetrates deep into the lungs (Schwartz and Neas, 2000). Generally, there are two aspects to the importance of knowing the elemental content of atmospheric particles. First there are heavy elements such as Cd, Pb, As, and Sb, that are in themselves toxic to human health. It is of interest to follow the ecocycles of these metals as environmental hazards, once they are released into the atmosphere and biosphere. The second aspect is that single elements or ratios between elements can be used as a fingerprint of a special source emitting other hazardous species that are less stable and more difficult to measure.

An Energy Dispersive X-ray Fluorescence (EDXRF) spectrometer with Mo secondary target has been chosen for direct analysis of the filters with sampled aerosol particles. EDXRF was selected because of the relative simplicity of the analysis, no sample preparation is needed and the availability of the technique in many routine laboratories. The use of Mo secondary target is advantageous since it decrease the continuum radiation coming from the x-ray tube and creates a semi monochromatic excitation source for the elemental analysis. Quantitative X-Ray Analysis Software (QXAS/AXIL) has been used for the quantitative analysis of the sampled atmospheric particles. A certified reference material (SRM2783, Air Particulate on filter media, NIST, USA) has been used in order to validate the obtained results.

The analysis resulted in determination of thirteen elements; Br, Ca, Cl, Cu, K, Mn, Ni, Fe, Pb, S, Sr, Ti and Zn. One example of a XRF spectrum is shown in figure 1. The measured concentrations of the potentially hazardous trace elements As, Cu, Sb, Cr, Mn, Ni and Pb were below the limits defined by international guidelines and national standards of ambient air quality.

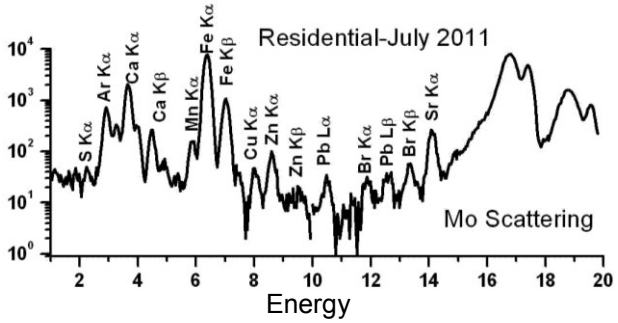

Figure 1. Example of the XRF spectrum of an aerosol particle sample collected in Taif.

This initial study is followed by long-term research required to validate the quantification of trace elements collected in this study. More samples are acquired at the two sites mentioned above and a newly added site dominated by traffic. In addition, the collected samples will be further studied using an Electron Spin Resonance (ESR) technique to investigate the existence of paramagnetic centers. These centers, if they exist in the samples, can be of great importance regarding the availability of radicals in the samples.

For this work we acknowledge the financial support by the Swedish Research Link program.

Time-resolved Measurements of Atmospheric Particulate Matter

M. Amodio, E. Andriani, P. R. Dambruoso, G. de Gennaro, A. Di Gilio

Department of Chemistry, University of Bari, Bari, Puglia, via Orabona, 4, 70126, Italy
Aerosol characterization, ionic fraction, PM2,5, AIM 9000D
alessia.digilio@uniba.it

Airborne particulate matter (PM) is a complex mixture of particles which show differences in size, physical and chemical properties and thus in the toxicological and carcinogenic effects they cause (Sager et al, 2009). The understanding of PM transport, mixing and transformation processes, and the identification of main factors influencing PM concentrations are relevant for developing appropriate control strategies for air quality. The determination of inorganic fraction in PM is very important to define the effective contribution of each source to fine PM. This fraction and in particular the ions, which constitute about 40-50% of total mass of PM2.5 and PM10, can be used as markers of different sources. Therefore, European Regulation suggest to characterize PM (ionic composition, organic carbon OC and elemental carbon EC) to obtain more detailed information concerning the different contributions to PM concentration (Annex IV of the air quality directive, EC, 2008).

The emitted pollutants undergo dilution with ambient air, and various types of transformations in atmosphere and during the transport process. The particle number concentrations, the information about the vertical diffusive properties of the low layers of the atmosphere, the meteorological data and the information obtained by aerosol models such as HYSPLIT and DREAM, and the characterization of ionic fraction of PM could be a useful tool to identify and characterize the different sources affecting PM concentrations (Amodio et al., in press).

In this work, the results obtained by applying an integrated approach in PM monitoring are shown. A system, located close to Chemistry Department of University of Bari was assembled with following instruments: SWAM Monitors, OPC monitor, PBL Monitor and Ambient Ion Monitor (AIM 9000D - URG Company). AIM instrument provides time-resolved direct measurements of anion and cation both in particulate (NO_3^-, SO_4^{2-}, Cl^-, NH_4^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, found in PM2.5) and gases phases (such as HCl, HNO_3, HNO_2, SO_2 and NH_3).

Time-resolved data provided by system and collected from the 29th September to the 1st November 2011, allowed to identify and characterize time-limited events. In sampling period, the PM_{10} concentrations exceeded the limit value established by the EU Directive (50 ug/m^3) in nineteen days. The results showed an increase in concentration of secondary pollutants when low dispersive atmospheric conditions and high $PM_{2.5}/PM_{10}$ ratio were determined. In these days the hourly nitrate concentrations and the natural radiation counts showed the same trend. On the contrary, when high dispersive atmospheric conditions and lower $PM_{2.5}/PM_{10}$ ratio were registered, the long-range transport events, such as natural or anthropogenic outbreak, occurred. As example sulphate and ammonium concentration and the natural radiation counts in the period from the 29th September to the 12th October are reported in Fig.1. From the 10th and the 12th October, the natural radiation counts and $PM_{2.5}/PM_{10}$ ratio decreased respect to other days; this period was characterized by gust event and wind blew from North-East. High hourly sulphate and lower ammonium concentrations were observed. In these three days, the information provided by aerosol models and 5-days backward trajectories at event hour, identify the outbreak from North-East Europe in the Southern regions of Italy. The hourly concentration of sodium and chloride (not shown), calcium and sulphate in this period showed the same behaviour (Fig.2). These results suggested a synergic contribution to PM concentrations of crustal contribution, due to the pollutants resuspension caused by gust wind, and a marine aerosol.

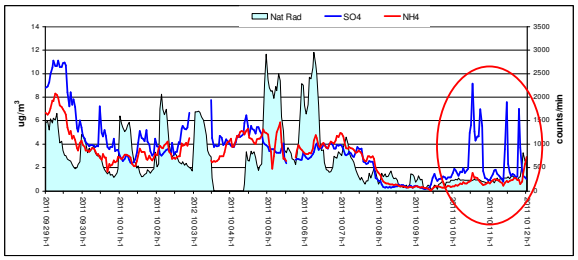

Fig. 1: natural radiative counts, ammonium and sulphate concentrations (ng/m^3)

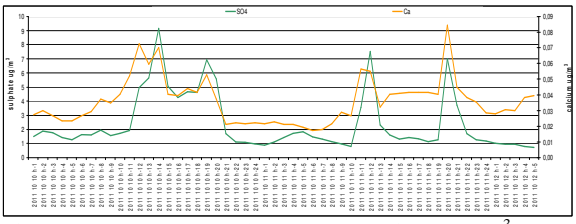

Fig. 2: sulphate and calcium concentrations (ng/m^3)

Keywords: PM2.5, chemical composition, time trend, elemental composition
Presenting author email: schwarz@icpf.cas.cz

Elemental and ionic compositions of $PM_{2.5}$ were measured daily at rural backround site Košetice that is located about 80 km SE from Prague, Czech Republic. The Košetice site is a part of EMEP, ACTRIS, and GAW networks. The measurement was carried out from October 2009 till October 2010. The samples were taken using a sequential sampler Leckel equipped with $PM_{2.5}$ inlet at 2.3m3/h. TEFLO filters (Pall, 47mm in diameter, 3µm porosity) were used. The samples were analysed using ion chromatography for water soluble ions and by PIXE, PESA and RBS methods to determine content of up to 40 elements.

The results were compared with data measured daily at the same site for 14 months from Dec 1993 to January 1995 R. Krejčí who sampled the aerosol $PM_{2.5}$ fine fraction on polycarbonate Nuclepore filters and analysed samples using PIXE.

Meteorological data, and trace gases concentration are available for both campaigns. The air mass back trajectories were calculated for both campaigns. The results are compared both from view of individual elements and sources determined using PMF analysis of the data.

Ratios 1994/2010 of yearly median elemental concentrations are shown in Fig. 1.

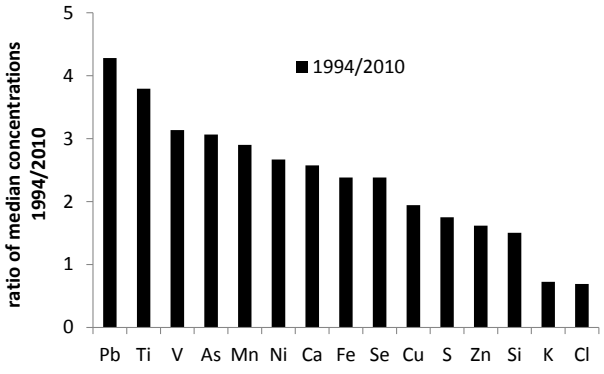

Figure 1. Ratios of median concentrations of individual elements in 1994 and 2010 data.

It is clear that most of elemental concentrations decreased during the time and some of them substantially. Lead and titanium decreased about 4 times, vanadium, arsenic, manganese, and nickel decreased about 3 times. Sulphur was found to be the most abundant element of the analysed ones. It decreased only 1.7 times despite much larger decrease of the SO_2 emissions. Potassium median concentrations were even higher in 2010 than in 1994.

An example of seasonal variation of several elements in both years is depicted in Fig. 2.

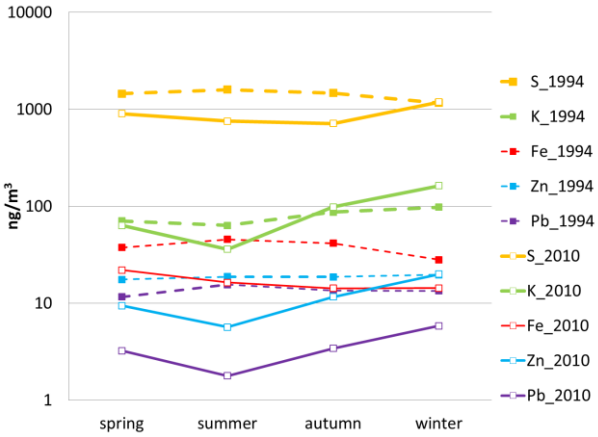

Figure 2. Seasonal median elemental concentration in aerosol fine fractions in 1994 and 2010 at the rural background site Košetice

Although seasonal trends may be influenced by year to year meteorological variations, it seems that residential heating plays an increasing role in total aerosol burden. The most pronounced differences can be seen in lead seasonal trend. In 1994, lead from the traffic exhibited a maximum in summer, while in 2010 it shows a clear minimum in the same season. Winter maxima are seen now for all depicted elements except iron, where the dust resuspension plays a major role Higher concentration of potassium found in the aerosol fine fraction in winter 2010 is probably related to an increasing use of biomass burning for residential heating due to supportive measures and lower price in comparison with the other fuels.

This work was supported by the Czech Science Foundation under the grants No. 205/09/2055 and 209/11/1342. The authors would like to thank Mr. Jan Čech from the Košetice station for operating the sequential sampler in the recent campaign and Dr. Milan Váňa from the same site for supporting data delivery.

Temporal and spatial variability of the total particle number concentration in the Venice area

Andrea Pigozzo[1], Alessio De Bortoli[2], Salvatore Patti[2], and Laura Manodori[3]

[1]Associazione CIVEN, Venezia, ,I-30175, Italy

Keywords: CPC, number concentration, ultrafine particles.
Presenting author email: pigozzo@civen.org

Ultrafine airborne particles have been recognised to be toxic for the human health (Oberdörster, 2001) and they are becoming a primary concern in the air quality management and regulation. In a such framework, the present study aims to evaluate the temporal and spatial variation of ultrafine particles concentration at 5 sampling sites in the Venice mainland, where different human activities and sources of pollution could be identified

To collect a robust data-set, an intensive measurement campaign has been carried out over one year by means of a condensation particle counter (CPC Grimm, mod. 5.403; range of the detectable particles: 4 nm – 3 μm); samplings have been performed for 15 consecutive days at every site, with a temporal resolution of 1 minute. The sampling stations have been identified as rural, industrial, urban background, urban and traffic sites.

The analysis of the preliminary results allows to observe the presence of a clear seasonal trend at every site, with the highest concentrations detected in winter and the lowest ones in summer, as reported in Figure 1. Moreover, the obtained data-set has confirmed the expected spatial distribution of the particles concentration, in agreement with the surrounding anthropic sources and the results previously reported by Morawska *et al.* (2009). In detail, the rural site shows the minimum median concentration (total particle number concentration: $8x10^3$) whilst the traffic oriented site exhibits the maximum median concentration (total particle number concentration: 4.5×10^4).

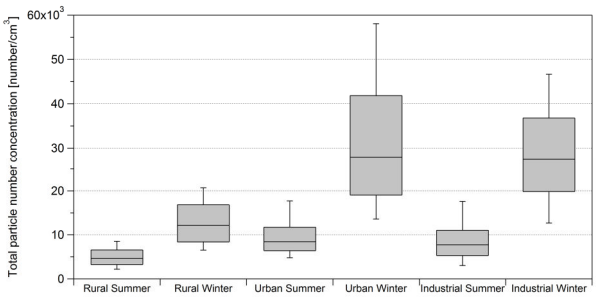

Figure 1. Box plot (minimum, 25th percentile, median, 75th percentile, maximum) of the particle number concentrations at the rural, urban and industrial sites in summer and winter

As depicted in Figure 2, a circadian variability of the particle concentration has been detected at the traffic site, with two maximum peaks in correspondence of the traffic rush hours in the morning and the late afternoon. These peaks may be related to the major input of fresh pollutants emitted by motor engines, which increase the formation of secondary aerosol that is the main responsible for the ultrafine fraction and the increasing of the total number concentration (Wang *et al*., 2010). The same trend has been observed at the urban site too, but it was completely lacking at the rural station.

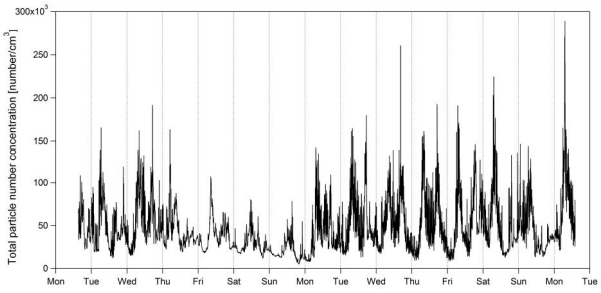

Figure 2. Smoothed trend of total particle number concentration at the traffic site.

Presenting author email: johan.boman@chem.gu.se

This study was undertaken based on a growing global concern on the effect of airports on local air (Woody et al., 2011). It is the first to report trace element concentrations of aerosol particles at an international airport in Africa. Studies like this are important since a degraded air quality in a world of increasing urbanization and industrialization constitutes a direct threat to human health (Lighty et al., 2000).

Measurements were made at the Jomo Kenyatta International Airport, Nairobi, between May 6th 2011 and May 17th 2011. Outdoor aerosol particles were collected using an Andersen TM dichotomous impactor, whereas personal samplers were used for indoor particle collection. The Andersen impactor collect particulate matter of size segregated coarse and fine fractions on Teflon filters. Coarse and fine particle fractions are defined as particles between 2.5 and 10 µm aerodynamic diameter and particles smaller than 2.5 µm, respectively. Indoors only fine particles, also known as $PM_{2.5}$, were collected. Collection was carried out for 12 hours twice a day (day and night) outdoors and eight hours indoors. The shorter period indoors was chosen to mimic the normal working hours of the staff at the airport.

Mass concentration levels of particulate matter (coarse and fine) and Black Carbon (BC) were determined gravimetrically and by use of a Black Carbon photometer, respectively. Trace elements were determined using the secondary target based Energy Dispersive X-Ray Fluorescence (EDXRF) spectrometer at the Institute of Nuclear Science and Technology, University of Nairobi, Nairobi, Kenya. Quantification was done by the QXAS/AXIL software package.

The outdoor mass concentration range of PM_{10} and $PM_{2.5}$ at Jomo-Kenyatta International Airport were 18 – 67 µg m^{-3} and 4 – 28 µg m^{-3}, respectively. This is in most cases lower than the drafted Kenyan annual limits of 50 µg m^{-3} and 35 µg m^{-3}, respectively. Similarly the concentrations were higher than the World Health Organization (WHO) 24-hour guideline value of 50 µg m^{-3} and 25 µg m^{-3}, respectively, on a few occasions only. Median Pb mass concentration was 65 ng m^{-3} in the PM_{10} fraction. This is significantly lower than the WHO recommended limit of 500 ng m^{-3} in PM_{10}. The concentrations of PM, BC and detected elements indicate that the air at the airport is not more polluted than at other public places in Nairobi, and many other busy places in Africa and elsewhere.

It is anticipated that this study will provide baseline data that could help evolve a health related air pollution abatement program and provide evidence based advice to policy making.

The work is supported by International Science Programmes (ISP), Uppsala, Sweden.

Urban air quality monitoring networks are requested to provide accurate and relevant data on air pollution levels which serve as basis to assess limit value compliance and the need of mitigation actions. Scientific and technological progress as well as new epidemiological and toxicological research results trigger a continuous demand to re-adjust the monitoring strategies and instrumentation.
On this background one major task of the EU FP7 project AirMonTech is to collect and evaluate information on recently developed and future monitoring technologies for regulated and potential future pollutants and proxy metrics. Metrics and available measurement technologies being reviewed are listed in Table 1.

Particulate Matter	**Gaseous pollutants**
Total number concentration	NO
Number size distribution	NO_2
Surface concentration	NO_x
Shape, morphology	SO_2
Mass concentration	O_3
Elemental composition	NH_3
Molecular composition	VOCs
Sulphate	HCl
Nitrate	HNO_3
Ammonium	HNO_2
Elemental carbon	
Organic carbon	
Light absorbing aerosols	
Reactive oxygen species	
Macrophage mobility decrease	
Polycyclic aromatic hydrocarbons	
Primary biological aerosol particles	

The information is obtained from scientific literature, manufacturer's files and researchers in the field of measurement technology development. It subsequently is processed in a standardised way to make it accessible via the AirMonTech database. The content of the database is based on hands-on experience and will be publicly available. It will facilitate the decision which metric to measure and which technique to use for a given situation and will also build on information coming from all stakeholders.

Although this process has not yet been accomplished, some general trends in monitoring instrumentation and regarding new metrics and proxies are already apparent. On the one hand, multi-component monitoring instruments increasingly gain attraction, on the other hand the development of miniaturised and mobile instruments offer new monitoring approaches which might be more suitable for exposure assessment than current approaches. The difficulties to translate the well-established health effects of particulate matter into toxicological mechanisms further motivates the development of monitoring technologies for specific physico-chemical particle proxies which are thought to better reflect the health relevant fraction of the ambient aerosol than its total mass. While some of these more advanced multi-component are already marketed and used in air pollution research, others still have to be further developed to make them usable within AQ monitoring networks.

Magnetic properties of PM10x collected at rural site during heating and non-heating seasons

E. Petrovsky[1], B. Kotlik[2], A. Kapicka[1], R. Zboril[3] and M. Roxer[1]

Keywords: PM10, magnetite, concentration, pollution, industrial source
Presenting author email: b.kotlik@szu.cz

Magnetic properties of environmental samples can serve as fast and relatively cheap proxy method to investigate occurrence of iron oxides. These methods are very sensitive in detecting strongly magnetic compounds such as magnetite and maghemite and can reveal concentration and assess grain-size distribution of these minerals (e.g., Sagnotti et al., 2009). This information can be significant in estimating e.g. the source of pollutants, monitoring pollution load, or investigating seasonal and climatic effects.

We studied magnetic properties of PM1, PM2.5 and PM10, collected over 32-48 hours in a small settlement in south Bohemia during heating and non-heating season. The site is remote, of rural character, with negligible traffic and industrial contributions to air pollution. Thus, the suggested seasonal effect should be dominantly due to local (domestic) heating, burning wood or coal.

Table 1. PMx concentration, magnetic moment and estimated concentration of magnetite in samples from non-heating and heating periods.

		Heating	Non-Heating
TSP	[μg/m³]	**40.6**	13.0
	Magnetic moment	6.26e-05	**7.09e-05**
	Magnetic conc.	1.48e-02	**6.20e-02**
PM10	[μg/m³]	**38.4**	9.4
	Magnetic moment	4.08e-05	4.36e-05
	Magnetic conc.	1.20e-02	**5.26e-02**
PM2.5	[μg/m³]	**36.8**	7.5
	Magnetic moment	**2.22e-05**	1.81e-05
	Magnetic conc.	0.74e-02	**2.95e-02**
PM1	[μg/m³]	**26.9**	6.5
	Magnetic moment	1.00e-05	**1.92e-05**
	Magnetic conc.	0.46e-02	**3.71e-02**

In our contribution we show typical differences in PMx properties in the two periods. Concentration is much higher in the winter (heating) period (Table 1). In both summer and winter samples, Fe-oxides of typical spherical shape with diameters below 5 μm were observed (Fig. 1). Fe-oxieds are observed mainly in PM10 fraction. Magnetic parameters sensitive to grain-size distribution of Fe-oxides are different for summer and winter PM10 samples, with clear shift towards finer particles in summer (Fig. 2). This may reflect different source of PM, with dominant natural particles from agriculture and land-use activities in summer, compared to those produced by domestic heating in winter.

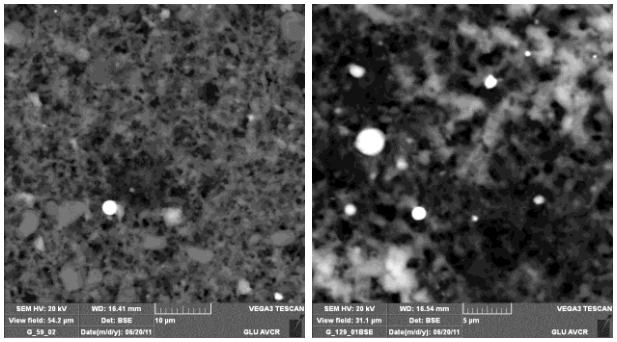

Figure 1. SEM of PM10 of sample from non-heating (left) and heating (right) period.

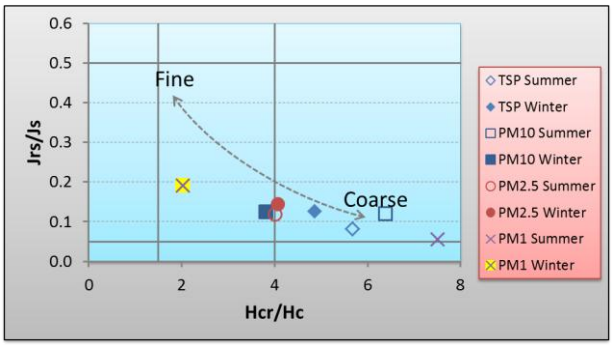

Figure 2. Diagram of magnetic parameters sensitive to grain-size distribution of magnetite/maghemite. Coarse is related to multi-domain magnetite (few μm and more), while Fine corresponds to single-domain magnetite (<0.5 μm).

Our results suggest that magnetic minerals reflect well specific seasonal properties of air pollutants in sites where domestic heating is the dominant source of pollution.

Presenting author email: willy.maenhaut@ugent.be

Within the framework of two research projects from the Flemish Environment Agency (VMM), PM10 samples, which were collected on 47-mm diameter Pallflex Tissuquartz filters, are analysed for organic, elemental, and total carbon (OC, EC, and TC). In the first project (P1), the samples were collected at 7 sites in parallel every fourth day from February 2010 to February 2011, whereas in the second project (P2) the samples are collected at 12 sites in parallel every fourth day from July 2011 through June 2012. All samples from P1 and all those taken in the course of 2011 within P2 were analysed by thermal-optical analysis with the NIOSH temperature protocol (Birch and Cary, 1996) and simultaneous measurement of transmission (TOT) and reflectance (TOR). A subset of 70 samples from P1 was also analysed with the EUSAAR2 protocol (Cavalli *et al.*, 2010) using TOT and TOR.

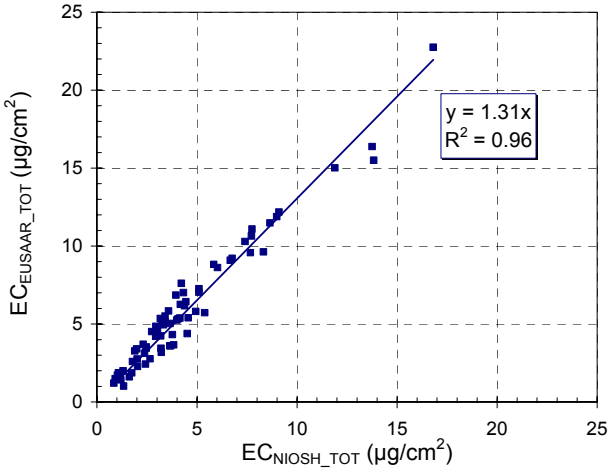

Figure 1. Comparison of EUSAAR2 and NIOSH TOT EC for the subset of 70 samples from project 1.

The scatterplot of EUSAAR2 TC versus NIOSH TC for the subset of 70 samples from P1 (not shown) indicated that there was very good agreement between the TC data from the two temperature protocols; the regression line, when forced through the origin, had a slope of 1.016 with R^2 = 0.995. Figure 1 shows the scatterplot of EUSAAR2 TOT EC versus NIOSH TOT EC for the same subset of samples; the slope is now 1.31 and thus substantially larger than 1. The scatterplot of EUSAAR2 TOR EC versus NIOSH TOR EC (not shown) had a slope of 1.09 with R^2 = 0.95. The average EUSAAR2/NIOSH ratios and associated standard deviations for EC in TOT and TOR for the 70 sample (70s) subset of P1 are given in the top part of Table 1. The two average ratios are somewhat larger than the slopes of the corresponding scatter plots, but that for TOT is again larger than that for TOR.

Table 1. Averages and associated standard deviations for two types of ratios for EC and different sample sets.

EUSAAR2/NIOSH ratio for EC	mean ± s.d.
P1_70s_TOT	1.36 ± 0.24
P1_70s_TOR	1.20 ± 0.18
TOR/TOT ratio for EC	**mean ± s.d.**
P1_70s_EUSAAR2	1.51 ± 0.32
P1_70s_NIOSH	1.73 ± 0.48
P1_all_NIOSH	1.77 ± 0.66
P2_all_NIOSH	1.30 ± 0.45

The average TOR/TOT ratios and associated standard deviations for EC, as obtained for the 70 sample subset of P1 with the EUSAAR2 and NIOSH protocols and for the samples of P1 and P2 (separately) with the NIOSH protocol, are given in the bottom part of Table 1. It appears that the average ratios with NIOSH in P1 for the subset of 70 samples and for all (644) samples are quite similar, which suggests that the subset was representative for the entire sample set of P1. The TOR/TOT ratio for EC obtained with EUSAAR2 is clearly lower than that obtained with NIOSH. It is further noteworthy that the difference between the TOR and TOT EC tends to be larger than the difference between the EUSAAR2 and NIOSH EC. One can also conclude from the standard deviations that the variability in the TOR/TOT ratio is larger than the variability in the EUSAAR2/NIOSH ratio. Finally, it appeared that the various ratios did not seem to depend much upon the filter loading, sampling site, or time of the year.

Road traffic impact on size-segregated atmospheric aerosols loading at Madrid

F. Mirante[1], C. Alves[1], C. Pio[1], [2]M. Fernandez, M.A. Revuelta[2] and B. Artiñano[2]

[1]CESAM, Department of Environment and Planning, Aveiro University, 3810-193 Aveiro, Portugal
[2]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), 28040 Madrid, Spain

Keywords: urban aerosol, size distribution, OC/EC, ions, metals
Presenting author email: casimiro@ua.pt

Road traffic and favourable climatic conditions for photochemical formation and dust re-suspension are the causes of atmospheric aerosol levels often above legislation limits. It is important to take strategies for urban particulate pollution control based on information concerning the sources of the aerosol. With these objectives, two campaigns were performed at two contrasting sites, in the city of Madrid.

Size-segregated (<0.5µm, 0.5-1µm, 1-2.5 µm, 2.5-10 µm) particulate matter was collected with hi-vol samplers simultaneously at two sites (roadside and urban-background) during two one-month long campaigns (summer 2009 and winter 2010). After collection, the organic and elemental carbon fractions were determined by a thermo-optical method, water-soluble ionic species were measured by ion chromatography, organic compounds by gas chromatography-mass spectrometry, while metals were analysed by inductively coupled plasma mass spectrometry.

Roadside enrichements (*REs*) were defined as the fractional difference between the concentrations at the roadside and urban background site:

$$RE_i(\%) = \frac{x_i^R - x_i^{UB}}{x_i^R} \cdot 100$$

where: *i* is a given chemical component (variable),
x is the concentration of the component *i*,
R and *UB* are the sampling sites for which the concentrations of component i are compared.

Differences in PM mass and composition between a kerbside station and an urban background station can be attributed to the adjacent traffic (Oliveira et al., 2010; Snyder et al., 2010).

In summer, the highest enrichments were in fine fraction, whereas in winter were in coarse fraction (Fig. 1). The *REs* were ≥ 80% for Mn, Ni, Cu, Zn, Cd, Sb, Sn, and Rb. In winter, these tracers of traffic emissions were lower, except for Zn. The mineral elements resulting from road dust re-suspension, such as Sr and La had a *RE* of 100 and 97%, respectively, in summer. Very low values were obtained in winter. The *EFs* for Ca^{2+} and Sm were 40-47% in summertime, while values of 70 and 27% were obtained in the cold season. A considerable difference was registered between EC and OC in summer; this difference was not so significant in winter. EC is only emitted as primary particles and it was enriched by 75, 71 and 68% in PM_1, $PM_{1\text{-}2.5}$ and $PM_{2.5\text{-}10}$, respectively in summer and 68, 55 and 72% in winter. OC could be primary and secondary. Their *Res* were 41% in all fractions in summer and 68, 76 and 65% in PM_1, $PM_{1\text{-}2.5}$ and $PM_{2.5\text{-}10}$, respectively, in winter. For $PM_{1\text{-}2.5}$ only five enrichements higher than 50% were obtained (Mn (59%), Zn (64%), Sb (75%), Sn (66%) and Ti (98%)) in summer, but in winter these elements were also higher than 50%. Lower enrichments were obtained in the coarse fraction than in the fine fraction for the tracers of traffic emissions and mineral matter in summer; the opposite happens in winter.

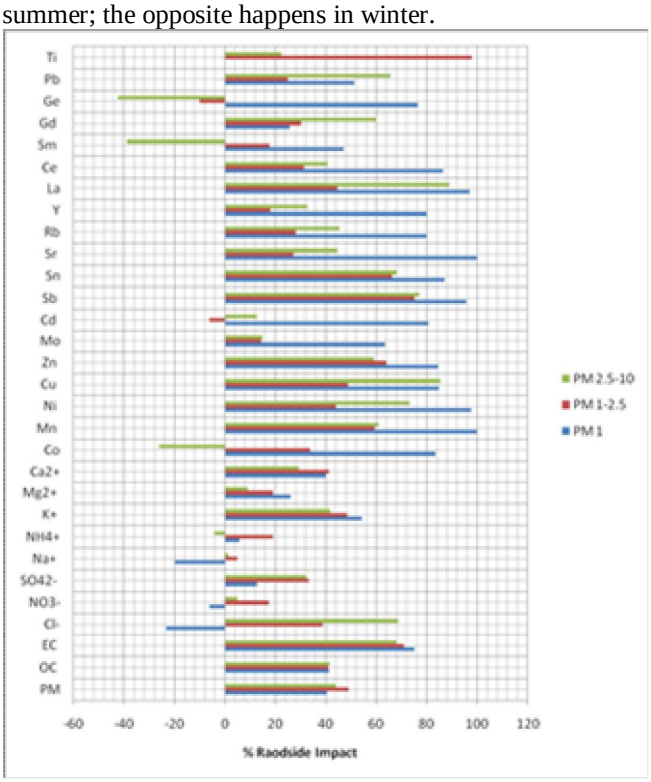

Figure 1.Roadside enrichments in summer.

Preliminary research on the ammonium content of particulate matter from indoor air of pig housing systems

T. Ulens[1], N. Van Ransbeeck[1], H. Van Langenhove[2] and P. Demeyer[1]

[1]Technology and Food Science Unit, Institute for Agricultural and Fisheries Research, Merelbeke, East Flanders, 9820, Belgium

Presenting author email: tim.ulens@ilvo.vlaanderen.be

In a recent report, published by the Flemish Environment Agency (VMM) and the Flemish Institute for Technological Research (VITO), a method was formulated to map the different source contributions to PM10 and PM2.5 in Flanders. The conclusion in this report was that, apart from cross border contributions, the agricultural sector provides the largest contribution with regard to PM10 (54%) and PM2.5 (49%) (Deutsch *et al.*, 2010). These contributions were calculated by combining the emissions of primary particulate matter with the secondary particulate matter formation originating from ammonia emissions by agricultural activities.

In this approach however, it was not taken into account that secondary particulate matter (in this case ammonium salts) can possibly be formed indoor in the animal housing systems. Recent reports by the VMM indicate that ammonium, nitrate and sulphate contribute respectively about 7 %, 22 % and 12 % to the total atmospheric PM10 concentration and about 12 %, 21 % and 18 % to the total atmospheric PM2.5 concentration in Flanders (VMM, 2010;Vercauteren *et al.*, 2011;VMM, 2009). If ammonium salts are indeed formed indoor, the contribution of these salts is probably being counted twice: once as primary emissions from animal housing systems and again as secondary particulate matter, originating from ammonia emissions.

During the period of March to June 2012 experiments will be conducted to investigate this hypothesis. First, samples of PM10 and PM2.5 will be collected inside an experimental pig housing system at ILVO. These samples will be quantified gravimetrically and analysed on their ammonium content via colorimetric tests. Based on these results, a more extended sampling campaign will be carried out at three farms to verify the initial findings in real practice. The results and conclusions of these experiments will be presented at the conference.

If these experiments result in a clear indication that primary particulate matter from animal housing systems contain significant amounts of ammonium salts, a more in depth research approach will be set up to further investigate this phenomenon. This would also urge to review the contribution of agricultural activities to the PM10 and PM2.5 situation in Flanders.

This work was supported by the Boerenbond, a professional association for Flemish farmers.

Seasonal variations of ions and metals in urban PM1 aerosol

P. Mikuška[1], K. Křůmal[1], M. Vojtěšek[1], N. Kubátková[1,2] and Z. Večeřa[1]

[1] Institute of Analytical Chemistry of the ASCR, v.v.i., Veveří 97, 602 00 Brno, Czech Republic

Keywords: atmospheric aerosols, metals, ions, PM1.
Presenting author email: mikuska@iach.cz

Epidemiological studies (Schwartz *et al.*, 1996; Pope, 2000; Brunekreef and Holgate, 2002) have suggested a statistical association between health effects and ambient fine particle concentrations, especially the submicron fraction (PM1) that can penetrate deep into the alveolar region of the lungs. Chemical composition of PM2.5 and PM10 is subject of many studies, however, relatively little attention has so far been paid to PM1 aerosols. Determination of their composition is essential to understand their properties and reactivity and hence their environmental and health effects (Singh *et al.,* 2010).

Daily samples of PM1 aerosol particles were collected in Brno and Šlapanice during a week in winter and summer of 2009 and 2010. Aerosols sampled using a high-volume sampler (DHA-80, Digitel, 30 m^3/h) on cellulose-nitrate filters (150 mm, Sartorius) were analysed for metals (Al, K, Ca, Fe, Mn, Zn, Cu, Pd, Cd, Ba, As, Pb, V, Ni, Sb) by ICP method. Aerosols sampled in parallel using a low-volume sampler (1 m^3/h) on Teflon filters (47 mm, Zefluor) were analysed for ions (nitrate, sulfate, nitrite, fluoride, chloride, oxalate, Na^+, K^+, NH_4^+, Ca^{2+}, Mg^{2+}) by IC. Application of annular diffusion denuder placed between cyclone inlet (1 µm, URG) and Teflon filter eliminates interference of gaseous pollutants like SO_2, HNO_3, NH_3 and others (Mikuška et al, 2012).

Brno represents a big city with 370 000 inhabitants while Šlapanice is a small town with 6 000 inhabitants.

Metals and especially ions form in winter season significant part of mass of PM1 aerosols, metals 4.5-4.9% (Šlapanice - Brno) and ions 37.1-40.7% (Šlapanice - Brno) while in summer their contribution to PM1 was much smaller, metals 1.4-1.8% (Šlapanice - Brno) and ions 24.6-18.7% (Šlapanice - Brno).

The concentrations of metals were, in general, in winter higher than in summer. In winter period, the concentrations of metals in Šlapanice were higher than those in Brno whereas summer concentrations of metals at both localities were comparable. The highest mean winter concentrations were found for lead and potassium originating from combustion of wood and coal (Figure 1) while in summer high concentrations were found for lead, potassium, calcium, aluminium and zinc.

Sulfate, nitrate and ammonium prevail among ions in winter while in summer the contribution of nitrate and ammonium decreases.

Local traffic in summer and coal and wood combustion during household heating in winter were identified as the main emission sources of PM1 aerosols in both towns. Secondary aerosol components formed a significant part of aerosols during the whole year.

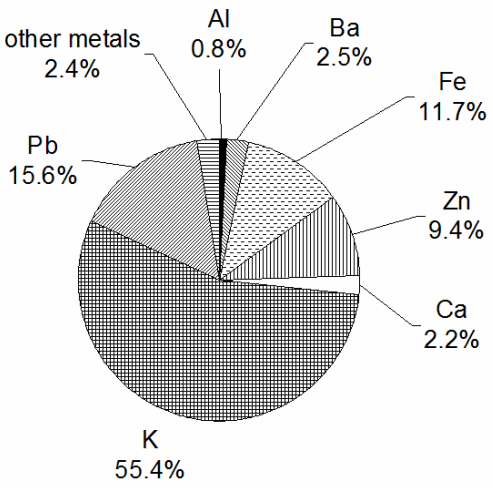

Figure 1. Relative mean contribution of analysed metals to the total metal content of PM1 aerosols in Brno during winter 2010.

Atmospheric fine ($PM_{2.5}$) particulate matter are classically sampled by filter collection or impaction but these offline methods are often subject to sampling artifacts (volatilization and reactivity), partly due to the long sampling times. These methods are also labor intensive and time consuming due to sample treatment (collection, extraction) and analysis. Online techniques such as Time-of-Flight Aerosol Mass Spectrometry (Canagaratna *et al.*, 2007) with a few minutes temporal resolution have been developed to overcome these limitations.

In this work, we have coupled real-time measurements and offline analysis from filter sampling. The chemical composition of fine particulate matter sampled at an urban background site (Douai) and an industrialized coastal site (Grande-Synthe near Dunkirk) located in Northern France (summer and winter field campaigns for each site) was investigated in order to compare both measurement methods.

$PM_{2.5}$ were simultaneously collected on 12 quartz fiber filters during 24h using a low-volume sampler. Each filter was then extracted by pressurized fluid extraction before being concentrated and analyzed by specific methods according to the target compounds: Polycyclic Aromatic Hydrocarbons (PAH), mono- and dicarboxylic acids (Mirivel *et al.*, 2009; 2011). Elemental Carbon (EC) and Organic Carbon (OC) concentrations were also measured by the Thermo-Optical Transmittance method with a Sunset Lab EC/OC analyzer following the NIOSH protocol.

In addition, a High Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS) has been deployed to measure size-resolved average chemical composition of the non-refractory submicron ($NR\text{-}PM_1$) aerosols. Black Carbon (BC) concentrations were also monitored by an Aethalometer every 10 minutes.

Good agreements between online measurements and offline chemical analysis data have been shown for the whole campaign results, highlighting the relevance of coupling both methods. BC concentrations measured in $PM_{2.5}$ were well correlated with EC measurements at both sampling sites (Figure 1).

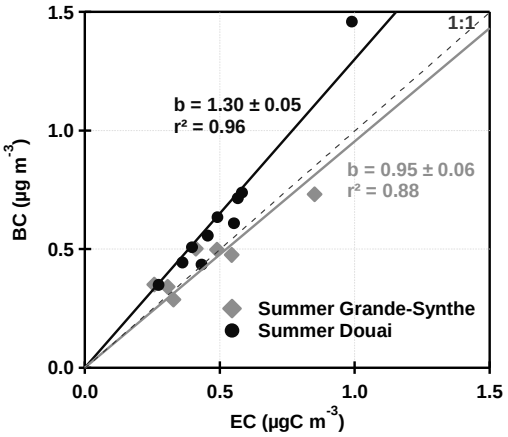

Figure 1. Comparison of BC and EC summer concentrations measured in $PM_{2.5}$ in Douai and in Grande-Synthe.

Another interesting comparison was made between 10 particulate PAH (2 C_{16}, 2 C_{18}, 3 C_{20} and 3 C_{22}) concentrations determined from filter analyses and the PAH concentrations measured by the AMS for the corresponding masses (m/z = 202, 228, 252, 276 and 278). Very similar time series were observed corresponding to a good linearity between measurements. Good correlations between OM/OC ratios have also been obtained in agreement with literature data. The results will be presented and discussed in details.

Our laboratory participates in the Research Institute of Industrial Environment (IRENI) which is financed by the Communauté Urbaine de Dunkerque, the Nord-Pas de Calais Regional Council, the French Ministry of Education and Research, the CNRS and European funds (FEDER).

Presenting author email: marossi@arpa.emr.it

The aim of this study is to characterize the composition and seasonal variations of water-soluble organic compounds present in the atmospheric aerosol in the surroundings of a municipal waste incinerator (MWI) near to Bologna, a great urban centre in Northern Italy. This study is a part of an intensive environmental and epidemiological monitoring program (MONITER project) that has been designed and developed by the Environmental Protection Agency of Emilia Romagna Region (ARPAER), in order to evaluate the impact of the MPWI emissions on the ambient air and to estimate the exposure levels to toxic or carcinogenic compounds for a population living in the neighbourhood of this incinerator (www.moniter.it). Samples were collected during intensive summer 2008 and winter 2009 campaigns in 8 monitoring sites selected in order to compare points where the incinerator has the highest impact with those where the incinerator impact is negligible.

The analyzed compounds included 18 dicarboxylic acids and 7 sugars, as important chemical tracers that may give relevant information on the relative strengths of primary emission sources and secondary photochemical processes affecting air quality (Pietrogrande *et al*, 2010).

In both the seasons the most abundant compound is levoglucosan, as the major by-product from biomass burning.

The abundances of the main dicarboxylic acids -- C3-C9 n-alkanoic and pthalic acids --exhibit a seasonal pattern with higher winter concentrations (mean total concentrations are were 60±18 ngm^{-3} and 23±9 ngm^{-3}, in winter and summer, respectively).

The distribution profiles and the diagnostic ratios of these markers allowed to identify primary emission sources (power plants, vehicular circulation, biomass burning) associated with secondary constituents from both biogenic (e.g. pinonic acid) and anthropogenic precursors (e.g. phthalic and benzoic acids) (Pietrogrande *et al*, 2011). The distinct seasonal patterns of abundances (Figure 1) suggests that the contribution of primary sources is significantly enhanced in winter in comparison with summer, when secondary atmospheric processes are dominant

This result is consistent with the winter atmospheric conditions in Po valley, caracterized by lower mixing heights, possible formation of the inversion layers, and less chance of wet deposition that confine vertical distribution of pollutants to the first hundred meters of the atmosphere contributing to the accumulation of air pollutants. Consequently, the secondary production of diacids is promoted by higher abundance of the organic precursors.

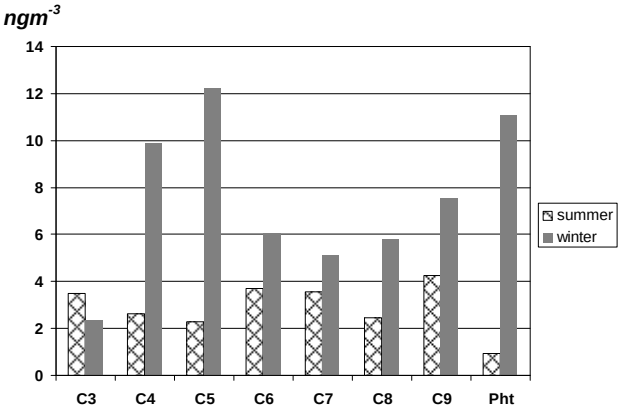

Figure 1. Seasonal pattern of the abundances of dicarboxylic acids (mean values computed on 8 sampling sites).

The spatial variations of the concentration of the target compounds show a homogenous PM composition in the sites around the municipal incinerator, reflecting the regional nature of primary sources and atmospheric processes, not significantly impacted by emissions from the MWI.

This work was financially supported by the Moniter project of the Environment Agency of Emilia Romagna region (ARPAER).

GC-MS method for the simultaneous analysis of water-soluble organic compounds in PM: response surface methodology for optimizing solvent extraction.

M.C. Pietrogrande, D. Bacco, S. Chiereghin

Department of Chemistry, University of Ferrara, Ferrara, 44121, Italy
Keywords: water soluble organic compounds, chemical analysis, GC-MS, air quality.
Presenting author email: mpc@unife.it

In recent years the increasing interest in water-soluble organic compounds (WSOCs) in the atmosphere is fuelled by their potential role in affecting the global climate, since they alter the hygroscopic properties of atmospheric particle, affecting their ability to act as cloud condensation nuclei and can also contribute to higher atmospheric absorption of solar radiation and atmospheric heating. In addition, some WSOCs – such as dicarboxylic acids and saccharides – are potentially useful molecular tracers, since they can have several different sources including primary emissions from biomass burning and fossil fuel combustion, as well as photochemical oxidation of organic precursors of both biogenic (e.g. pinonic acid) and anthropogenic precursors (e.g. phthalic and benzoic acids) (Pietrogrande *et al*, 2010).

GC–MS is the most widely applied technique for the characterization of organic aerosols since it yields excellent separation efficiency, sensitivity and high number of species analyzed. Due to their high polarity, hydrophilicity and low volatility, carboxylic acids and saccharides have to be converted into volatilizable and stable derivatives — i.e., trimethylsilyl derivatives using BSTFA(N,O-bis(trimethylsilyl)-trifluoroacetamide) as silylation reagent (Pietrogrande *et al*, 2011).

Indeed, multi-residue analytical methodologies, that achieve simultaneous analysis of several compounds, are useful for reducing the complexity and time required for sample preparation and analysis in order to provide a large amount of reliable data. With this aim, the proper selection of the extraction operating conditions is a critical step, since they are essential to achieve the highest yield for several target analytes with a wide range of water solubility and volatility.

This paper describes the optimization of the extraction operating conditions to develop a GC-MS procedure for the simultaneous analysis of carboxylic acids and saccharides in atmospheric aerosols, providing the low detection limits and the high reproducibility required by environmental monitoring.

The factors considered were the solvent type (characterized by polarity *p'* parameter) and extraction volume (10-20 ml). The response surface methodology (RSM) including central composite design (CCD) was applied to fully investigate the experimental domain of the operative parameters using a limited number of experiments (Basaglia *et al*, 2011). The response surface computed by the RSM model shows the simultaneous dependence of the extraction yield on the combination of the two variables, solvent polarity and volume (Figure 1).

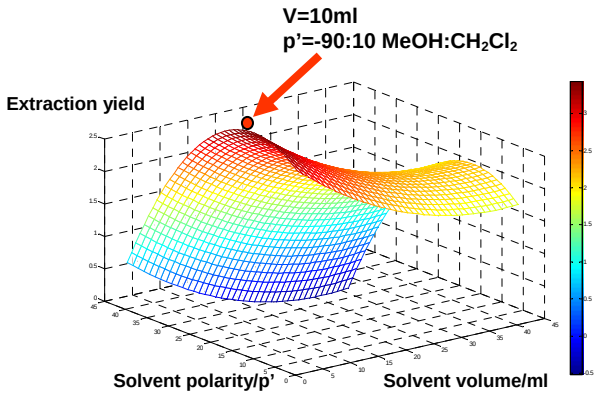

Figure 1. 3D surface plot showing the interacting effects of solvent polarity and extraction volume on extraction yield

The plot clearly shows that the optimum extraction solvent is a mixture of metane:dichlorometane (90:10) using a volume of 10 ml.

The optimized procedure provides low detection limits ($\leq$2 ngm^{-3}) and good reproducibility (RSD%$\leq$13%) that makes it suitable for environmental monitoring.

The developed protocol was extended to 22 target analytes that are relevant chemical markers, i.e., 15 carboxylic acids and 7 sugars.

In addition, the suitability of the optimized procedure was verified by application to PM filters collected under different conditions, i.e., different seasons (summer vs. winter), different sampling sites (urban vs. rural), different particle size dimensions ($PM_{2.5}$ vs. PM_1).

This work was partially supported by the Supersito project of the Environment Agency of Emilia Romagna region (ARPAER).

Total and water-soluble fraction trace element analysis of PM2.5 samples from the city of Patras, Greece

M. Manousakas[1], H. Papaefthymiou[1], K. Eleftheriadis[2]

[1]Department of Chemistry, University of Patras, Patras, Achaia, 26500, Greece

Airborne particulates are generated through a variety of processes and mechanisms and are emitted from numerous sources (both natural and anthropogenic). Toxicological studies have implicated metal content (particularly the water-soluble fraction) as a possible harmful component of particulate matter (2). Thus, elemental analysis of airborne particulates (both quantitative and qualitative) is of great importance.

In the current study PM2.5 samples were collected from the city of Patras, Western Greece, in order to investigate the city's air quality. Patras represents a common urban coastal environment (about 200,000 citizens) with no large industrial activities in the vicinity of the city. It is known from previous studies (1) that the city has high PM2.5 levels that in many cases exceed the safety limits. However results concerning PM elemental analysis on the water soluble fraction have not been reported yet.

PM2.5 sampling was performed in the city centre, from August 2010 to August 2011 using PTFE filters. A low volume sampler (PARTISOL-FRM MODEL 2000) was installed in the roof of a public building and was operated at 16.7 L/min for 24h in all cases. The sampler was approximately 25 meters above the ground level, thus having no immediate interaction with ground sources (traffic). Twenty samples were selected to be analyzed by ICP-MS. One half of each filter sample was digested and analyzed for total trace metal levels and the other half was leached for obtaining the water soluble metal fraction.

Microwave digestion of PM followed by chemical analysis by ICP-MS is one of the most accurate methods for the determination of trace elements (total) in particulate samples. For the digestion a mixture of HNO_3/HF was used. The water soluble fraction was extracted with ultra pure water using ultrasonication, and the extraction time was 30 min.

The efficiency of the digestion procedure was tested using the certified reference material, NIST SRM 1648a. The recoveries of the elements (with the exception of Al and Cr) ranged from 87 to125%.

Fifteen elements were analyzed in the PM2.5 samples (Al, As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Rb, Sr, Ti, V, Zn). Al, Zn, and Fe displayed the highest concentrations, whereas Rb, As, Co the lowest ones. Tables 1 show the mean concentration and the solubility for each element.

The water soluble fraction of the analysed elements ranged between 5 to 42 %.

Table 1. Mean concentration, Standard Deviation and Solubility of the trace elements in the PM 2.5 samples.

Elements	**Mean Concentration (ng/m^3)**	**Standard Deviation**	**Solubility (%)**
Al	5532.3	5820.2	5
As	1.9	3.3	7
Cd	52.3	52.8	10
Co	0.7	0.9	11
Cr	5.8	3.0	9
Cu	10.5	20.3	42
Fe	163.3	190.6	7
Mn	6.9	8.9	37
Ni	11.7	14.3	29
Pb	15.4	31.9	16
Rb	2.7	4.8	7
Sr	9.6	13.1	13
Ti	99.3	90.6	6
V	4.3	2.7	24
Zn	402.9	603.5	35

Among the elements analyzed, the most water soluble and consequently bioavailable were the elements Cu, and Zn at a level of about 40%. Ti, Al and Fe were almost insoluble in the water (5-7 %). Cu and Zn are expected to originate from anthropogenic sources, are easily dissolved in water, while Ti, Al and Fe as refractory elements are not easily dissolved even in strong acids.

This work was supported by K. Karatheodoris Program Grant D.165 from the Research Committee of the University of Patras.

The present study was performed on the campus of the University of Alicante, located next to the town of San Vicente del Raspeig (55,000 inhabitants), approximately 6 km from the Spanish Mediterranean coast. A grey cement production plant that uses a dry manufacturing process is located 1.5 km southwest of the campus. Twenty-four hour PM10 samples were collected approximately every four days from January to December 2010 using a high volume Digitel DL77 sampler. The device was located 15 m above ground level, on the roof of the Faculty of Sciences. Ion chromatography analyses were carried out in order to obtain the concentrations of the main anions (Cl^-, NO_3^-, SO_4^{2-} and $C_2O_4^{2-}$) and cations (Na^+, NH_4^+, K^+, Mg^{2+} and Ca^{2+}).

Annual mean and daily maximum values were compared with those obtained at the same site between September 2005 and August 2006 (table 1), when another cement manufacturing facility, situated ~ 1 km northwest of the sampling site, was still operating (Yubero *et al*, 2010). This plant, which used the semi-wet process for white cement production, closed in May 2008.

Table 1. Concentrations for PM10 and associated ions ($\mu g/m^3$) measured in the University of Alicante.

	2010		2005/06	
	Mean	Max	Mean	Max
PM	21.6	59.7	40.5	120
Cl^-	0.58	3.48	0.91	3.81
NO_3^-	2.27	9.05	2.70	8.77
SO_4^{2-}	2.33	9.28	4.24	16.06
$C_2O_4^{2-}$	0.22	0.55	–	–
Na^+	0.66	2.96	0.78	2.91
NH_4^+	0.48	3.15	0.59	4.75
K^+	0.20	0.96	0.33	0.97
Mg^{2+}	0.11	0.34	0.13	0.37
Ca^{2+}	1.27	3.59	3.13	7.71

Mean and maximum PM10 concentrations in 2010 were considerably lower than the values previously measured. Such decline however cannot only be explained by annual changes in meteorological conditions. A factor that could play a part in the observed reduction is the closure of the white cement manufacturing plant. This facility represented an important contribution to local SO_2 emissions, which in the atmosphere is rapidly oxidised into particulate sulphate. Additionally, global emissions of gaseous precursors (NO_x, SO_x and NH_3) of particulate nitrate, sulphate and ammonium in Europe have experienced a decrease since the beginning of the economic crisis. Sulphur oxides emissions showed the highest reduction, which is consistent with the observed trend in sulphate concentrations. As can be calculated from the data presented in table 1, sulphate average levels in 2010 were 50% lower than in the period 2005-2006, while the decrease in nitrate and ammonium levels was only 16 and 19%, respectively.

Atmospheric levels of Ca^{2+} were also greatly reduced in 2010. In the study area, soluble calcium is mainly emitted by wind and traffic-induced dust resuspension (favoured by the scarce precipitation), Saharan intrusions, fugitive dust emissions from the nearby quarries that supply the cement plants with the necessary raw materials, and channelled emissions from cement kilns (Yubero *et al*, 2010). A fall in the demand for cement could have accounted for the decrease in Ca^{2+} emissions produced by the extraction, transport and storage of raw materials as well as from the cement manufacturing process. Another possible cause could be the increase in the number of rainy days in 2010 (63 against 38 in 2005-2006), although the annual accumulated precipitation was very similar (377 and 375 L/m^2, respectively).

Sodium and magnesium concentrations were similar for both study periods and the observed variations are most probably due to annual changes in sea-salt emissions. Finally, PM10 chloride can have both natural and anthropogenic origins. Coarse Cl^- (> 2.5 µm) mainly comes from the sea (Yubero *et al*, 2010), while fine Cl^- is primarily emitted from road traffic and combustion processes at the cement plants (*Galindo et al*, 2011). The higher reduction of Cl^- levels compared with those of Na^+ and Mg^{2+} can be attributed to a decrease in fine chloride emissions from anthropogenic sources.

Particle source characterisation of a cement plant with automated scanning electron microscopy

M.F. Meier[1,2], T. Zünd[2] and B. Grobety[2]

[1]Department of Geosciences and FRIMAT, University of Fribourg, 1700 Fribourg, Switzerland
[2]Particle Vision GmbH, 6025 Neudorf, Switzerland
Keywords: CCSEM, cement particles, EDS, source characterisation.
Presenting author email: mario.meier@unifr.ch

Several mechanic processes, such as milling, lead to dust formation during cement production. Therefore cement plants can be important local sources for PM. The aim of this study was to obtain chemical/mineralogical fingerprints of two different potential dust sources.

For that reason two samples were taken in a cement plant with an active sampling device, depositing particles on polycarbonate filters. The first sample was obtained in the raw mix milling hall (RMH), the second one in the hall of clinker milling (CMH). The filters were analyzed by computer controlled scanning electron microscopy (CCSEM) coupled with energy dispersive spectroscopy (EDS). This setting allows to obtain data from several hundreds of particles in a few hours.

The filter from RMH was dominated by Calcite ($CaCO_3$) and clays. But also Pyrite, aluminium-hydroxides, iron-oxides, calcium-silicates, alkali-sulphates and silica fume particles could be detected in that sample. On the filter from CMH, most of particles were rich in calcium containing phases, such as calcium-silicates, -carbonates, -sulphates and - aluminates. Additional alkali-sulphates and silica fume particles could be found. All other phases observed on the first filter were almost absent.

Most of the analysed particles can be explained by processes of the cement production. Calcite and clays are the main raw material. Aluminium-hydroxides, iron-oxides and Pyrite are additive raw materials. During heating and sintering (clinker production), the raw mix materials undergo phase changes and clinker (calcium-silicates and -aluminates) gets formed. This process also produces alkali-sulphates. Calcite, calcium-sulphate and silica fume finally are cement additives, added before the clinker milling step.

The results show that the two sources can be distinguished clearly and give two different fingerprints which are shown graphically in Figures 1 and 2. Whereas the filter, containing mainly raw mix particles, shows a pattern which would be quite similar to the one of other sources (e.g. limestone quarry), the fingerprint of clinker milling is very characteristic and can be used for the local air quality assessments in the neighbourhood of cement plants. Because CCSEM analyses the chemical compositions of every single particle, this method is a very suitable to obtain chemical/mineralogical fingerprints of particle sources.

Physical activity has become a social need among people, and is clearly proved that exercise is a way to prevent all-cause and cardiovascular-related death, diabetes mellitus and obesity (Warburton, Nicol, & Bredin, 2006; Zisser, Gong, Kelley, Seidman, & Riddell, 2011; Ruivo & Alcântara, 2012). However, athletes and the common individual can be at risk when they are practicing exercise in polluted environments due the fact that 1) the ventilation rates increase and the quantity of pollutants inhaled increase proportionally; 2) most of the air is inhaled through mouth, bypassing the normal nasal mechanisms for filtration of large particles and 3) the increased airflow velocity carries pollutants deeper in to the respiratory tract (Carlisle & Sharp, 2001). Physical activity can take place in two defined settings: outdoor (cycle lanes, sport campus, tennis court) or indoor (most of all in fitness centers). In Portugal, 12% of the people practice sport in fitness centers, little above the EU mean, with 11% (Eurobarometer 72.3, 2010). In fitness centers, physical activity is frequently performed in spaces with poor Indoor Air Quality (IAQ) due to the fact that large amount of people is concentrate in small spaces that often have deficient ventilation. The objective of this work was to assess the IAQ in three types of gymnasiums: health clubs, neighborhood gymnasiums and scholar gymnasiums. In each gymnasium all occupied spaces of the building were grouped by zones with expected similar IAQ. The groups were made according to the ventilation system in each zone, the type of activity, thermal loads and emission sources. In each zone at least one measurement was made.

Measurements of Particles with diameter lower than 10 µm (PM_{10}), CO_2, CO, H_2CO, VOCs and O_3 concentrations were performed in the selected indoor environments using automatic portable equipments. Measurements were performed during 24h in order to recognize daily patterns and identify pollutant sources. PM_{10} were sampled with a low volume sampler during the occupied period. Particles mass concentration was determined by gravimetry with a Mettler Toledo microbalance (UMT5). Filters were weighed before and after sampling in a humidity and temperature controlled room. Elemental analysis of PM_{10} sampled in the filters was performed by using Neutron Activation Analysis. Airborne microorganisms (fungi and bacteria) were collected by impaction method using a Microbial Air Monitoring Equipment. Microorganisms were also collected in surfaces (gymnasiums equipment) by swab. After sampling, processing and culturing (solid media) of the samples, quantitative (colony forming units counting) and qualitative (microscopy) results were obtained, with characterization and identification of microorganisms.

The high levels of CO_2 and microorganisms measured in the selected gymnasiums indicated that the ventilation systems were inadequate and highly contributed to the establishment of poor IAQ.

Observations of elevated aerosol particle number and mass concentration events in Vilnius city

S. Kecorius, K. Plauškaitė, S. Byčenkienė and V. Ulevicius

Department of Environmental Research, SRI Centre for Physical Sciences and Technology, Savanoriu 231, 02300 Vilnius, Lithuania

Keywords: Number concentration, SMPS, Black carbon, Alpha Ångström coefficient.

Presenting author email: simolas2008@gmail.com

Aerosol particles have negative effects on human health regarding respiratory and cardiovascular diseases. Anthropogenic sources, such as industry and traffic, play an important role for overall atmospheric pollution throughout the year. Additionally, these constant emissions were superimposed by seasonal sources, especially to the wood combustion in winter and road dust in spring. Thus aerosol number, mass, size distribution and optical properties measurements are of great importance (Kennedy, 2007).

The aerosol particle number concentration, size distribution and optical properties were measured in Vilnius urban background site (54°38'36", 25°10'58") from 2011-09-01 to 2012-02-01 using a condensation particle counter (UF-02, sampling flow: 1 l/min, working liquid: butanol, cut-size: 4.5 nm), scanning mobility particle sizer (SMPS, sheath air flow: 5 l/min, sample flow: 1 l/min, size range: 8.693 – 839.6 nm) and a Magee Scientific company Aethalometer™, model AE31 Spectrum, (370, 450, 520, 590, 660, 880 and 950 nm). Simultaneously, aerosol particle mass (PM_{10}) and various gases (NO_X, CO, SO_2) concentrations were measured in The Environmental Protection Agency monitoring station (54°40'23", 25°14'56.81").

The absorption coefficient b_{abs} for airborne particles is defined with the Lambert-Beer's law (Eq. 1):

$$I = I_0 e^{(-b_{abs}x)}, \quad (1)$$

where I_0 is the intensity of light passing through a pristine portion of the filter and I – the intensity passing through a medium with thickness x. The wavelength-dependent optical absorption coefficient of the light can be described by: $b_{abs} \propto \lambda^{-\alpha}$, where α is the Ångström coefficient – an aerosol specific optical parameter (Sandradewi, 2008, Collaud Coen, 2010).

Unusually high pollution event was observed during the January 17 – 19, 2012. Aerosol particle size distribution with one high concentration mode was registered at the end of the January 17 (Fig. 1A, box a). This plume in all particle size ranges was related to specific meteorological and pollutant emission conditions. On the same day the highest aerosol number, black carbon and PM_{10} concentrations measured between 16:00 - 23:00 h were $13 \cdot 10^4$ 1/cm^3, 33 µg/m^3, 84.1 µg/m^3 respectively (Fig. 1B). Three distinct, well separated modes of aerosol particle size distribution were registered on the January 19, which represented different aerosol emission sources. Accumulation mode region with geometrical mean diameter d_g = 102 nm (Fig. 1A, box b) proclaims heating caused aerosols, while at the same time modes with geometrical mean diameters d_g = 8.36 nm and d_g = 80 nm (Fig. 1A, box c) represents traffic impact on high aerosol particle concentration.

The comparison of the diurnal cycle of the SO_2 and $\alpha_{660\text{-}950}$ showed that trends of the SO_2 and $\alpha_{660\text{-}950}$ were very similar, while cycles of the NO_X and CO were different. Analysis of the CO and NO_X ratio revealed, that the Ångström coefficient (Fig. 1A) values between 1 and 1.4 relate to the traffic impact, while values higher than 1.5 - to the wood combustion, which is explained by the domestic heating.

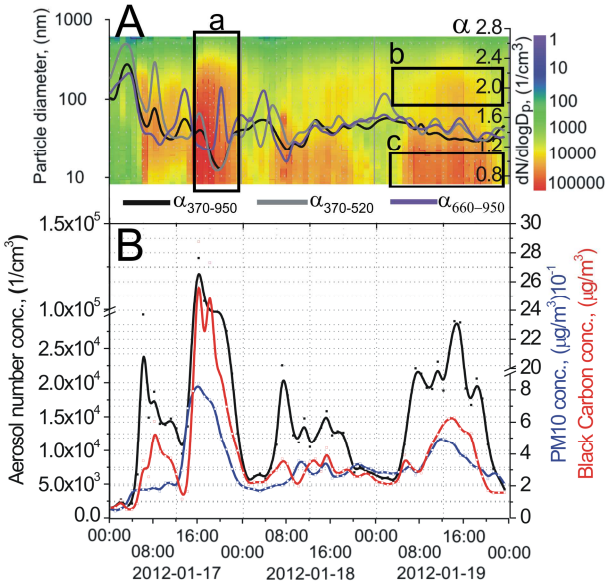

Figure 1. A - Ångström coefficient and particle size distribution, B - Aerosol number, mass (PM_{10}) and black carbon concentrations, January 17 – 19, 2012.

While air quality in Europe has improved substantially over the past decades, pollution from particulate matter (PM) remains a major environmental problem, especially in big urban agglomerations. The scope of this works was to examine the spatial variability of major aerosol parameters such as PM mass, particle number and black carbon concentrations across the Greater Athens Area (GAA), through the use of a mobile measurements platform (Mobilab). The city of Athens has been known to face air pollution problems over the last decades, with frequent exceedances of the daily PM_{10} air quality standard in certain stations (Aleksandropoulou et al., 2012). The main objectives of this survey were to examine the spatial distribution of PM (especially of their traffic-related components), to evaluate the effectiveness of the National Monitoring Network (NMN) in characterizing the Athens city population exposure and to identify potential local sources or "hot-spot"areas.

Measurements were conducted during 12–23/9/2011. The parameters measured were: particle size distribution (SMPS, OPC), PM mass concentration (photometer) and black carbon (portable aethalometer). All instruments were sampling from a thin walled tube inlet 6 mm in diameter situated on the top of the vehicle, extended well in front of the vehicle body, isoaxial to the incoming flow during movement in order to minimize losses and contamination. In addition, a GPS system was constantly monitoring Mobilab's exact position over time. During the day the vehicle was moving around the GAA, while at nights fixed measurements were performed at selected locations. During these night-time measurements, 12-hr gravimetric samples were also collected by a MOUDI impactor.

Table 1. Variation of aerosol parameters across the GAA

	Day-time	Night-time
PM_{10} ($\mu g\ m^{-3}$)	16 - 83	22 - 57
$PM_{2.5}$ ($\mu g\ m^{-3}$)	13 - 67	8 - 42
Total number conc. ($10^4\ cm^{-3}$)	1.8 – 12.0	0.6 – 3.2
BC ($\mu g\ m^{-3}$)	1.4 – 7.0	0.5 – 3.5

All measured parameters exhibited significant variability across the city (Table 1). Very high levels were measured in heavy-traffic areas during the day, especially for number concentration and BC. The obtained PM_{10} concentrations were compared to the levels measured by the NMN stations, selecting for each area the closest available station. Mean values were calculated both for the Mobilab campaign measurement period as well as for the last three years reported by the NMN (2008-2010). Day-time data were grouped in large regions covering areas in the North (N), Northeast (NE), Northwest (NW), East (E), West (W), South (S) and the city centre (Figure 1). The results indicate that in general the NMN stations provide a representative picture of population exposure in the wider area covered by them. Very high short-term exposures were measured on-road, especially for the traffic-related parameters, number concentration and black carbon (Figure 2).

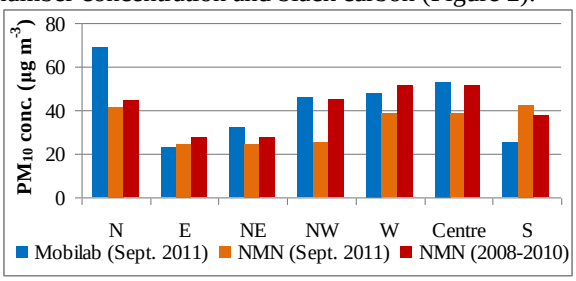

Figure 1. Comparison of mean day-time PM_{10} conc. measured by Mobilab with levels reported by NMN

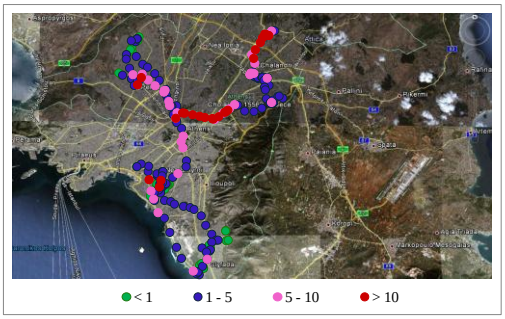

Figure 2. Variation of 2-min averages of black carbon ($\mu g/m^3$) during a 9-hr drive (23-9-2011, 8:00 – 17:00).

Particulate matter (PM) ambient concentration levels are still a major environmental problem in several urban areas in the E.U., while new evidence of its long term impacts on human health continues to emerge. As the E.C. is moving towards the implementation of the thematic strategy on Air Pollution, information on PM_{10} and $PM_{2.5}$ concentration levels, as well as their main constituents, will be very useful in developing new regulations and evaluating current measures. In this framework, Life+ project ACEPT-AIR is aiming, among others, in constructing an updated database on PM concentrations and chemical speciation for three big urban cities in Greece (Athens, Thessaloniki and Volos). The obtained data will be further utilized for source apportionment.

This work presents the results from the Athens measurement campaigns, conducted during warm and cold period of 2011 – 2012 (around 50 days per season). PM_{10} and $PM_{2.5}$ were measured gravimetrically on a 24-hr base, at two sites: (1) N.C.S.R. "Demokritos" urban background station (GAW-DEM, 2007) and (2) Nea Smyrni station of the National Monitoring Network (Figure 1). Two types of filters were used for each size fraction (Teflon / Quartz) in order to allow for detailed chemical speciation. Elemental (EC) and organic (OC) carbon will be determined through thermal-optical analysis. Atomic Absorption Spectrometry and X-Ray Fluorescence will be used for the determination of major and trace elements and Ion Chromatography for ionic species. Analysis of filters is still in progress.

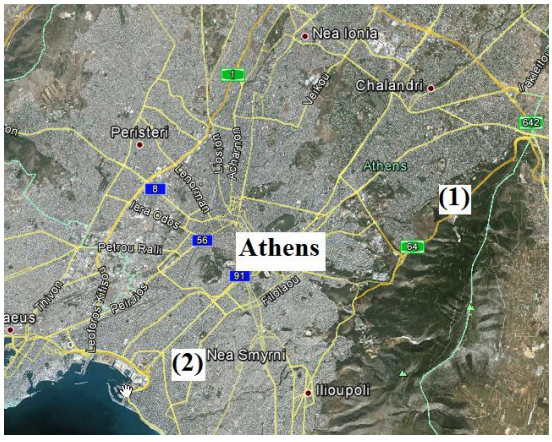

Figure 1. Map of Athens Greater Area and measurement sites: (1) Demokritos and (2) Nea Smyrni stations.

Basic statistical data on the measured PM_{10} and $PM_{2.5}$ concentrations at the two sites are presented in Tables 1 and 2, respectively. Similar PM levels were measured at the two sites during warm season. PM concentrations were low, indicating a background character for both sites. This was further supported by the initial results on chemical composition. Elemental and organic concentrations at both sites were relatively low with an average EC/OC ratio of 0.2.

Table 1. Basic statistics for PM_{10} concentrations measured at Demokritos (DEM) and N. Smyrni (NSM) stations (μg m^{-3}).

	Warm season		Cold season	
	DEM	NSM	DEM	NSM
Mean	24.4	23.7	16.5	41.1
St. Deviation	7.5	7.4	5.1	24.5
Minimum	6.2	11.4	5.3	17.0
Maximum	49.5	39.0	31.9	133.2

Table 2. Basic statistics for $PM_{2.5}$ concentrations measured at Demokritos (DEM) and N. Smyrni (NSM) stations (μg m^{-3}).

	Warm season		Cold season	
	DEM	NSM	DEM	NSM
Mean	12.4	16.2	10.8	22.8
St. Deviation	4.1	5.9	3.6	14.9
Minimum	4.9	6.0	4.4	7.5
Maximum	25.9	30.1	17.2	73.5

Demokritos station exhibited even lower concentration levels during cold season, which may be also attributed to the meteorological conditions (heavy rainfall during many of the measurement days). At N. Smyrni, on the contrary, the situation was very different during cold season. The measured levels were very high, with exceedances of both the 24-hr limit value for PM_{10} and the annual target value for $PM_{2.5}$. The higher residential density of the area, in comparison to N.C.S.R. "Demokritos" campus and the surrounding neighbourhood, in conjunction with the intensive use of fireplaces during this period may account for this great increase of both PM_{10} and $PM_{2.5}$ concentrations.

This work was supported by the European Commission LIFE+ Environment Policy and Governance programme.

Determination of refinery emission pollutants impact on an urban atmosphere

M.A. Barrero, M. Goikoetxea and L. Cantón

Department of Applied Chemistry, University of the Basque Country, 20018, Donostia-San Sebastián, Spain
Keywords: PM10, trace metals, volatile organic compounds, oil refinery
Presenting author email: miguelangel.barrero@ehu.es

The urban aerosol composition is directly related to the specific anthropogenic activities in the area. Though the road traffic is considered to be the main source of pollutants in urban areas, industrial emissions which can be of a very different nature, can also contribute with a wide range of contaminants. One special case of industrial facilities is oil refineries, which are known sources of gaseous pollutants such as sulphur dioxide or volatile organic compounds (VOCs) and particulate matter.

In this work, we evaluated the influence of refinery emissions in an urban area by analysing the variations of PM_{10} and VOCs concentrations and physicochemical and meteorological parameters.

The sampling sites were selected in two residential areas located in the immediate surroundings of an oil refinery, in the Basque Country coast. Site 1 was located less than 200 m to the Northwest from the refinery, and Site 2 was situated about 400 m to the Southwest.

PM_{10} and VOCs samples were collected during 24 h periods twice a week during one year, parallel at each site. PM_{10} samples, on quartz fibre filters, were analysed for metal composition by ICP-MS and for polycyclic aromatic hydrocarbon (PAH) by GC-FID and GC-MS. VOCs samples, on activated charcoal tubes, were analysed by GC-FID and GC-MS.

An automatic station of the Basque Government's Air Quality Monitoring Network measured the concentrations of some major pollutants (CO, NO_x, O_3, $PM_{2.5}$, SO_2) and meteorological variables (temperature, relative humidity, atmospheric pressure, solar radiation and wind speed and direction).

Some differences were found regarding the behaviour of particulate matter and the volatile organic compounds in the gas phase. While both sites showed similar composition and levels of PM components, VOCs exhibited large differences between sites. In Site 1 (the site located most of the time downwind the refinery), some samples exhibiting high levels of light hydrocarbons were collected. This was confirmed by a correlation analysis, that showed that particulate matter and VOCs in Site 2 (usually upwind the refinery) were significantly correlated while in the downwind site they did not correlate (Figure 1).

The concentrations of all the pollutants were evaluated with the wind direction. In general, both sites showed the highest levels of anthropogenic PM_{10} components with easterly winds, while VOCs were detected in higher concentrations with easterly winds in Site 1 and with northerly winds in Site 2.

These findings indicate that particulate matter pollution can be considered to be more general, disperse, while VOCs can be related with more punctual, local emissions.

In addition, a factor analysis was performed to help in the elucidation of the sources of air pollutants affecting the area of study.

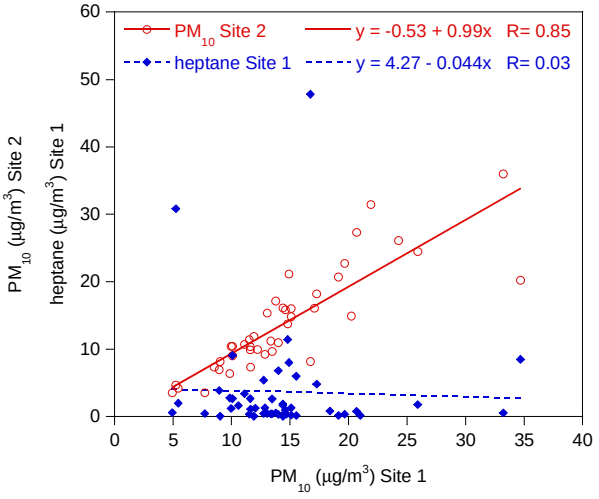

Figure 1. Dispersion plot of PM_{10} (Site 2) and heptane concentration (Site 1) with PM_{10} (Site 1).

Determination of water content in atmospheric particulate matter

C. Farao[1], C. Perrino[2], S. Canepari[1], E. Marconi[1], M.L. Astolfi

[1]Department of Chemistry, Sapienza University of Rome, Rome, 00185, ITALY
[2] C.N.R. Institute of Atmospheric Pollution Research, Monterotondo St., Rome, 00015, ITALY
Keywords: particulate matter, determination of water, chemical composition
Presenting author email: carmela_farao@libero.it

It is well known that water is able to interact with organic and inorganic hygroscopic compounds of atmospheric particulate matter (PM). This interaction has been widely studied and its influence on several chemical and physical characteristic of PM has been well documented (Hu et al., 2011). Several studies has evidenced the role of water in determining the position of ammonium salts vapor-solid equilibria that are responsible for one of the most relevant sampling artifact in PM collection (Vecchi et al., 2009), but the mechanism of this dependence is still largely unknown.
The quantitative determination of water in PM has been attempted in a few studies. Most of them are performed by a differential evaluation of the PM mass before and after exposing the sample to controlled relative humidity conditions (Kitamori et al., 2009). These studies demonstrate that the amount of retained water depends on the dimension and chemical composition of particles, but no information are given about the type and strength of water-particle interactions.
In a recent study concerning the application of thermogravimetric analysis (TGA) to PM samples (Perrino et al, 2012), we evidenced that the release of water occurs at different temperatures, depending on the strength of the interaction between water and PM. However, due to the presence of other volatile species evolving in the same temperature ranges, the TGA does not allow a reliable quantitative determination of water.

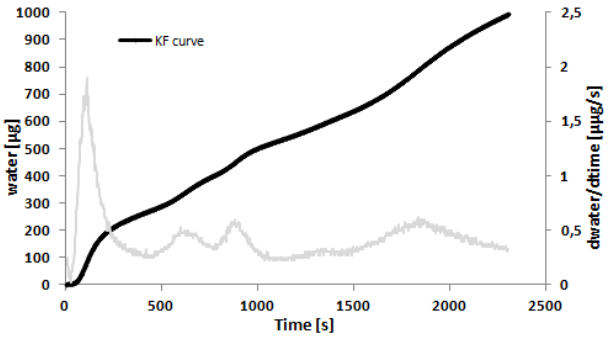

Figure 1. Karl-Fisher curve of NIST1648

In this work we report the optimization and validation of a new simple method for the quantitative determination of water in PM and its first application to a series of real PM_{10} samples. The analysis are performed by a coulometric Karl-Fisher system equipped with a controlled heating device. Different water contributes are separated by the application of a proper thermal ramp. The optimal heating condition, consisting in three heating steps (50°-120°C, 120°-180°C, 180°-250°C) allows to distinguish four different types of water in reference materials NIST1648 and NIST1649a (urban particulate matter; figure 1). The analytical performance of the method have been verified by using two standard materials, HYDRANAL Water Standard KF-Oven 220 ° C-230 ° C and Water Standard Oven 1%, containing 5.55 % and 1% by weight of water respectively. The recovery with both standards is greater than 95% and detection limits are of ca. 20 µg. A sufficiently good repeatability (ca. 10-15%) is obtained both on reference materials and real PM_{10} samples.
The application of the method to real PM_{10} samples has evidenced that the amount of water is subjected to very relevant variation, as a function of the PM chemical composition. Mass percentages of ca. 3-4 % have been obtained in most of the samples, but values up to about 15% have been reached when the chemical composition of PM was dominated by secondary inorganic ions and organic matter. Very different thermal profiles have been also evidenced. To try an identification of the type of the released water, the method has also been applied to some hygroscopic compounds (pure SiO_2, Al_2O_3, NaCl, Na_2CO_3, ammonium salts and carbohydrates) that are likely present in PM.

Keywords: PM2.5, long-range transport, chemical composition, SEM.
Presenting author email: trippetta@imaa.cnr.it

Atmospheric aerosols are a complex mixture of suspended solid and liquid particles with different physical and chemical properties (e.g., size distribution, optical properties and chemical composition). They can originate both from anthropogenic sources – such as industrial activities, road traffic and residential heating – and natural sources – such as local soil, deserts, sea spray and volcanic eruptions.

The most relevant contribution to the atmospheric aerosol load in a given location is generally related to emissions from local anthropogenic and/or natural sources, although long-range transport contribution has been found to be often significant and needs considerations especially in Euro-Mediterranean regions (Nicolás et al., 2008).

Since the only PM concentration measurements are not enough to identify the PM origin, it would be of primary importance to characterize it from a chemical and mineralogical point of view and combine this information with model forecasts and remote sensing observations that allow the identification of the occurrence of long-range transport events over a study area (Caggiano et al., 2012).

In this context, PM2.5 daily samples were collected at the Institute of Methodologies for Environmental Analysis of the National Research Council of Italy (IMAA-CNR) located in Southern Italy (Tito Scalo - Potenza) from April to July 2010.

During this period, the PM2.5 daily concentrations ranged between 0.2 μg m^{-3} and 18 μg m^{-3}, with a mean value of 6 μg m^{-3}. Figure 1 shows the PM2.5 temporal pattern.

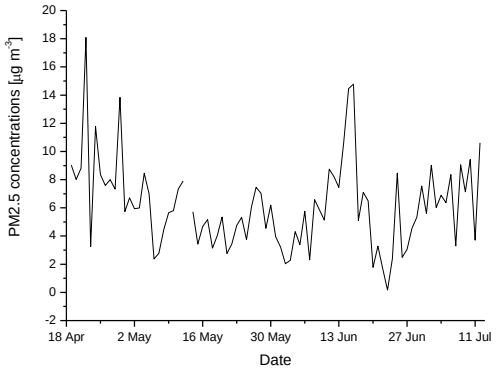

Figure 1. Temporal pattern of the PM2.5 concentrations measured at the CNR-IMAA site from April to July 2010.

The combined use of model outcomes and satellite observations allowed the identification of the occurrence of long-range transport events of different type over the area under study. In particular, two predominant long range transport events were identified: volcanic ash coming from the eruption of Eyjafjallajökull volcano located in Southern Iceland (63° 38' N, 19° 36' W, 1666 m a.s.l.) and dust particles coming from Sahara desert.

In order to evaluate the influence of these events on the PM2.5 measurements, PM2.5 chemical composition (Al, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Na, Ni, P, Pb, Ti and Zn) and mineralogical and morphological features of the PM2.5 single particles were analysed.

Results pointed out the falling to the ground both of volcanic ash and dust particles and their contribution to the increase in the PM2.5 concentrations.

Particulate air pollution exposure during commuting in three European cities

P. Taimisto[1], A. Pennanen[1], E. Vouitsis[2], Z. Samaras[2], M.P. Keuken[4] and T. Lanki[1]

[1]Department of Environmental Health, National Institute for Health and Welfare (THL), Kuopio, FI-70210, Finland
[2] Laboratory of Applied Thermodynamics, Aristotle University, Thessaloniki GR-54124, Greece
[3]TNO, Netherlands Organization for Applied Scientific Research, Utrecht, NL-3508 TA, Netherlands
Keywords: Exposure, Measurements, Traffic emissions, PM10/PM2.5.
Presenting author email: pekka.taimisto@thl.fi

In the Transphorm study exposure to $PM_{2.5}$ (particles up to 2.5 micrometers in diameter), PM_{10} (particles up to 10 micrometers in diameter), PNC (particle number concentration) and BC (black carbon) during commuting was measured. Measurements were performed in three European cities: Helsinki, Thessaloniki and Rotterdam during spring 2011. Measured modes of commuting included a bike, a bus and a car (Ford Focus Wagon with 1.6 litres gasoline engine, model 2008-2010) driven with both open and closed windows.

Measurements were performed with TSI DustTrak DRX 8533 ($PM_{2.5}$ and PM_{10}), TSI P-Trak 8525 (PNC) and Magee Scientific microAeth AE51 (BC).

In Rotterdam, Thessaloniki and Helsinki 2, 3 and 6 study routes were chosen, respectively. The number of study routes per city depended on city's geometry and the actual commuting routes of the citizens. The local municipal authorities assisted in choosing of the routes.

Measurement campaigns lasted for 6 days. One measurement day included 4 one-way drives with a bike, a bus, a car with open windows and a car with closed windows; all drives within one day were performed on the same study route. The average exposures by commuting mode in three study cities are presented in table 1.

Table 1. The average concentrations of photometric $PM_{2.5}$ ($\mu g/m^3$), photometric PM_{10} ($\mu g/m^3$), PNC ($1/cm^3$) and BC ($\mu g/m^3$) by commuting mode in the three cities.

Mode of commuting	Particle fraction	City		
		Helsinki	Thessaloniki	Rotterdam
Bicycle	$PM_{2.5}$	24.4	37.7	27.0
	PM_{10}	35.4	45.3	30.6
	PNC	13000	42600	20300
	BC	3.2	6.9	3.1
Bus	$PM_{2.5}$	29.2	84.9	20.6
	PM_{10}	42.1	131.5	22.5
	PNC	15000	49200	17900
	BC	4.5	8.5	4.2
Car, closed windows	$PM_{2.5}$	14.3	28.2	23.7
	PM_{10}	14.8	33.8	25.2
	PNC	11400	24900	26000
	BC	3.0	4.7	6.3
Car, open windows	$PM_{2.5}$	33.2	62.6	30.7
	PM_{10}	41.4	79.0	34.3
	PNC	36900	60900	34000
	BC	7.3	10.9	6.4

Conclusions

The lowest particle concentrations were encountered in a car with closed windows and the highest in a car with open windows. The cars used in the study were of the latest model and presumably with recently installed filters for incoming air, which explains the highly protective effect of the car body. Opening the car window greatly reduces car body's capacity to protect persons inside from air impurities.

The differences in exposures between cyclists and persons taking a bus were rather small, showing that the body of a bus does not provide much protection against particulate air pollution (obviously because the doors are frequently open). Interestingly, in Thessaloniki $PM_{2.5}$ and PM_{10} concentrations inside a bus were extremely high, most likely because of resuspension of road dust accumulated inside the bus. Exposures of cyclist tended to be somewhat smaller than concentrations inside a car with open windows, obviously because the cyclists do not cycle all of the time in the middle of the vehicular traffic flow (i.e. next to emissions).

The differences in the levels of exposure were in the expected direction: the highest levels in Thessaloniki, the lowest in Helsinki, while Rotterdam was in-between the two. However, commuters' exposures to PM_{10} were higher in Helsinki than Rotterdam, obviously due to road dust accumulated during the winter because of sanding of icy roads and use of studded tyres. Further, exposure to black carbon were higher in Helsinki than in Rotterdam, perhaps depending on the proportion of diesel cars in the car fleet, or on the age of the car fleet, which is higher in Helsinki.

Two years of measurements at a regional background site in the Balearics: first results

J. Pey[1], C. Bujosa[2], S. Caballero[3], X. Querol[1], A. Alastuey[1], M Sicard[4,5], B. Artíñano[6]

Keywords: Western Mediterranean, ChArMEx, chemical composition

Presenting author email: jorge.pey@idaea.csic.es

In the context of the ChArMEx (The Chemistry-Aerosol Mediterranean Experiment, https://charmex.lsce.ipsl.fr) initiative, a number of atmospheric parameters are being measured at a regional background site (Can Llompart; CLP) in the Majorca Island (Balearic Islands, Spain). In January 2010, in addition to routine measurements of PM_{10}, NO, NO_2, SO_2 and O_3 levels (since January 2000), additional instruments were installed, including: 1) a sequential high-volume sampler for PM_{10} collection on quartz micro-fibre filters; 2) an optical particle counter to determine real time concentrations of PM_{10}, $PM_{2.5}$ and PM_1; 3) an automatic collector of dry and wet deposition of atmospheric particles. Currently, hourly levels of NO, NO_2, SO_2, O_3, PM_{10}, $PM_{2.5}$, PM_1, air temperature, wind direction and velocity, atmospheric pressure and precipitation are measured. Furthermore, 24-hour PM_{10} samples are collected every four days in order to perform a complete chemical characterization (Pey *et al.* 2009) and a subsequent source apportionment analysis. Furthermore, two intensive sampling campaigns were performed in 2011, one in early spring and the other in mid-summer. For these campaigns, sampling of PM was done everyday and additional instruments were deployed: 1) a sequential high-volume sampler for PM_1 collection on quartz micro-fibre filters; 2) an ultra-fine particle counter for number concentration between 5-1000nm; 3) a multi-angle absorption photometer monitor for continuous reading of black carbon concentrations.

Mean PM_{10}, $PM_{2.5}$ and PM_1 levels for the whole period (2010-2011) were 17, 11, and 8 µg/m^3. Seasonal trend of PM levels differs from winter to summer, with higher background levels in summer due to stagnant conditions over the Western Mediterranean. Intense peaks of coarse PM are observed along the year owing to African dust inputs. High PM levels, mainly fine particles, are observed occasionally under winds transported throughout Europe. PM_{10} composition (2010) is made up of organics (23% organic matter and 1% elemental carbon), mineral matter (17%), sulphate (14%), sea spray (10%) and nitrate (7%) and unaccounted mass (28%), mostly thought as water (Figure 1). Intensive sampling campaigns (Figure 2) were useful to assess on black carbon (BC) and number concentration (N) levels and time-variation. Thus, mean levels of BC were 560 ng/m^3 and number concentration was around 7100 cm^{-3} (spring campaign). Both parameters followed similar trends to those observed for PM_1 but BC also displayed fresh anthropogenic inputs from road traffic, and N peaked occasionally at midday because of new-formation of particles from photochemical reactions (Figure 3).

Effect of flooring, cleaning and foot traffic on indoor air particulates

N. Mansouri[1], I. Colbeck[2]

[1]Science and Research Branch, Islamic Azad University, Tehran, Iran, 1998657151, Iran
[2]Department of Biological Sciences, University of Essex, Colchester, CO7 6LW, UK
Keywords: Floor cover, PM measurement, fine particle, PM_{10}, $PM_{2.5}$, PM_1
Presenting author email: colbi@essex.ac.uk

Indoor particulate matter is one of the major risk factors for chronic respiratory diseases (WHO, 2007). Scientific studies have shown that ordinary indoor activities such as walking over carpeted or hard floor areas can result in increased particulate concentrations in the indoor environment (Cheng et al., 2010). This current investigation was designed to assess the effect of foot traffic (FT) and type of floor covering (FC) on particle mass concentration (PMC) within various buildings in the University of Essex. Three types of hallways with different floor cover were included in the assessment: paint, carpet and concrete. PM_{10}, $PM_{2.5}$ and PM_1 concentrations were measured in 60-minute periods; with 1 minute intervals for each set of measurements, at 4 foot traffic modes : <2, 2-4, 5-8 and 9-12 persons per minute (p/m). This plan was repeated for three different points inside each hallway. FT in the hallways was measured by direct observation. Measurements were also undertaken in ambient air outside the building.

The measurements were carried out between 09.00 -17.00 at respiratory height. A GRIMM aerosol spectrometer, model 1.101 (Grimm Aerosol Technik GmbH, Ainring, Germany) was used for measurements. It had a sensitivity of 0.1 µg m^{-3} with a reproducibility of ±2%. All floors had been cleaned earlier in the day prior to sampling.

Table 1 shows the average concentrations and foot traffic for the various locations. Within the indoor environment carpeting resulted in the highest PM_{10} concentrations in comparison with other floor coverings for all foot traffic categories. Concrete floor coverings generally had lower PM_{10} concentrations than carpet and higher levels than painted floors. The one exception to this was for FT of 2-4 people per minute when the PM_{10} concentration for painted floors was higher.

The outdoor concentration was similar to that indoors at all locations with very low foot traffic. It is evident that both floor cover and foot traffic had effective role on resuspension of particles from floors. There was a statistically significant correlation between PM_{10} and foot traffic for all floor coverings ($p < 0.001$).

Earlier work has shown that an incremental foot traffic intensity of one person per minute over a carpeted hallway can increase the PM concentration by 1.0 µg m^{-3} and 0.8 µg m^{-3} for 1 to 5 µm and 5 to 7.5 µm particles, respectively (Cheng et al., 2010). The results in the current study indicate a near linear relationship between foot traffic and increasing PM_{10} with an increment of approximately 3.0 µg m^{-3} per person. For fine particulate the relationship was semi exponential (Fig 1). This means that human activity such as walking has more effect on the resuspension of coarse particles than fine ones. A number of factors can influence resuspension such as walking pace, walking style, dust loading, dust type, relative humidity and the effective indoor mixing volume.

Table 1. The average and standard deviation of outdoor and indoor air particulate concentrations (µg m^{-3}) for 3 different floor coverings

Flooring	PM size	Foot traffic (persons/minute)			
		<2	2-4	5-8	9-12
Fabric paint	PM_{10}	5.3 (0.96)	13.6 (1.61)	16.3 (1.89)	20.4 (3.51)
	$PM_{2.5}$	1.9 (0.35)	2.2 (0.26)	2.7 (0.43)	3.7 (0.29)
	PM_1	0.9 (0.10)	1.1 (0.15)	1.4 (0.34)	2.1 (0.13)
Carpet	PM_{10}	9.8 (1.24)	17.8 (3.34)	26.8 (4.66)	36.3 (6.00)
	$PM_{2.5}$	2.9 (0.15)	3.1 (0.35)	4.2 (0.28)	5.7 (0.57)
	PM_1	1.8 (0.13)	2.0 (0.25)	2.2 (0.19)	2.8 (0.47)

Evolution of PM_{10}, $PM_{2.5}$ and PM_1 in a semi-arid industrial environment

M. Santacatalina[1,2] and A. Carratalá[2]

[1]General Foundation, University of Alicante, 03690, Alicante, Spain
[2]Department of Chemical Engineering, University of Alicante, P. O. Box 99, 03080, Alicante, Spain

Keywords: Ambient PM, PM_{10}, $PM_{2.5}$, PM_1.
Presenting author email: milagros.santacatalina@ua.es

This work presents the evolution of ambient PM, PM_{10}, $PM_{2.5}$ and PM_1, in a semi-arid industrial environment, comparing two annual periods of study, May 2007 - April 2008 (before the economic crisis) and May 2010 - April 2011 (during the economic crisis). Levels of PM in the second period have decreased in concordance with the reduction of industrial activity due to the economic crisis. The three fractions present similar trends in the first period of study, with higher levels in winter months with the influence of several PM sources. In the second period, the seasonal variation is less noticeable due to the low levels in all months.

The study zone is a semi-arid industrial environment located in the southeast of Spain, with the mineral components of particulate matter as the main PM_{10} (Santacatalina *et al*, 2010) and $PM_{2.5}$ (Galindo *et al*, 2011) source. These characteristics have an effect on PM levels. Saharan dust events are common in the area due to the proximity of the African continent and they also have a lot of influence on PM levels. Three fractions of PM (PM_{10}, $PM_{2.5}$ and PM_1) were measured with a continue particle size analyzer (model Grimm 1.108). Data from two periods of study were compared, May 2007 - April 2008 and May 2010 - April 2011. The first one corresponds to a period previous to the height of the economic crisis, and the second one corresponds to a period during the economic crisis, with a significant decrease of the industrial activity in the area. The sampling point was located on the roof of the building of Research Technical Services of the University of Alicante, in the new Scientific Park of Alicante.

In the first period of study, levels of PM_{10} were high, with peaks of monthly average higher than 40 $\mu g/m^3$ (annual limit). In the case of $PM_{2.5}$, levels did not exceed the annual limit of 25 $\mu g/m^3$, and PM_1 levels were below 20 $\mu g/m^3$ (Figure 1). The annual averages were 34, 16 and 10 $\mu g/m^3$, respectively. In the second period, levels of PM decrease in the three fractions about 50% (Figure 1). The annual average were 17, 7 and 5 $\mu g/m^3$, respectively. Ratio values have not changed from the first period to the second period 0.5-0.4 $PM_{2.5}/PM_{10}$, 0.3-0.3 PM_1/PM_{10} and 0.6-0.7 $PM_1/PM_{2.5}$, and they have the same trend along the study periods. Data show the PM_{10} fraction as a critical pollutant in the area despite the low levels in the second period. PM levels in the second period can be considered as a baseline data that should not increase when the zone gets the industrial activity back.

Concerning the seasonality of the three fractions, the highest levels have occurred in winter months. This is more obvious in the first period of study, probably due to the influence of several PM sources as industrial activity, traffic, dust resuspension... and this is less marked in the second period, due to the decrease of levels in general.

African intrusions and meteorological factors were also studied and do not show a clear pattern explaining the decrease in the second period.

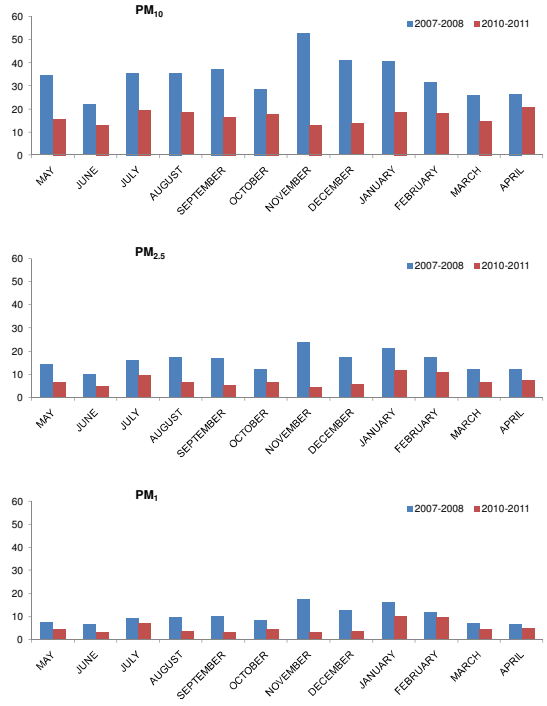

Figure 1. PM_{10}, $PM_{2.5}$ and PM_1 concentrations ($\mu g/m^3$) in both study periods.

Emission measurement of PM size distribution from road wear

M. Maasikmets[1, 2], E. Teinemaa[1], T. Arumäe[1]

[1]Estonian Environmental Research Centre (EERC), Marja 4d, 10617Tallinn, Estonia; [2]Estonian University of Life Science (EULC), Institute of Agricultural and Environmental Sciences, Kreutzwaldi 5, 51014 Tartu, Estonia
Keywords: ELPI, road dust, resuspension, SEM.
Presenting author email: marek.maasikmets@klab.ee

In most developed countries, exhaust emissions from vehicles are controlled by legislation and therefore are expected to decrease drastically in forthcoming years. Non-exhaust emissions are more difficult to address and even zero emission vehicles will contribute to non-exhaust emissions. Non-exhaust emissions include particles from brake wear, tyre wear, road surface abrasion and resuspension in the wake of passing traffic. (Thorpe & Harrison, 2008). Suspended road dust will remain a problem because of an increasing number of vehicles in urban and rural areas. Only few real-world measurements of road dust resuspension have been performed to date. There is still a knowledge gap regarding the dominant mechanisms leading to road dust emissions, although resuspension of surface particle loading obviously plays an important role. (Pirjola et al. 2010). In practice, quantification of road dust emissions is complicated because of the many different factors that might need to be controlled —vehicle type and speed, tire type, pavement type and conditions, the use of road salt and sand (Hussein et al. 2008).

In current study the mobile measurement system was used to quantify the relative importance of road PM emission and suspension of accumulated dust versus direct pavement wear, tire type (studded and summer), pavement type, and vehicle speed. Measurements were performed during March-October on selected roads with different pavements and traffic conditions in Estonia. Particle number concentration and size distribution from 40 nm to 10 µm with 1-sec time resolution were measured by ELPI (Electrical low pressure impactor, Dekati Ltd.), behind the left rear tire with the sampling rate of 29.25 l/min. The minimum detection level at 1 stage for the mass concentration is 0.01 µg/m^3 and for the number concentration 142 1/cm^3. The upper concentration limit at 13 stage for the mass concentration is 8269 mg/m^3 and for the number concentration 2.7E+04 1/cm^3. PM samples on impactor plates were also analysed by SEM (scanning electron microscopy, Zeiss EVO MA15 with Inca EDS) technique for chemical composition and morphology.

Results

The initial data does not show very clear relationship between the vehicle speed and total PM emitted. With certain fractions there is quite strong correlation between emission and vehicle speed. Humidity of the road surface had strong implication on the PM emissions. Pavement composition has significant impact to the road wear and therefore PM emission.

The SEM chemical composition analysis of the PM fractions shows that the PM8.17 fraction contains mainly Si (36.79 %) and Ca (8.90 %), the PM2.5 fraction contains mainly Si (38.75%), Fe (19.20%), Cr (11.29%), K (3.34%) and Ca (2.36%) and in PM0.04 fraction mainly Si (32.30%), Ca (13.14%), Mg (6.65%) and Fe (5.47%) was detected.

Better characterization of road composition on selected sections before each measurement is needed. Measurement techniques and setup of the measurements is necessary to modify further to identify and subtract background levels including concentration spikes generated by passing cars and contribution of the exhaust emissions of own vehicle.

PM_{10} sampling inlets comparison: EPA vs EU

P. Panteliadis, H.J.P.Helmink, P.C.Koopman, M.Hoonhout, D.de Jonge and J.H.Visser

Department of Air quality, Public Health Service Amsterdam, 1018WT, The Netherlands
Keywords: PM10, ambient air sampling inlet, low volume sampler, continuous particulate monitor
Presenting author email: ppanteliadis@ggd.amsterdam.nl

Uncommon deviations were observed between the continuous particulate monitor BAM (Met One instruments Inc, Oregon, USA) and the reference PM10 KFG/LVS sampler (Comde-Derenda GmbH, Stanhsdorf, Germany) during measurements at monitoring station Reijndersweg; located near the coastline of North Holland, at the west side fence of a 750 hectare steel production plant. The equivalence criteria between the continuous and the European reference, EN 12341 (1999) compliant method were met for 2010 despite the unexpected deviations. However, a greater, mainly slope, correction, had to be applied in the results of Reijndersweg monitoring station in comparison to other locations of the monitoring network of the Province of North Holland and Amsterdam.

A thorough investigation of monitors and samplers, including equipment exchange at the Reijndersweg monitoring station was initiated in response to the previously mentioned findings. Yet, the deviations between the two methods were not resolved.

In October and November 2011 two field comparisons of parallel measurements were performed at Reijndersweg with the use of the following sampling equipment:

First campaign (8-10-2011 / 26-10-2011):
- BAM with EPA PM10 inlet **(1)**
- TEOM 50°C EPA PM10 inlet **(2)**
- Derenda LVS with EU PM10 inlet 2,3 m^3/h **(3)**
- Derenda LVS with EPA PM10 inlet at 1 m^3/h **(4)**

Second campaign (28-10-2011 / 26-11-2011):
- BAM with EU Digitel 10/01/00 inlet **(5)**
- TEOM 50°C with EPA PM10 inlet **(2)**
- LVS with EU PM10 inlet 2,3 m^3/h **(3)**
- LVS with EPA PM10 inlet at 1 m^3/h **(4)**

During the first campaign, a Derenda LVS was connected to an EPA (BAM BX802) sampling inlet with the use of a special adapter. The actual flow of the LVS was lowered to 1 m^3/h **(4)** and showed a great match with the BAM-EPA inlet combination **(1)**. Secondly, the equivalence between TEOM **(2)** and LVS-BAM **(4),** after slope and intercept correction, was just below 25%, which is the limit value for the equivalence test. Finally, all reference measurements according to EN12341 **(3)** showed significantly lower results when compared to the LVS-EPA **(4)**.

Throughout the second campaign a Digitel (10/01/00) PM10 sampling inlet (1 m^3/h) was mounted on the BAM with use of a special designed adapter **(5)**, which showed good similarity with the reference method **(3).** The LVS-EPA **(4)** combination seemed to overestimate all daily-averaged PM10 concentrations. Indicative results of the second campaign are shown in Figure 1.

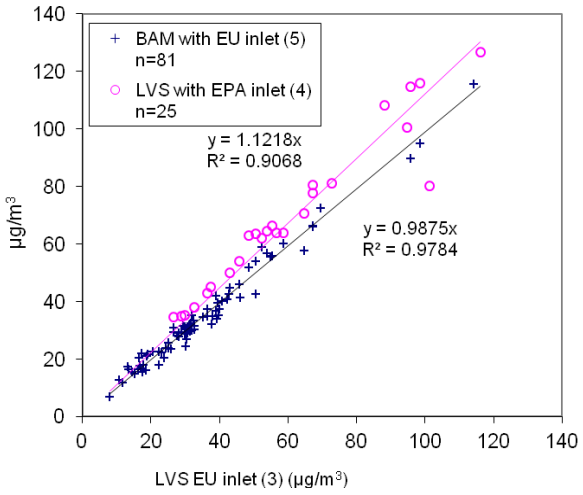

Figure 1. Comparison of Derenda LVS with EU inlet **(3)** vs BAM with EU inlet **(5)** and Derenda LVS with EPA inlet **(4)**.

Based on the limited dataset of the two campaigns, it can be concluded that significant deviations of PM10 measurements may occur due to specification differences between EPA and EU sampling inlets, in contradiction with TUEV report 2402 2605 – 2 (2000). The design of the Digitel PM10 inlet, besides the dimensional adaptation to the 1 m^3/h flow, is similar to the LVS Derenda, in accordance with EN12341 (1999). The BAM-Digitel combination can result to a significant improvement of both random and systematic deviation from the reference method, as described in EN 12341 (1999).

Extended research in additional locations, including PM2.5 sampling inlets has started in January and will conclude in April.

Source apportionment and sector analysis of organic aerosol in southern Sweden

J. Genberg[1], M. Sporre[1] and E. Swietlicki[1]

[1]Department of Physics, Lund University, Lund, Sweden
Keywords: Organic aerosols, Trajectory, Source apportionment.
Presenting author email: johan.genberg@nuclear.lu.se

The sources of organic aerosols have been extensively studied for several years since the data is valuable when verifying atmospheric models. In a newly published article a one-year source apportionment of organic aerosol from Vavihill in southern Sweden was presented (Genberg et al. 2011). The results showed significant differences in source contribution depending on the season of the sample. However, also within the seasons the sources varied. The low temporal resolution of the filter sampling did not permit a further analysis of the individual samples depending on air mass trajectories.

In this study a similar methodology has been used but filters where collected for 72 hours instead of one week. Four periods of constant air mass origin for the individual samples were found and used in this study.

The OC/EC results and temperature for the first interval is shown in figure 1a. The first period had air masses from the north and the daily mean temperature fluctuating between -10 and +5 °C. During the second period the air originated from the eastern sector and the daily mean temperature was stable at -2 °C for most of the period. The mean concentration from the four aerosol samples from the northern sector are 1.1 and 0.18 µg/m^3 for OC and EC. For the six east-samples the corresponding values are 2.59 and 0.33 µg/m^3.

The second interval is from the autumn months of October and November and the temperature is between -0 and +10 °C. During the first period the mean OC and EC concentrations are 6.2 and 0.61 µg/m^3. When the air mass origin shifts to the southern sector the OC and EC concentrations are 1.75 and 0.33 µg/m^3.

For these four investigated period both OC and EC are raised when the origin of the air mass changes from north or south to east. The results are consistent with what has been shown in Kristensson et al. (2008) where it was stated that air reaching Vavihill from the east contained more particles whereas the air is generally clean when originating from the north.

The results will be complemented with radiocarbon analyses and chemical tracers like anhydrosugars and several organic acids. This will enable a source apportionment with regard to the origin of the air masses.

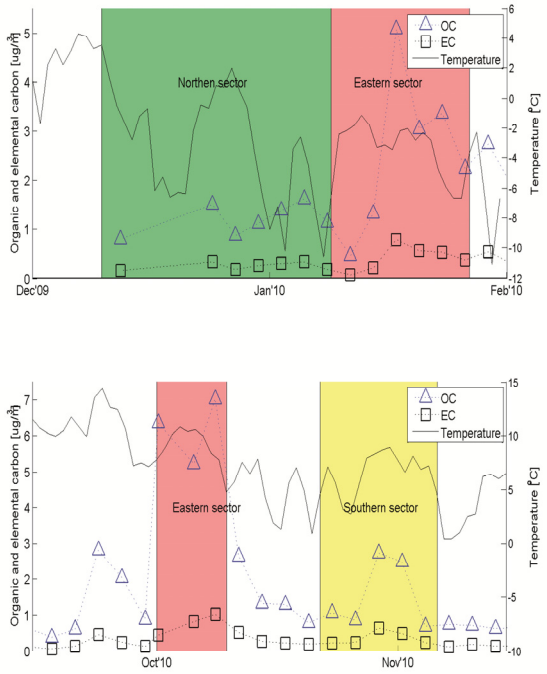

Figure 1. OC and EC results for the two studied intervals, both containing two periods with different wind directions. 1a shows results from December'09 to February'10. 1b shows results from mid-September'10 to mid-November'10

PM2.5 PCA-APCS Source Apportionment of a site monitored near a waste incinerator plant located in Bologna Area

M. Rossi[1], L. Pasti[2]

[1]Arpa Emilia-Romagna, Rimini, 47923, Italy
[2]Department of Chemistry, University of Ferrara, Ferrara, 44123, Italy
Keywords: Source apportionment, air quality, incinerator
Presenting author email: marossi@arpa.emr.it

Receptor modelling is one of the application of multivariate analysis dealing with the identification and quantitative apportionment of air pollutants to their potential sources (Hopke et al., 2006).

Various statistical multivariate models including principal component analysis-absolute principal component scores (PCA-APCS) have been proposed to identify and to ascertain the contribution of different sources to monitored ambient concentrations. Many studies have been reported on the apportionment of the PM, but most of them are focused only on the inorganic species of PM10, and there are only few works dealing with the apportionment of PM2.5 monitored near incinerator plants (Hopke et al., 2006). In this work the amount and distribution of both inorganic and organic components of PM2.5 were investigated and PCA-APCS method applied for source apportionment. The daily PM2.5 samples were collected in a monitoring station placed in the maximum impact area of the incinerator fallout previously determined by ADMS-Urban, a gaussian modified dispersion model.

Two extensive monitoring campaigns were performed: the first one was held in summer 2008 and the second one in winter 2009. The plant under study is located in a suburban-farming area, less than 10 km away from northeast of Bologna (Italy), in the southeast of Po Valley, which is a well known atmospheric polluted critical area.

PCA is generally employed to analyze the structure of multivariate datasets. PCA selects a smaller number of independent factors - starting from a large number of probably correlated variables - that can be used to explain the main sources of variance in the data. The factors are linear combinations of original variables.

APCS estimates the sources by employing the scores for each chemical species and for each day.

Results

Different sets of variables were selected. In the following the results referring to one of these sets are reported :

- Metals: Ni , Mn, Cd, Al, Fe, Sb, As;
- Inorganic ions: NH4+, K+ , Cl-, NO2-, NO3-, SO42-;
- Total Carbon (TC) e water solubile organic carbon (WSOC);
- Alcane: C29;
- PAHs: benzo[g,h,i]perylene, pyrene, fluoranthene

PCA-APCS method was applied and a 4 factors model was obtained. The predicted model seems to fit well the experimental data as can be seen in Figure 1. The adjusted square regression coefficient was 0.909. The 95% intervals of confidence of fitting parameters include their theoretical values of 1 for the slope and 0 for the intercept. The SSE is 1669 and RMSE is 4.848.

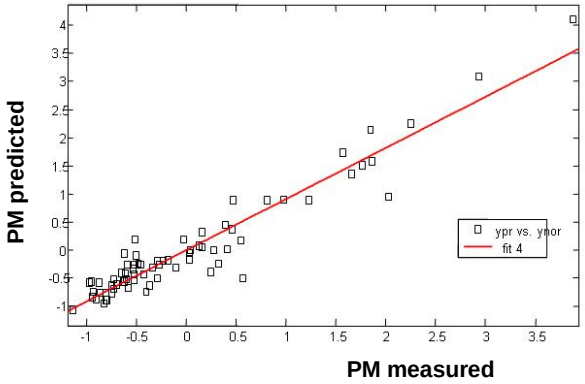

Figure 1. PM2.5 predicted by 4-factors PCA_APCS model vs. PM2.5 measured.

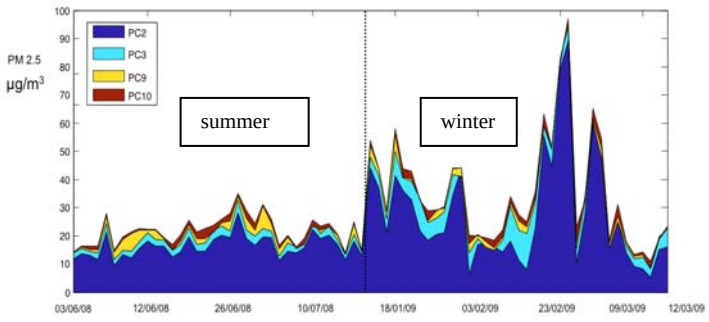

Figure 2. Temporal factors contribution to PM2.5 model.

The four factors shown in Fig.2 were associated with:
-Regional and secondary aerosol
-Vehicular emissions
-Biomass and/or secondary oxidized organic spiecies

Fine particles have a major impact on human health due to their ability to penetrate deeper into the lungs, as well as on the Earth's climate through both direct and indirect climate forcing (Penner et al., 2006). French emission inventories indicate that in Northern France industrial activities could be responsible for as much as 40% of the $PM_{2.5}$ concentrations, while urban sources like traffic and residential heating correspond to 16 and 24%, respectively, of the total 17,522 tons emitted annually on average (CITEPA 2005).

Field campaigns have been conducted at two sites located in Douai and Grande-Synthe, Northern France and during two seasons to measure real-time mass concentrations, diurnal trends and size-resolved average chemical composition of the non-refractory submicron aerosols (NR-PM_1) by a High Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS). Offline chemical analyses were also performed, and result comparison is presented in a companion abstract.

Figure 1 shows the time series of the chemical species measured by HR-ToF-AMS and their contribution to the total mass of NR-PM_1 in Douai in winter. Nitrates and organics were on average the dominant species (accounting each for ~ 1/3 of the total mass), followed by ammonium (17%), sulfates (13%) and chlorides (2%). A similar work has been realized for each site, highlighting significant concentration differences between sampling sites and periods.

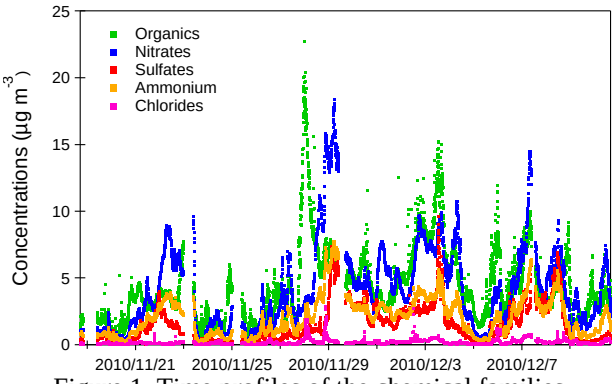

Figure 1. Time profiles of the chemical families measured by HR-ToF-AMS and their contribution to the total mass of NR-PM_1 in Douai in winter.

The HR-ToF-AMS has become a powerful tool for aerosol source apportionment (Baltensperger and Prévôt, 2008). Positive Matrix Factorization (PMF, version 3, Paatero and Tapper (1994)) can be applied to AMS data (Ulbrich *et al.* (2009)) to identify profiles related to emission sources or aerosol types, such as Hydrocarbon-like Organic Aerosol (HOA), Oxygenated Organic Aerosol (OOA), Biomass Burning Organic aerosol (BBOA) (Lanz *et al.*, 2007), or Cooking Organic Aerosol (COA) (Allan *et al.*, 2010). This approach has been applied to our HR-AMS data for all campaigns. Results will be presented and discussed in details.

Our laboratory participates in the Research Institute of Industrial Environment (IRENI) which is financed by the Communauté Urbaine de Dunkerque, the Nord-Pas de Calais Regional Council, the French Ministry of Education and Research, the CNRS and European funds (FEDER).

The effect of local heating on indoor and outdoor air quality in a rural settlement

M. Braniš[1] and J. Kozáková[1]

[1] Charles University in Prague, Faculty of Science, Institute for Environmental Studies, Albertov 6, 128 43 Prague 2, Czech Republic

Keywords: air quality, indoor air quality, PM_{10}, $PM_{2.5}$, local heating, rural settlement

Presenting author email: brains@natur.cuni.cz

There is an increasing evidence that use of solid fuels for local heating significantly affects air quality of rural settlements. Particulate matter concentrations increase namely during winter inversions and/or in deep valleys *(Hellén et al., 2008, Caserini et al., 2009)*. It has also been documented that under natural ventilation conditions indoor air quality is influenced by infiltration of the outdoor air. *Koutrakis et al., 1991)* and that indoor air is significantly affected by indoor activities, including heating (He et al., 2004). The aim of the study was to characterize outdoor and indoor air quality in a small settlement in the Czech Republic and ascertain to what extent the indoor air is affected by infiltration from outside and by human activity (including heating) taking place indoors.

Concentrations of size-resolved PM were monitored by a small Personal Cascade Impactor Sampler (PCIS) during two winter and one summer seasons in a small village situated in West Bohemia. Continuous concentrations of $PM_{2.5}$ were measured in parallel by a photometer DustTrak. Basic meteorological parameters (temperature, relative humidity, wind velocity, wind direction, precipitation and sun radiation) were monitored as well. Presence of persons and their activities in the house were recorded in a diary.

The average PM_{10} concentrations in the village were higher than average PM_{10} concentration in the nearby town. The summer average PM_{10} concentrations in the village were lower than those in the town (15.5µg.m^{-3} vs 17. µg.m^{-3}) while the winter PM_{10} concentrations in the village were significantly higher (31.1µg.m^{-3} vs 24.3µg.m^{-3}). The average indoor concentrations (PM_{10} and $PM_{2.5}$) were lower in the summer (9.6µg.m^{-3} vs 8.3µg.m^{-3}) than in the winter season (24.0µg.m^{-3} vs 20.7µg.m^{-3}).

The presence of people indoors resulted in indoor $PM_{2.5}$ concentrations higher than outdoors (I/O ratio 1.41). In the absence of people the $PM_{2.5}$ concentrations as well as the I/O ratio (0.55) dropped down. Fig. 1 shows size resolved mass concentrations of aerosol in different microenvironments and situations. Presence of people caused increase in concentrations of quasi-ultrafine particles (< 0.25µm) presumably due to heating and coarse particles (10-2.5µm) due to resuspension. Regarding ambient PM levels the highest PM_{10} and $PM_{2.5}$ concentrations were recorded during low temperature and low wind velocity periods.

The PM_{10} concentrations in the village highly correlated with those from the nearest town during the winter season (0.92). The correlation dropped to 0.67 during the summer (Fig. 2). Analysis of wind direction showed that the town emissions affected the village levels only exceptionally. We conclude that the major source of pollution in the village is not the transport from the nearest town but local heating of houses burning wood and coal in stoves.

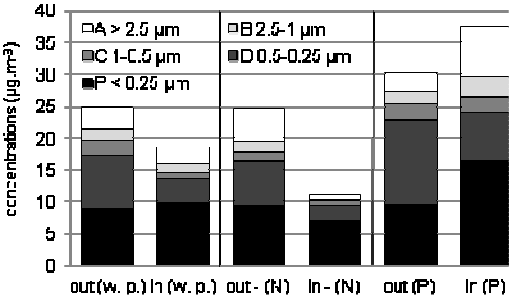

Figure 1. Size resolved mass concentrations of aerosol in different microenvironments (out-outdoor; in-indoor; w.p. - whole period; N - without people; P - with people.

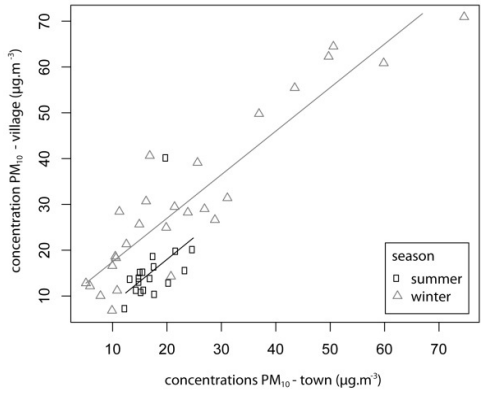

Figure 2. The association between PM_{10} concentrations in the village and the town in summer and in winter.

Presenting author email: purmahia@udc.es

Water soluble ionic compounds represent always a significant part of the atmospheric particulate matter mass. The major compounds in this fraction are inorganic anions (chloride, nitrate and sulphate), inorganic cations (ammonium, potassium, calcium, magnesium and sodium) and a complex and poorly characterized mixture of organic compounds, among which mono and dicarboxylic acids are the most commonly identified species (Yang 2008). The main sources and formation pathways for inorganic compounds are well known. In contrast, the origin of dicarboxylic acids and variables affecting their levels remain unclear in many respects (Ho, 2011).

In this work we present the data obtained from the analysis of inorganic (Cl^-, NO^{3-}, SO_4^{2-}, NH_4^+, Na^+, Ca^{2+} ,Mg^{2+} and K^+) and organic (oxalic, malonic, succinic, malic, acetic and formic acids) in two PM fractions (PM2.5 and PM10) and three different environments (urban, suburban and industrial) for 45 days, comprising a total of 270 samples. The three sampling points were located in the surroundings of the city of A Coruña (Spain). The data obtained was employed to identify the origins of mono and dicarboxylic acids in the three environments. For this purpose, principal component analysis with Varimax rotation was employed based on the association of acids with components related to inorganic compounds sources. Although eleven mono and dicarboxylic acid were identified, only those detected in more than a 50 % of the samples were considered for origin estimation.

In every case, oxalic was the acid with higher concentration followed by malonic and succinic.

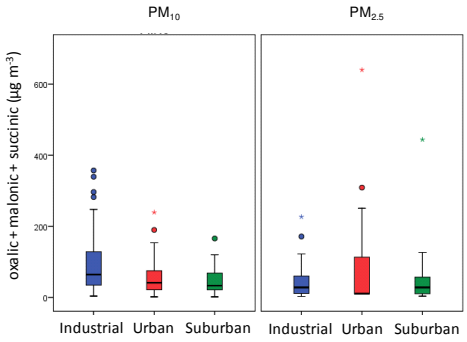

Figure 1. Distribution of major dicarboxylic acids in the three locations and two PM fractions.

As shown in figure 1, higher levels of organic acids were observed for industrial and urban environments, however, the distribution between fractions was different suggesting different formation mechanisms.

In all the locations the three main principal components were related to the three main sources of PM in this area: marine, crustal and secondary. In the suburban location a component related to biomass burning was also identified. The relation of dicarboxylic acids with these sources was employed to identify their sources.

In the industrial location, the dicarboxylic acids appear linked to secondary inorganic compounds (ammonium, nitrate and non-sea-salt sulphate) independently of the season and fraction considered, indicating a secondary origin.

In the urban location a clear distinction can be observed between cold and warm season. During winter, dicarboxylic acids show an origin independent of secondary generated compounds and the main origin can be related to direct emissions from traffic. During the warm season the contribution of photochemical generation increases and dicarboxylic acids appear related to inorganic secondary compounds.

In the suburban location dicarboxylic acids show an origin which can be interpreted as a combination of secondary formation and biomass burning.

Monocarboxylic acids present always an origin independent of the dicarboxylic and inorganic ions and are related to multiple anthropogenic and natural origins. The inclusion into the PCA of other compounds levels, which were available for the same samples (metals and organic compounds), was performed in order to clarify the origin of carboxylic acids.

Modelling of particulate matter concentration at regional and local scale

P. Brotto[1], F. Cassola[1], A. Mazzino[1], T. Giannaros[2], K. Markakis[2], A. Poupkou[2], D. Melas[2] and P. Prati[1]

Liguria is a very complex-topography region located in Northwestern Italy and consists of a narrow strip of land bordered by the Ligurian Sea, the Alps and the Apennines mountains, reaching elevations above 2000 m. Most of the population resides along the coast, where the main economic activities are concentrated as well. Environmental concerns are primarily associated with road and maritime transport, whereas industrial emissions are lower, apart from some local hot spots, typically corresponding to coal-fired power plants.

The Laboratory of Environmental Physics at the Department of Physics (DIFI) of the University of Genoa is currently involved in Transnational Action Plans projects (MED-APICE and Alcotra-AERA) aiming at the evaluation of air quality in the Liguria Region and in the urban area of Genoa, by means of numerical simulations as well as dedicated field measurement campaigns. In particular, the APICE (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions) project is focused on the evaluation of the environmental impact of harbour activities on urban air quality and the definition of long-lasting measures and shared strategies to reduce air pollution in port cities.

In this framework, an integrated air quality forecasting system has been implemented at DIFI. Meteorological fields are obtained by the mesoscale model WRF-ARW (Skamarock et al., 2008), whereas air quality simulations are performed using the photochemical dispersion model CAMx (ENVIRON, 2010). By means of subsequent nesting procedures, meteorological and pollutant concentration fields are obtained up to resolutions of order of 1 km.

Initial and boundary conditions needed to drive WRF simulations are provided by the global model GFS, operational at NCEP (National Center for Environmental Prediction). Large-scale anthropogenic emissions data have been obtained by the Aristotle University of THessaloniki (AUTH) processing the 2005 European dataset by The Netherlands Organization (TNO) (Visschedijk et al., 2007) with the MOSESS (MOdel for the Spatial and tEmporal diStribution of emissionS) code (Markakis et al. 2011) while high-resolution (1 km) gridded emission data have been obtained from the Liguria Region inventory. Biogenic and natural emissions have been computed from WRF outputs using the AUTH NEMO (Natural Emission MOdel) model (Poupkou et al. 2010).

The analysis of available anemometric measurements from different stations suggests that favourable conditions for the pollutant transport from the harbour area towards the city are mostly encountered during the warm season, due to the onset of diurnal sea breezes, whereas during Autumn and Winter months intense northerly (offshore) winds are prevailing, thus contributing to improve air quality in the urban area. For this reason for the purposes of the APICE project we decided to choose a simulation period running from May to September 2011. In the same period, a dedicated PM monitoring campaign has been carried out in three different sites in town, providing a large amount of data to be used for source apportionment studies by means of receptor models and comparison with outputs from CAMx simulations.

In particular, PM source apportionment has been performed using the CAMx PSAT tool to investigate the impact of harbour activities, industry, residential heating and road transport. A major outcome of this analysis is the identification of the most relevant risk activities and the design of scenarios connected with possible mitigation measures and control strategies that could be adopted for a sustainable development and the improvement of urban air quality.

This work was supported by the Programme MED under the APICE grant and the Programme Alcotra under the AERA grant.

Comparison of receptor models using synthetic organic aerosol mass spectra

H. Hagino[1], and T. Morikawa[1]

[1] Energy and Environmental Research Division, Japan Automobile Research Institute, Tsukuba, Ibaraki, 305-0822, Japan

Keywords: Aerosol mass spectrometry, Source Apportionment, PMF, CMB
Presenting author email: hhagino@jari.or.jp

The atmospheric aerosols, especially fine particles, are known to have adverse health effects on human populations. Understanding the composition of fine particles is necessary to identify their sources and to predict their effect on various atmospheric processes. Although organic aerosols are major components of the fine particles in urban atmospheres, the composition, formation mechanisms, and seasonal variation of concentrations of organic aerosols (OA) are not well understood. To study the organic aerosol source apportionment, several receptor models have been developed, such as the Chemical Mass Balance (CMB) and Positive Matrix Factorization (PMF) models. These receptor models have frequently been applied to $PM_{2.5}$ measurement for air quality management. However, few studies have applied receptor modelling to datasets of aerosol mass spectrometer (AMS). The AMS data has been used to chemically characterise the sources and evolution of OA at many worldwide (Zhang *et al*., 2007).

The CMB (CMB8J ; Hayakari and Hanaishi (2001)) and PMF (PMF2 ver4.2 ; Paatero (2000)) were demonstrated to synthetic datasets that suppose ambient organic aerosol mass spectra from two sources. Two different organic aerosol mass spectra scenarios using different sources were considered. The scenario assumed that the similar time variations occurred between diesel exhaust particles as primary organic aerosol (POA) and *m*-xylene-derived secondary organic aerosol (SOA) (Figure 1).

The time trend of PMF and CMB agree well with a good correlation. However, PMF separate out factors corresponding to POA and SOA, then two sources that made relatively uniform contributions to the synthetic dataset. In addition, PMF resolved factor profiles also have similar profile abundances. The CMB represented that the source apportionment with the POA and SOA profile has a better fit to the synthetic dataset.

Each receptor model has its strengths and weaknesses. These weaknesses include CMB might misspecify sources and have collinearity problem (Lowenthal, *et al*. 1992); for PMF, it should interpreted as sources and aerosol components. In addition, PMF might fail to separate out some factors (sources) (Brinkman *et al*., 2006).

The CMB is an ideal approache when the profiles of the emissions for all relevant sources are known and do not change with time. The more dataset from laboratory and field studies need to be analysed to evaluate the receptor models.

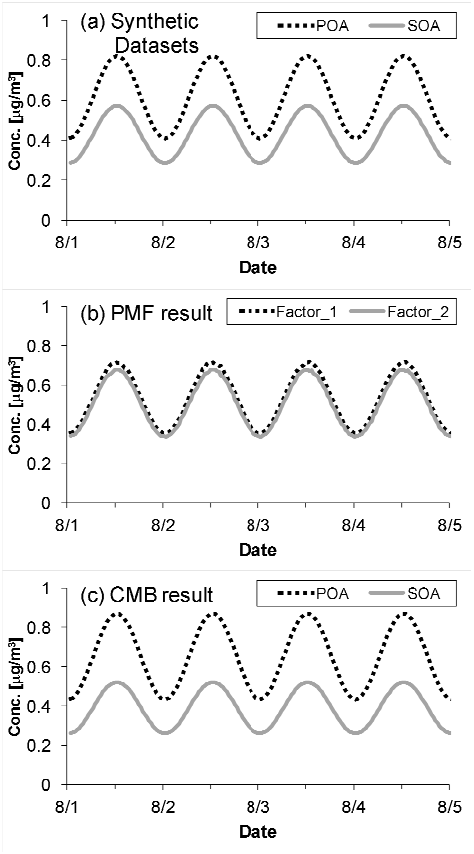

Figure 1. Time trends of synthetic dataset (a), PMF analytical result (b), and CMB analytical result (c).

Indoor air studies, with main focus on particulate matter, are a relevant subject nowadays, especially in environments like primary schools, where the occupants are characterized as very sensible to pollutants due to their specific physical characteristics. Due to its high penetrability and toxicity, the concern about $PM_{2.5}$ has increased and its characterization in environments like these is essential to understand the exposure level of the children.

Fig. 1 shows the primary school location (which village is characterized as a rural area).

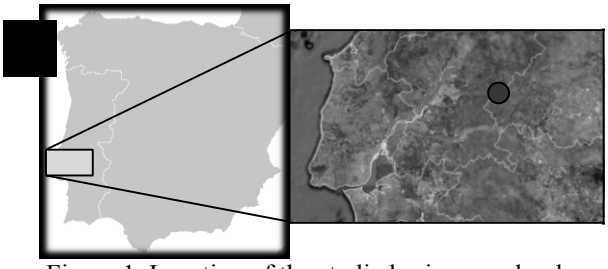

Figure 1. Location of the studied primary school.

A Partisol sequential sampler was placed inside of a classroom, where a slow combustion stove was in use for house heating (by means of wood burning), to collect $PM_{2.5}$. The sampling period was from 8 to 19 of March 2010. The sampler used Teflon^{TM} filters with a diameter of 47 mm to collect particles for the period of classes (09h-17h30) and the overnight period (17h30-09h), at an air-intake rate of 16.7 L min-1. For chemical identification, one half of the filter was analyzed by Instrumental Neutron Activation Analysis - INAA (As, Au, Br, Ce, Co, Cr, Fe, K, La, Na, Rb, Sb, Sc, Sm and Zn) and the other half was analyzed by ion chromatography for the determination of water soluble ions (Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+} and Ca^{2+}).

Source apportionment was determined by Principal Component Factor Analysis (PCA) (Almeida et al., 2006) using STATISTICA software, for both types of periods.

Values of $PM_{2.5}$ concentrations above 200 $\mu g.m^{-3}$ were registered for 2 consecutive days, during classes. Mean values of $PM_{2.5}$ concentrations were 100 and 41 $\mu g.m^{-3}$ for classes and overnight periods, respectively. Table 1 shows the concentrations of the elements and soluble ions that were used for the source apportionment.

Table 1. Concentrations of the chemical elements and soluble ions determined in the $PM_{2.5}$. P. - Parameter.

P.	Concentration $ng.m^{-3}$			P.	Concentration $ng.m^{-3}$		
	Mean	Min	Max		Mean	Min	Max
As	0,92	0,15	3,75	Sc	0,27	0,01	0,98
Au	0,13	0,01	0,52	Sm	0,20	0,01	0,58
Br	4,7	2,3	7,1	Zn	20	6	42
Ce	3,8	0,7	10,4	Cl^-	253	8	658
Co	0,47	0,07	1,19	NO_3^-	1131	481	1829
Cr	10,4	0,7	40,6	SO_4^{2-}	1491	308	3461
Fe	882	124	2551	Na^+	315	15	753
K	1707	113	4986	NH_4^+	468	88	947
La	1,06	0,02	2,75	K^+	460	88	1492
Rb	8,7	2,5	18,0	Mg^{2+}	70	9	124
Sb	0,38	0,10	0,66	Ca^{2+}	600	174	1369

During classes' period, 4 factors were assessed and explained 93% of the variance. The overnight period displayed also 4 factors which explained 98% of the variance. Soil, secondary and marine aerosols, wood burn (through its fingerprint, K^+ (Canha et al., 2012)) and industry/traffic were identified as sources. The found sources differed in the 2 studied periods. The following up of this study is to determinate the sources contribution to $PM_{2.5}$ concentrations, by means of MLRA, to understand them, compare both types of sampling periods and propose mitigation measures.

Characteristics of heavy metals in $PM_{2.5}$ at Fukuoka, Japan, based on daily analysis of year-round samples

N. Kaneyasu[1], A. Takami[2], K. Sato[2], S. Ymamamoto[3], Y-P. Kim[4], and I-S. Kim[4]

Presenting author email: kane.n@aist.go.jp

The emission rates of particulate matters and their precursory gases originating in East Asia are expected to increase in the first half of this century, and there is much concern about their influence on Japan, which is located on the leeward side of the westerlies. From this viewpoint, we measured the mass concentrations and chemical compositions of $PM_{2.5}$ in the upwind areas of Japan, including urban areas such as Fukuoka City (population 1,400,000; representative metropolis in western Japan), and isolated islands such as Fukue Island (population 40,000; located 190 km west of Fukuoka). The present study analyzes the behavior and seasonal characteristics of the metallic components in $PM_{2.5}$, which are important in view of their health effects and their use as tracers of emission sources.

At Fukuoka, year-round $PM_{2.5}$ filter samples are collected daily on quartz-fiber filters using a high-volume air sampler equipped with a $PM_{2.5}$ separation impactor. Metallic components are determined by ICP-AES after dissolution into HF-HNO_3-H_2O_2 mixed solution. $PM_{2.5}$ mass concentrations are monitored by TEOM 1400a. Figure 1 shows a comparison of the monthly averaged $PM_{2.5}$ concentrations in Fukuoka City, Nagasaki City (population: 300,000; located 100 km southwest of Fukuoka), and Fukue Island. The similarity in the concentrations and temporal variations of $PM_{2.5}$ suggests that even in a city as large as Fukuoka, the $PM_{2.5}$ mass concentration throughout the year is dominated by regional air pollution rather than domestic urban air pollution.

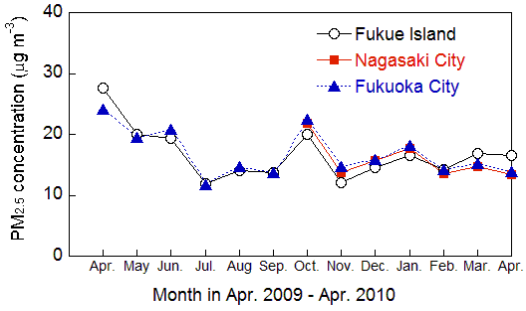

Figure 1 Time series of monthly average $PM_{2.5}$ concentrations in Fukue Island, Fukuoka City, and Nagasaki City.

Figure 2 shows the daily concentrations of metallic components in $PM_{2.5}$ at Fukuoka (Dazaifu district). Most metallic components show synchronous fluctuations, except V, Fe, and Al. The drastic increases in Fe and Al concentrations are apparently caused by the occurrence of Asian Dust (Kosa) events. The intervals of fluctuations for other metallic components, i.e., Pb, Zn, Mn, and Cd, is about 3 to 5 days, and the drastic increase in these concentrations corresponds to the passage of cold fronts. The relatively long-term (3 to 4 days) increase in concentrations, especially for Zn in spring, is accompanied by the passage of migrating anticyclones. This suggests that the increase in the Pb, Mn, and Cd concentrations is mainly caused by the long-range transported pollutants from the Asian continent and the increase in Zn concentration can be attributed to both domestic and long-range transported pollutants. The results of source apportionment analysis for the metallic components will be discussed in the presentation.

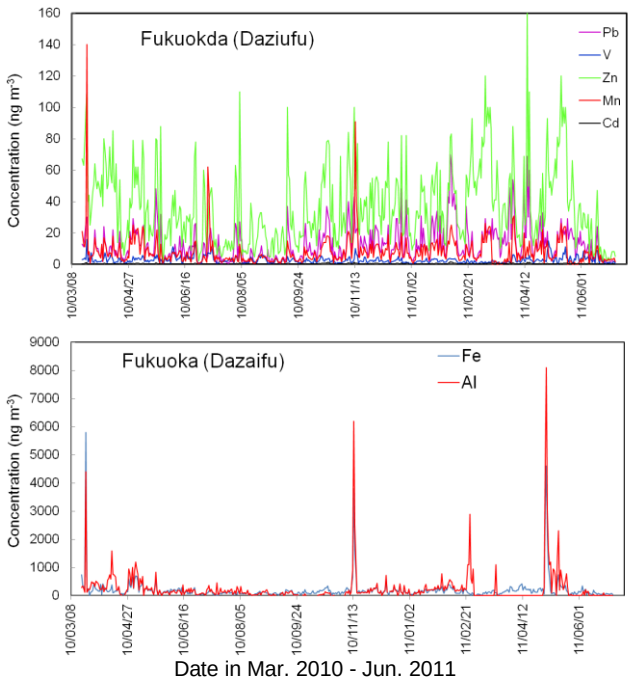

Figure 2 Daily concentrations of metallic components in $PM_{2.5}$ at Dazaifu district of Fukuoka. (Top) Concentrations of Pb, V, Zn, Mn, and Cd. (Bottom) Concentrations of Fe and Al.

Keywords: PM10, Source Apportionment, Statistical Analysis, Back trajectories.
Presenting author email: masiol@unive.it

This study combines a set of chemometric procedures for discriminating the role of weather conditions, local processes and remote contributions in determining the levels and chemical composition of airborne particulate matter. PM_{10} data were collected in a semi-rural coastal site near Venice (Italy), located on the eastern border of the Po Valley. This area is affected by worrying concentrations of several atmospheric pollutants causing a constant hazard for living inhabitants. This situation is favoured by a high level of urbanization, industries and some peculiar orographic features limiting air circulation (Rampazzo et al., 2008a;b; Squizzato et al., 2012). In particular, PM_{10}, known to be correlated to several adverse health effects, reaches levels frequently exceeding the limit and target values fixed by the European Directives.

A one year-long sampling campaign included the determination of PM_{10} mass concentration, the elemental and water soluble inorganic ions compositions using the gravimetric method, the Particle Induced X–ray Emission (PIXE) technique and ion chromatography, respectively. Finally, the concentrations of PM_{10}, 12 elements (Al, Si, K, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn) and 6 ions (Cl^-, NO_3^-,SO_4^{2-}, Na^+, NH_4^+, Mg^{2+}) were determined and the relative analytical uncertainties quantified .

Seven sources were identified and apportioned using the Positive Matrix Factorization (PMF) model: sea spray, mixed combustions, pollution, aged sea salt, mineral dust, secondary sulphate and secondary nitrate. The factor profiles are reported in Figure 1.

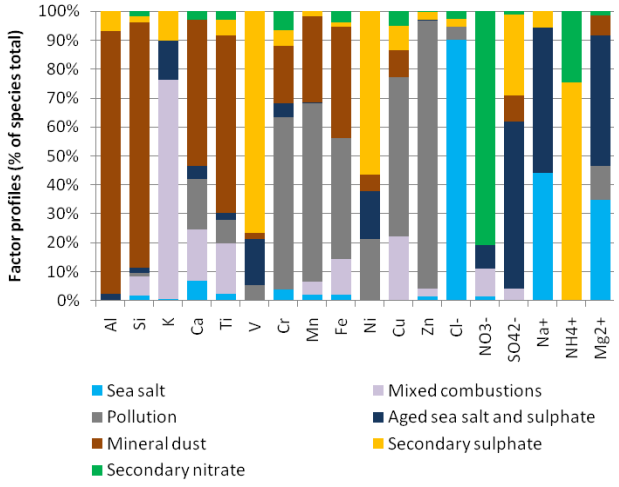

Figure 1. Factor profiles from PMF.

The relationships between PM_{10} mass, modelled source contributions and some weather parameters including solar radiation, temperature, relative humidity and precipitation were investigated. The importance of air temperature and relative humidity on secondary components, the direct relationship between sea spray and wind speed and the inverse correlation between pollution and wind speed were highlighted.

Using the approach proposed in Masiol et al. (2010), days with similar source profiles were grouped. Identified clusters were interpreted on the basis of their chemical composition, wind direction data and back-trajectories to extract further detailed information on potential source locations and possible links between meteorological conditions and PM_{10} chemical composition.

The differences in PM_{10} levels and source profiles between groups shows that the production of sea salt is strongly influenced by local winds. Differently, typical primary pollutants (i.e. combustion and pollution) increased during low wind regimes.

External contributions were investigated by using the air mass backward trajectories and by considering a forecast model analysis (ICoD-DREAM aerosol and dust maps). The increase of combustion and traffic-related pollutants was observed when air masses originated from Central and north-western Europe and the rise of secondary sulphate when air masses passed over the Po Valley. Conversely, anthropogenic contributions dropped when the origin was the Mediterranean area and Northern Europe.

The use of this approach gives detailed information on potential source locations and results may be used as a suitable instrument to design local and national air pollution control strategies.

This work was carried out using the AN2000 PIXE facility of the Legnaro laboratories of INFN, Padua (Italy).

INTRODUCTION

The Lower Fraser Valley of British Columbia is a complex airshed impacted by both urban sources from the metropolis of Vancouver and agricultural sources from adjacent agricultural areas. Although PM levels rarely exceed air quality guidelines or objectives, levels are of concern due to impacts on human health and visibility. In this study, a source apportionment analysis was performed on PM2.5 speciation data, collected at two monitoring sites. Positive Matrix Factorization (PMF) receptor modelling was employed to identify local sources and to inform airshed management efforts.

METHODOLOGY

Air quality monitoring data was collected from two stations, Burnaby South and Abbotsford, in the Lower Fraser Valley Airshed. Burnaby South is located in a suburban area bordering the eastern boundary of Vancouver, and Abbotsford is located in an agricultural-based area located 75 km east-southeast of downtown Vancouver. Both stations are part of the National Air Pollution Surveillance (NAPS) network and are run by Metro Vancouver and Environment Canada. Speciated 24-hour ambient aerosol samples were collected following a one-in-three day sampling schedule from December 2003 to December 2008.

PMF analysis was conducted using the EPA PMF3.0 software developed by the US Environmental Protection Agency. This graphical user interface employs the second version of the Multilinear Engine algorithm (Paatero, 1999) to determine the PMF solution.

Correlation analysis was applied to the PMF-resolved source contributions versus various gaseous pollutants (CO, NO, NO2, SO2, O3), individual VOCs and meteorological parameters (wind speed, relative humidity, temperature) to provide further insight into the identification of sources. Conditional Probability Function (CPF) analysis (Ashbaugh et al., 1985) was applied to resolved source contributions to estimate the likely direction of the individual sources from receptor sites.

RESULTS AND DISCUSSION

Eight and seven factor solutions were identified for Burnaby South and Abbotsford, respectively. The relative contributions of resolved factors relative to the total PM2.5 concentrations are illustrated in Table 1.

Factor	Burnaby South (%)	Abbotsford (%)
Secondary Nitrate	20	24
Secondary Sulphate	20	13
Vehicle Emission	20	21
Crustal Elements	12	16
Oil Combustion	6	9
Sea Salt	9	10
Burning	9	7
Diesel	4	-

Table 1. Contribution of resolved factors relative to total PM2.5 concentrations at Burnaby South and Abbotsford.

Overall, both sites exhibited similar source profiles and contributions. Strong seasonality was observed for burning, secondary sulphate, secondary nitrate, and oil combustion factors at both sites. Two vehicle related factors, vehicle emissions and diesel, were identified at Burnaby South, although the diesel factor only accounted for a small fraction of the total PM2.5. At the more rural location of Abbotsford, higher secondary nitrate was observed, as there was more NH_3 available to react with NOx from vehicles. Secondary sulphate was higher at Burnaby South due to the closer proximity to SO2 sources (marine and refineries).

Correlation analysis of PMF-resolved source contributions and individual VOCs helped confirm the validity of some of the sources. For example, the diesel factor was positively correlated with several diesel-related VOCs such as toluene, xylene, nonane, styrene, and decane. Significant contributions from crustal elements were identified at both sites. Conditional probability function (CPF) results identified the general direction of local sources from receptors. These included industrial, residential, agricultural, vehicle and marine vessel emissions. Other sources, such as emissions from oil refineries and marine biogenic influences were also identified. Results from studies such as this can help provide policy makers and air quality managers the information needed to develop effective air quality management plans.

Application of Positive Matrix Factorization to particle size distribution data from a suburban site in South East Queensland, Australia

Mark Hallas, Adrian J. Friend, Godwin A. Ayoko*

International Laboratory for Air Quality and Health, School of Chemistry, Physics and Mechanically Engineering, Queensland University of Technology, Brisbane, QLD 4001, Australia

Keywords: PMF, Source apportionment, PM.

Presenting author email: g.ayoko@qut.edu.au

The adverse effects of the size of airborne particles on human health have been well established. Therefore to facilitate the formulation of mitigating measures information that aid the understanding of the source, transport and accumulation of particles is critically required. Although extensive studies have been performed on the spatiotemporal variation of particle number concentration as a functions size distribution in indoor and outdoor in South East Queensland, there is a dearth of information on the sources of particles as a function of particle size distribution in this region (Friend et al, 2012).

The objective of the current study was to apply Positive Matrix Factorization to particle number size distribution data collected at a suburban site located at latitude -27.5441º and longitude 152.9987º on Sherwood road in Rocklea Queensland. The site was close to the Brisbane Produce Markets and Oxley Creek, and its air quality was influenced by local sources such as commercial and private vehicles, farming fields, and waterways, including the Brisbane River and Pacific Ocean to the east. Ipswich Motorway is about 2 kilometres to the east of the site, and railway lines and residential areas are also located nearby. This site was used for some of our previous air quality studies (Friend et al, 2011a and 2011b).

Particle number concentration was recorded at the site every 15 minutes from 1 September to 13 October 2009. The data obtained were pre-treated before Positive Matrix Factorisation (PMF) and other statistical analyses. This process involved the removal of obvious outliers and the grouping of the particle size data into six groups: 20-30nm, 30-50 nm, 50-70 nm, 70-100 nm, 100-200 nm and >200 nm. Subsequent analysis of the data by Positive Matrix Factorization revealed instructive details about the possible sources of the particles. Thus, four sources were identified and these are tentatively assigned as : unknown source, Traffic I, Traffic II and nucleation. These sources contributed 5.4%, 24.6%, 34.5% and 35.5% respectively to the particles at the site. The variations of the weekend/weekday, hourly and PM/AM contributions of each source were also examined, with the representative result shown in Figure 1 below. To facilitate the identification of the possible sources of the particles, meteorological information has been incorporated into the results obtained from PMF analysis.

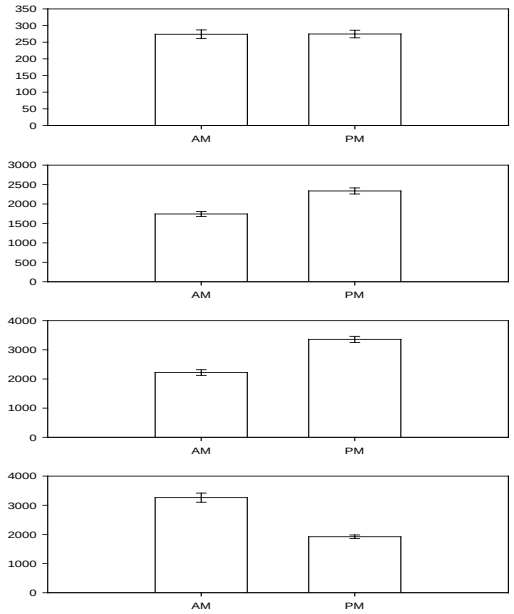

Fig 1: PM/AM source contribution for the four factors.

It was hoped that the comprehensive information provided by the overall results about the receptor site, would aid the development of appropriate measures for controlling and reducing the potential effects of air pollution in the area.

Keywords: $PM_{10}/PM_{2.5}$, Urban Areas, Traffic, Source Apportionment

Presenting author email: smarta@itn.pt

At urban areas in the South Europe, PM_{10} and $PM_{2.5}$ levels frequently exceed the legislated limits as a consequence of road traffic and favourable climatic conditions for photochemical formation and dust suspension.

The main objective of this study was to characterize the Air Particulate Matter (APM), in Setúbal (Portugal) and to evaluate the impact of traffic emissions in the concentration and composition of respirable particles.

In order to evaluate the influence of the traffic emissions on atmospheric particles, sampling was performed simultaneously at two locations: one directly impacted by fresh car emissions (traffic station) and the other considered as urban background (background station) (Fig.1).

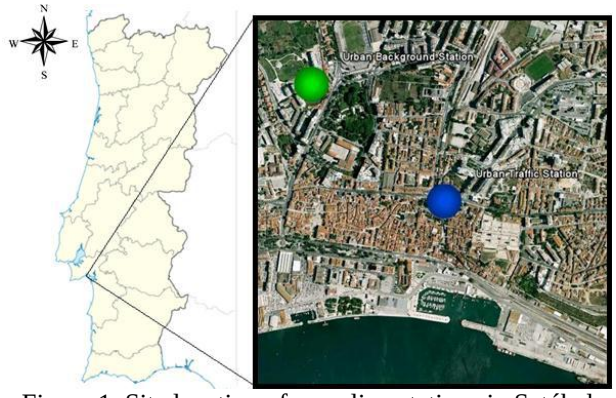

Figure 1. Site location of sampling stations in Setúbal (background and traffic station).

At each site, a Gent Sampler was used to collect $PM_{2.5}$ and $PM_{2.5-10}$. Sampling was made during two 12 hour periods, one during the day and the other during the night. The exposed filters were analysed by k_0 based Instrumental Neutron Activation Analysis (k_0-INAA) for elemental characterization. Hourly PM_{10} concentrations were also measured with beta attenuation monitors.

In order to apportion the contribution of traffic for the concentration and composition of the particles, complementary statistical methods were used: 1) Principal Component Analysis (PCA) and Multilinear Regression Analysis (MLRA) were applied; 2) comparisons between sampling stations (traffic and background) were made and 3) comparisons between different time periods (day/night and weekday/ weekend) were performed.

Figure 2 shows the average hourly PM_{10} concentrations in traffic and background stations. The ratio traffic/background (r=1.27) indicated that as expected the traffic station had higher PM_{10} concentrations than the background station.

Results show that there was an increase of PM_{10} concentration at around 9h00 to 12h00, reaching 27µg.m^{-3}, on traffic station. After that there was a decrease of the concentrations followed by a second peak with a maximum value at 22h00 that reached the value 40 µg.m^{-3} on the traffic station. This increase can be explained by the formation of a strong atmospheric stability and a low mixing layer height during this time period.

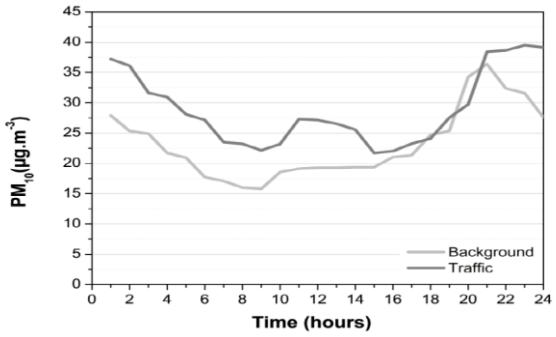

Figure 2: Hourly average PM_{10} concentrations in traffic and background stations (values in µg.m^{-3}).

Chemical analysis showed that the elements associated with traffic (Zn, Sb and As) and dust re-suspension (Fe, Sc, La and Sm) presented higher concentrations in the traffic station, during the day and in the weekdays.

PCA/MLRA results showed that the comparison between source contribution a) for roadside and urban background stations, b) for day and night periods and c) for weekday and weekend, constitutes a suitable approach to assess the contribution of the traffic to the air suspended particles.

Presenting author email: Tarja.Yli-Tuomi@thl.fi

In order to assess the exposure to and health effects of current residential wood combustion, outdoor $PM_{2.5}$ samples were collected in Kuopio, Finland, at a residential area favouring residential wood combustion during heating season (Nov 2008 - May 2009). At the same time, a cohort of 37 elderly residents was followed for home outdoor, home indoor, and personal exposure concentrations as well as health endpoints. The aim of this work was to determine the temporal variation of wood combustion related $PM_{2.5}$ at the central outdoor monitoring site.

Two EPA-WINS impactors (EPA Well Impactor Ninety-Six, BGI Inc, Waltham, MA, USA) were used to collect daily $PM_{2.5}$ samples on Teflon and quartz fibre filters. Teflon filters were used to analyse concentrations of inorganic ions, while levoglucosan, EC and OC were analysed from the quartz fibre filters.

A number of chemical species have been used as particle phase biomass burning emission tracers. A commonly used organic tracer is levoglucosan, a sugar anhydride produced during the combustion of cellulose (Simoneit, 1998). Jordan *et al* (2006) have shown that levoglucosan is stable during atmospheric transport and present at expected levels. Furthermore, levoglucosan emissions from woodstoves are relatively constant (Jordan and Seen, 2005).

Oxalate can originate from primary emissions of biomass burning (Yamasoe *et al*, 2000) and/or be formed as a secondary product by the oxidation of gaseous organic compounds (Kawamura and Ikushima, 1993). In Kuopio, the ratio of oxalate to levoglucosan increased in spring with increasing solar radiation, and thus, oxalate could not be used as a tracer of biomass burning.

Smoke from biomass burning is known to be high in potassium, but K^+ is present also in particles from other sources. Thus, K^+ is not an ideal tracer for wood combustion, but was included in the dataset for source apportionment.

EPA PMF 3.0.2.2 was applied to analyse $PM_{2.5}$ sources. Five factors were resolved and interpreted as long/regional range transported aerosol (LRT), salt, soil, traffic emissions and wood combustion. The factor associated with wood combustion was characterized by high concentrations of levoglucosan, K^+, EC and OC. This factor explained 96 % of levoglucosan and 64 % of K^+ concentrations, on average. Interestingly, over 20 % of the K^+ concentration was associated with the LRT factor.

The average ambient $PM_{2.5}$ concentration was 6 µg/m³ of which wood combustion related particles, $PM_{2.5wood,}$ composed 23 %. Concentration of $PM_{2.5wood}$ varied from 0 to 5 µg/m³ during the heating season (Fig.1). Correlation between outdoor temperature and $PM_{2.5wood}$ was only moderate (r= -0.36), possibly because wood smoke was emitted also from sauna stoves.

A remarkable portion of ambient $PM_{2.5}$ was associated to residential wood combustion. Although the concentrations were low, the results can be used in epidemiological time series study to assess the health effects.

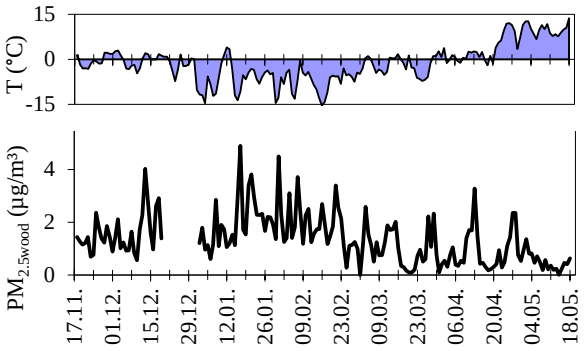

Figure 1. Temporal variation of outdoor temperature and wood combustion related $PM_{2.5}$ in a residential area in Kuopio.

Keywords: aerosol characterization, Indo-Gangetic plains

The Finnish Meteorological Institute (FMI), The Energy and Resources Institute (TERI) and Joint Research Centre (JRC) conducted aerosol mass measurements in Gual Pahari, Gurgaon, India from April 2008 to March 2009. The work belongs to the frame of the EUCAARI (European Integrated project on Aerosol Cloud Climate and Air Quality interactions) project (Kulmala et al. 2009). Chemical speciation of particulate matter of such a long-term dataset and identification & quantification of sources at a location near to "hot spot- Delhi" is of utmost importance.

Coarse ($PM_{2.5-10}$) and fine ($PM_{2.5}$) aerosols were sampled using a Dichotomous Partisol Plus 2025-D sequential air sampler, (Rupprecht & Patashnick Co., Inc. USA). Here, we present the results analysed for the fine fraction. The 24-hours weekly sampling was carried out, and filters were analyzed for water soluble ions (Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, Ca^{2+}, K^+, Mg^{2+}), OC and EC. The measurements in Gual Pahari ($28^0 43'$ North, $77^0 15'$ East, 243 m above sea level), were conducted in an open area surrounded mainly by light vegetation. The surroundings represent a semi-urban environment, Delhi is located north of the station about 25 km.

The temporal pattern of overall aerosol concentrations shows distinct variability (Hyvärinen et al. 2010). The highest concentrations were observed during the winter months (Dec to Feb) due to the low and stable boundary layer. Concentrations decreased in March-June due to increasing temperatures and a higher boundary layer. The lowest concentrations were observed during the rainy months (June to August/Sept) due to wet deposition. Similar seasonal trend was observed for OC, EC and WSIS (water soluble inorganic species) (Fig.1&2). The WSIS constituted 30% of annual average $PM_{2.5}$ with SO_4^{2-}, NH_4^+ and NO_3^- being the dominant ions followed by K^+. It is noteworthy that variability of SO_4^{2-}, NH_4^+ and NO_3^- exhibits similar pattern (Fig. 2) suggesting their dominant occurrence as $(NH_4)_2SO_4$ and NH_4NO_3 salts, the scattering aerosols in nature.

During the post-monsoon and winter periods there were high concentrations of source markers such as K^+, OC, EC, SO_4^{2-}, NH_4^+ and NO_3^-. Peaks for K^+ and OC may be due to higher biomass burning. NO_3^- is high in winters which could be due to emissions from biomass burning, vehicles and important role of meteorology. These relate to greater emissions of both primary and secondary PM precursors during winter due to the higher cooking, heating load and photo-chemistry. The higher OC to EC during winter ratio supports higher secondary organic aerosol (SOA) formation in this season.

Primarily, biomass burning and vehicular exhausts are the major sources that seem to dominate the aerosol $PM_{2.5}$ composition over this region. Further work is aimed at quantifying the sources as to use chemical tracers and Positive Matrix Factorization (PMF).

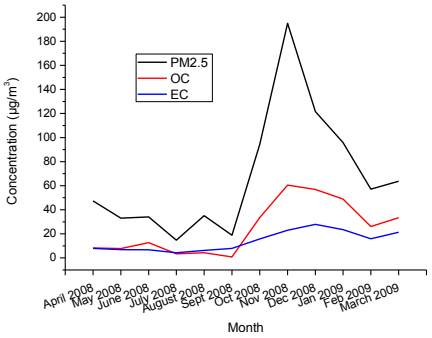

Figure 1. OC and EC in $PM_{2.5}$.

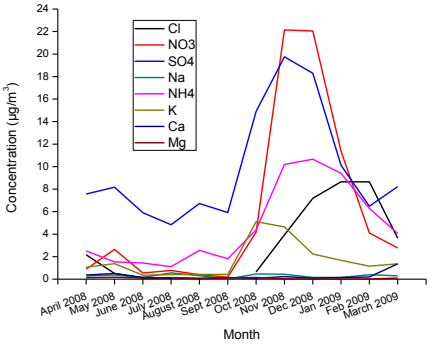

Figure 2. Soluble ions in $PM_{2.5}$

This work was made as part of the project EUCAARI, which is funded by the European Commission.

Determination of the elemental composition and the source profiles of particulate matters in Bolu

E. Özlü[1] and S. Yenisoy-Karakaş[1]

[1]Department of Chemistry, Abant Izzet Baysal University, Bolu, 14280,Turkey

Keywords: receptor modeling, metals, ions, total carbon
Presenting author email: bayindir_e@ibu.edu.tr

The variation of the sources of PM (natural or anthropogenic) causes the changes in particle diameter. The size of the particles is significant to determine the sources of pollutants, investigate health effects, and understand the effects on climate and residence and removal mechanisms of pollutants. Aerosols also affect the balance of global radiation by scattering or absorbing light. Absorbing radiation by fine particles causes heating whereas, scattering light by coarse particles causes cooling (Rastogi, 2009).

Distribution of elemental concentration of particles, relationship between each parameter and meteorological aspects and quantitative analysis results of all components can be determined by statistical evaluation.

Daily aerosol samples were collected during two campaigns (summer and winter) in Abant Izzet Baysal Universty campus in Bolu. Fifteen metals (Al, Cd, V, Mg, Ca, Fe, Pb, K, Cr, Mn, Ni, Cu, Zn, Co, As), ions (Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}) and total carbon were determined in both $PM_{2.5-10}$ and $PM_{2.5}$ size fractions.

Among the all parameters, contribution of SO_4^{2-} to $PM_{2.5}$ (28.3%) was the highest and the average concentration was 2.7 μg m^{-3}. In $PM_{2.5-10}$ the maximum concentration percent ratio belongs to Al (17.4 %) with 1.62 μg m^{-3} and Ca (37.5 %) with 3.3 μg m^{-3}. Total carbon showed no significant difference in both $PM_{2.5}$ and $PM_{2.5-10}$ samples. According to the ion balance calculations in $PM_{2.5}$ the anion/cation ratio is 1.03 and in $PM_{2.5-10}$ this ratio is calculated as 0.82. In fine particles all anions and cations were determined however, in coarse particles 18% of the anions could not be explained. The reason is the disability of the determination of CO_3^{2-} and HCO_3^- which are important among anions. In order to determine the sources of the parameters $PM_{2.5}/PM_{2.5-10}$ ratio in summer period was calculated. This ratio was greater than 1 for SO_4^{2-}, NH_4^+, Cl^- and Pb. In winter the ratio for As, K, SO_4^{2-}, NH_4^+, NO_3^- and Pb was greater than 1. In winter period this indicated that As, K and NO_3^- were mostly originated from the anthropogenic sources and they show seasonal variation due change of transboundary movement of pollutants with respect to meteorological parameters and change in human activities.

In this study for the determination of the source profiles of each pollutants, basic receptor modeling methods like enrichment factor analysis and factor analysis are used and for the determination of source regions of pollutants wind sector analysis was applied.

In enrichment factor analysis, Mn, Al, V and Co are found as crustal origin in both size of particles. Magnesium, K, Ca, Cu and Cr are moderately enriched and Ni, Pb, Zn, As and Cd are highly enriched (anthropogenic origin (Yenisoy-Karakaş, 2008)) again in both size.

Wind sector analysis summarize that in fine particles ($PM_{2.5}$) As, Pb, Cd, Cu and Cr were emitted from residential areas. Manganese, Pb, As, Ni, Cr and total carbon are due to traffic emission. In coarse particles ($PM_{2.5-10}$) all crustal elements come from agricultural zone in Nort-East, East-South-East and South-South-East directions. Arsenic and NO_3^- were emitted from coal and local traffic, respectively.

In factor analysis the 69% of whole data in $PM_{2.5}$ and 72% of the whole data in $PM_{2.5-10}$ can be explained with 5 factors. In $PM_{2.5}$ Al, Fe and NH_4^+ are in first factor (impure soil) which explains the 23.6% of variance. The second factor (traffic, anthropogenic) explains the 15.1% of the total variance. Nitrate, Pb, SO_4^{2-} and TC have high factor scores. In the third factor (coal, traffic) Ni, Cr and Mn have high factor scores and this factor explains the 12.8% of the variance. Arsenic, NH_4^+ and SO_4^{2-} are included in the fourth factor (secondary aerosols) which explains the 10.4% of the variance. The last factor (iron-steel works) explains only 8.7% of the total variance. In this factor Mn, Zn and SO_4^{2-} have high factor scores.

In $PM_{2.5-10}$ Factor 1 (soil) explains the 25.9% of the total variance and where Ca, $PM_{2.5-10}$, Fe, K, Mg, TC have high factor scores. The second factor (impure soil) explains the 15.3% of the variance. Aluminum and Fe have high scores whereas K, Mg and Mn have low factor scores. Nickel and Mn are included in Factor 3 (iron-steel works) which explains the 11.4% of the total variance. Manganese and Ni are the tracers of the iron-steel works. The fourth factor (coal) includes only Cr with factor score 0.86 and it explains 10.4% of the total variance. The last factor (traffic) explains only the 8.7% of the total variance. High factor score of lead (0.80) implies the source of factor is traffic emission.

This study was funded by TUBITAK-(The Scientific and Technological Research Council of Turkey) scientific research project with the grant number 108Y089.

Beijing suffers from air pollution since the 1980s and ambient PM becomes a major problem now (Garland et al., 2009). A lot of emission reduction measures were performed to improve the air quality during the Olympic Summer Games in 2008, which has cut down coarse particles largely (Schleicher et al. 2011). The $PM_{2.5}$, which is more harmful than PM_{10}, is still a problem and related investigation becomes more important.

To discuss typical aerosol characteristics during different seasons together with meteorological influences, two sequential high volume samplers (Digitel DHA-80, Hegnau, Switzerland) were used to collect automatically $PM_{2.5}$ samples at the campus of the CUGB which is located in the North West of Beijing from June 2010 to June 2011. Meteorological parameters including wind speed and direction, temperature, relative humidity and atmospheric pressure were obtained from the site ZBAA whose data are available at an internet page of the University of Wyoming (http://weather.uwyo.edu/upperair/sounding.html).

During the research period, the annual average $PM_{2.5}$ concentration determined by gravimetry was 27 $\mu g\ m^{-3}$ which is lower than the results documented by Shi et al (2003) for 2001. They found an annual average $PM_{2.5}$ mass concentration of 106 $\mu g\ m^{-3}$, which is approximately seven times higher than the annual average of the National Ambient Air Quality Standard of the United States (NAAQS) for $PM_{2.5}$ (15 $\mu g\ m^{-3}$). Our $PM_{2.5}$ concentration ranged from 3 to 107 $\mu g\ m^{-3}$. The lowest $PM_{2.5}$ mass concentration was in January 2011 and the highest in April 2011. However, these values are obviously lower than those monitored before 2008 Olympic Games.

The comparisons of $PM_{2.5}$ mass concentrations with meteorological parameters, provide some correlations with wind speed and relative humidity. It is also influenced by wind direction and precipitation and it is influencing visibility.

Minor and trace elements are measured by PEDXRF (Polarized Energy Dispersive X-ray Fluorescence). Factor analysis is used to identify the sources of $PM_{2.5}$ in Beijing. From this can be concluded that the aerosols are originated from geogenic sources (found from Fe, Ti and Ba), which is like to be resuspended road dust and dust storm, and also from anthropogenic sources (found from Zn, As and Pb), such as vehicle exhaust, chemical industry, coal combustion and fertilizer application.

In order to identify the source of the dust storm which happened on 30/04/2011 in the Beijing area, the HYSPLIT model (Hybrid Single Particle Lagrangian Integrated Trajectory) was applied. It was originated from the Gobi desert.

Due to the relevant role of aerosol in affecting climate, studies of variability in aerosol chemical composition at marine sites coupled with optical properties are requested in order to understand the complex aerosol-climate interactions, and reduce the uncertainty in the determination of the aerosol radiative forcing. In particular the Mediterranean region has been identified as one of the "Hot-Spots" in future climate change projections (Giorgi and Lionello, 2008).

In order to understand the contribution of natural and anthropic sources and the aerosol optical properties in the Central Mediterranean Sea, continuous observations of greenhouse gases concentration, aerosol properties, total ozone, ultraviolet irradiance, and other climatic parameters are routinely carried out at Lampedusa (35° N, 12.6° E). Since June 2004, a continuous campaign of PM10 sampling has been performed. A spot campaign with 8-stage impactor was also carried out in spring 2008. Each filter was analyzed for main and trace ions, and selected metals (HNO_3, pH = 1.5). Half of PM10 filters were analysed by PIXE for total elemental content.

Since 2010, PM10 was sampled on quartz filter, thus allowing EC and OC determination by thermo-optical methods as well.

In figure 1 the mean composition of PM10 is shown.

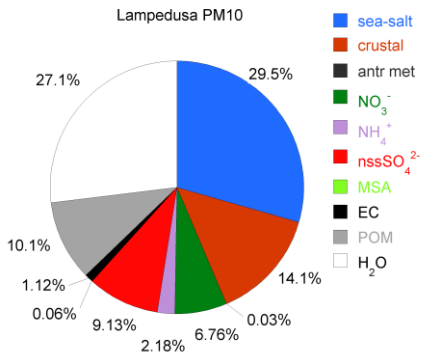

Figure 1. Pie plot of PM10 mean composition over 2004-2010 sampling periods at Lampedusa Island. Mean values of EC and POM are refer to a shorter time period than other measurements.

Crustal content was evaluated by Al, Si, Ca, non-sea-salt Na, K and Fe oxides, revealing that during strong Saharan dust events PM10 is often higher than 50μg m^{-3} and dust contribution is about 50%. The crustal aerosol amount and contribution to PM10 shows a very small seasonal dependence; conversely, the aerosol optical depth displays an evident annual cycle, with a strong summer maximum (monthly average aerosol optical depth at 500 nm up to 0.28 in June-August). When cases influenced by dust are excluded, also the aerosol optical depth displays a very small seasonal change, suggesting that the limited variations of the marine boundary layer produce a limited variability of the surface and lower tropospheric dust contribution.

The Positive Matrix Factorization (PMF) model has been applied to the chemical data in order to obtain the source apportionment of the PM10 at Lampedusa. The main sources impacting the site are: Saharan dust, primary marine, secondary anthropic and natural from biogenic emission.

Among the anthropic sources reaching the remote site of Lampedusa, heavy oil combustion emissions are identified using V and Ni as specific marker of this source. Back trajectory analysis shows that the selected events are affected by sea going ship and not by local pollution (i.e. Lampedusa harbour) or long range transport from refineries or power plants, confirming their provenience from the ship tracks crossing the Strait of Sicily (Becagli et al , 2011).

The campaign with 8-stage impactor shows that Al and Fe in Saharan dust events are distributed in the coarse fraction. Conversely, in events characterized by high contribution of aerosol from heavy oil combustion the same elements other than the specific marker of this source (V, Ni) are distributed in the sub-micrometric aerosol fraction.

Rome-Ciampino airport is a military and civilian airport located 14 km south of the centre of Rome (Italy).
This one runway airport, the second of the city, became in recent years a hub for low-cost carriers that in the last decade have increased in flight frequency, making it now the tenth busiest airport by passenger traffic in Italy.
The purpose of this study was to investigate the impact of aviation traffic emissions on the air quality of the area: a conurbation just outside the circular motorway Greater Ring Road (GRA) around Rome, impacted by a number of different anthropogenic sources and where residential homes, commercial activities and schools border the Terminal.
The effect of Ciampino aircraft noise exposure on the residents was recently investigated (S.E.R.A. project), but no information about the airport apportion to air quality and its health effects in a such polluted area was available yet.
To this scope, two air monitoring campaigns were carried out during the 2011 (summer) and the 2012 (winter) in the area surrounding the airport.
Two mobile stations were placed 400 m south of the end of the runway, under the take-off route followed in prevailing wind conditions. In this sampling site the parameters listed below were continuously measured:

- Particulate Matter mass concentration (PM_{10}, $PM_{2.5}$);
- Particle Number Concentration > 10 nm (PNC);
- Particle Size Distribution, 0.3-10 µm (PSD);
- Carbon Monoxide (CO);
- Nitrogen Oxides (NO, NO_2, NO_X);
- Sulfur Dioxide (SO_2);
- Ozone (O_3);
- Aromatic and Carbonyl Volatile Organic Compounds (VOCs)
- Light-scattering Coefficient of atmospheric aerosols;
- Light-absorption Coefficient;
- Aerosol Vertical Profile and Planetary Boundary Layer (PBL) height.

Additionally, in the same period, two 15 days campaigns in 46 sites with diffusive samplers (Nitrogen Dioxide, NO_2, Aromatic and Carbonyl compounds) were realized to implement a Land Use Regression model (LUR) in a 8x8 km domain, that helped to highlight the differences in spatial distribution of measured pollutants, in relation with the main pollution sources existent in the area.
Preliminary results showed that combining radar flight tracks and continuous sampling data, the direct contribution of take-off operations to the air quality of nearby areas was revealed (see Figure 1: Particle Number Concentration, 0.01 µm - 3 µm, temporal profile with one minute resolution).

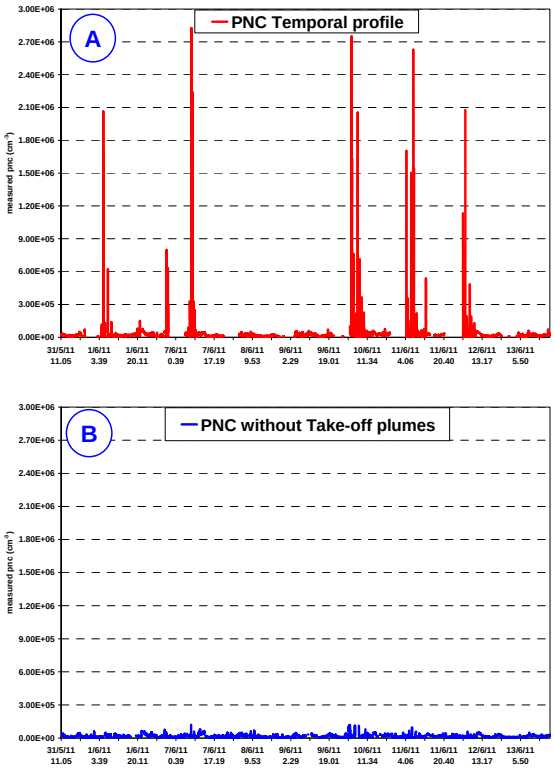

Figure 1. Summer campaign: comparison between with/without take-off plumes (A and B) PNC temporal profile measured by the Condensation Particle Counter placed 400 m south of the end of the runway.

This relation between PNC and the airport activities was an aspect otherwise invisible using standard averaging periods (hour or day), since confused or hidden in the complex mix of urban activity emissions.

PM2.5 source apportionment in Milan by UNMIX receptor model

G. Lonati[1], C. Colombi[2] and S. Cernuschi[1]

[1] DIIAR – Politecnico di Milano, P. za L. da Vinci, 32, 20133, Milano, Italy
[2] ARPA Lombardia – Dipartimento di Milano – Via Juvara, 22 - 20129 Milano, Italy

Presenting author email: giovanni.lonati@polimi.it

Milan is a well-known "hot spot" for particulate matter pollution in Europe, facing severe problems for compliance with PM10 and PM2.5 air quality limits. Source apportionment studies mainly focused on PM10 through Chemical Mass Balance and Positive Matrix Factorization receptor modelling whereas only few works considered PM2.5 and none by means of the UNMIX model (Henry, 2002; 2003)

In this work the UNMIX receptor model has been applied for the PM2.5 source apportionment of to a rather extended set of daily samples (about 120) collected at an urban background site in Milan. The samples, representative of the different seasonal PM2.5 levels, have been speciated for the chemical composition in terms of carbon components (elemental and organic carbon), major inorganic ions (Cl^-, NO_3^-, SO_4^{2-}, NH_4^+) and 13 trace elements (Lonati et al., 2008).

The model has a good ability in reconstructing the measured PM2.5 mass (Figure 1) based on 8 chemical species: EC, OC, NO_3^-, SO_4^{2-}, NH_4^+, Cu, Pb, Zn. Correlation between measured and modelled concentration data is in excess than 0.81 for all the chemical species and up to 0.99 for the ionic species.

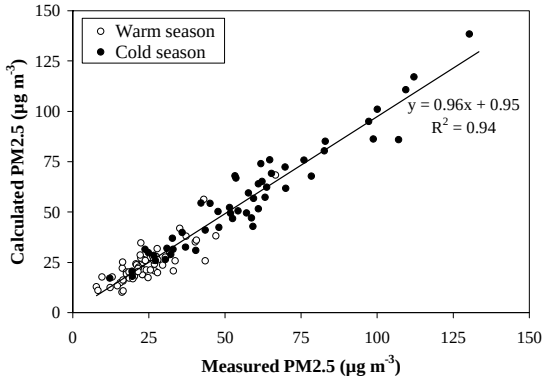

Figure 1. Scatter plot of the measured and calculated PM2.5 mass concentrations.

The model apportions the PM2.5 mass among four sources, identified as traffic emissions, combustion processes, secondary nitrate and secondary sulphate, based on the corresponding source profiles; only a small fraction of the mass (~2%) is not apportioned to any source. On annual basis the average contributions to the PM2.5 mass vary in a rather narrow range (Figure 2), with very similar values for traffic, combustion, and secondary nitrate source (~11 µg m^{-3}) and a smaller contribution from secondary sulphate (~7 µg m^{-3}). Overall, the secondary inorganic sources account for almost half of the total PM2.5 mass, in agreement with the results obtained by Marcazzan et al. (2003) through Principal Components Factor Analysis technique applied to a different dataset. Conversely, the model does not recognize a source related to soil resuspension.

The estimated source contributions are characterized by a remarkable seasonal and daily variability. During the cold season (Oct-Mar), combustion processes and secondary nitrate each account for about 33% of the PM2.5 mass, with the traffic source responsible for 22% and the secondary sulphate source for 10% only. In the warm season (Apr-Sep) both traffic and secondary sulphate account for about 30% of the PM2.5 mass whereas secondary nitrate and combustion processes for 16% only. The huge increase in the winter contribution of these latter sources, both in absolute and relative terms, is consistent with the additional emission of domestic heating and with the meteorological conditions fostering the ammonium nitrate atmospheric presence in the urban atmosphere.

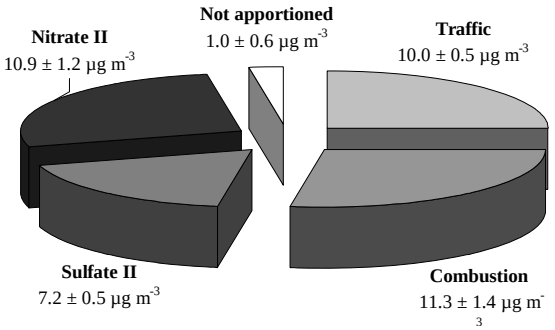

Figure 2. PM2.5 source apportionment in Milan (annual mean ± mean standard deviation).

PM_{10} is one of the most used parameters to assess the air quality in Europe. The identification of its sources is one of the main goals of environmental research and plays an important role in PM abatement strategies. In this study, a Principal Component Analysis (PCA) has been applied to chemical composition in the coarse (PM_{10-1}) and fine (PM_1) fractions in order to determine the main sources contributing to these size fractions. In this sense, a multilinear regression analysis (MRLA) has been then conducted to determine the contribution of each source to each fraction. In addition, we have studied the influence of dust intrusions from North Africa in PM_{10} speciation levels. These cases have been selected according to calima database (www.calima.ws).

The measurements were performed in Granada (37.16º N, 3.58º W, 680 m a.s.l.) from 2006 to 2010 using two high-volume samplers (flow rate 30 m^3 h^{-1}) for sampling PM_{10} (CAV-A/MSb) and PM_1 (Digitel DHA-80). Quartz fibre filters (150 mm) were used to collect particulate matter and were conditioned and treated pre- and post-sampling. Sampling usually starts at 7:00 GMT and ends 24h later. More information about the measurement station and the sampling procedure can be found in Lyamani et al. (2010) and Titos et al. (2012). Once the levels of bulk particulates were obtained by weighting the filters using gravimetric techniques, we apply to the filters different laboratory treatments for determining the levels of major and trace components following the procedure of Querol et al. (2009). With this procedure we obtained the concentration of major species (Total Carbon, SiO_2, CO_3^{2-}, Al, Ca, Na, Mg, K, Fe, SO_4^{2-}, NO_3^-, Cl^- and NH_4^+) and trace elements (Li, P, Ti, V, Cr, Mn, Co, Ni, Cu, Zn, As, Se, Rb, Sr, Mo, Cd, Sn, Sb, Ba, La, Ce, Hf, Pb, Bi, Th, U, among others). Quantitative errors have been estimated to be less than 10% for most of the components, and around 15% for K and P.

A varimax rotated PCA was applied to selected variables using the STATISTICA 8 software. PM_{10-1} and PM_1 were analysed separately. For the coarse fraction, the first component (PC1) is clearly identified with mineral dust. It exhibits high factor loadings (>0.70) for SiO_2, Al_2O_3, Ca, K, Mg, Fe, Li, P, Ti, Cr, Mn, Ga, As, Se, Rb, Sr, Cs and Ba, and explains 58% of the variance. This mineral matter is associated with dust re-suspension from roads, construction/demolition activities and dust intrusions from North Africa. PC2 explains 10% of variance and is characterized by high factor loadings for carbon, Sn and Sb (these latter elements are mainly associated to tyre and brake abrasion). The third component explains 5% of the variance and presents high factor loadings for Cl and Na, thus, being associated with marine aerosols.

For PM_1, the first component is also related with mineral particles although the factor loadings and the explained variance are lower than for PM_{10-1}. PC2 presents high factor loadings for carbon, Pb, NO_3^- and Sb being associated with traffic emissions (17% explained variance). PC3 is highly loaded with Ni, Co and V and it is related to fuel-oil combustion. PC5 presents high factor loadings for Se, SO_4^{2-} and As. The contribution of each source to PM_1 is shown in Figure 1.

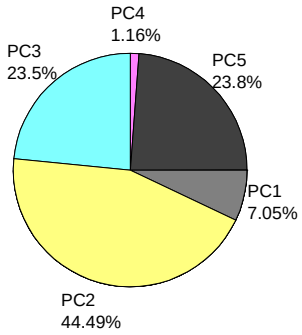

Figure 1. Source contribution to PM_1.

Considering the dust events, levels of PM_{10} increase significantly, which is especially marked for the mineral fraction (Σ SiO_2, CO_3^{2-}, Al, Ca, Mg, K, Fe). Surprisingly, other species such as non marine SO_4^{2-} or NO_3^- also increase during African dust outbreaks.

Residential wood burning has a remarkable effect on fine particles concentrations during cold season even on urban areas where heating of buildings is mainly based on centralized district heating system. Large amounts of PM are still emitted e.g. in heat storing fireplaces and sauna stoves in suburban small house areas. In the recent study it was estimated that during the average cold season the contribution of wood combustion emissions to fine particles ranged from 18 % to 29 % at the urban sites and from 31 % to 66 % at the suburban areas in Helsinki Metropolitan area, Finland (Saarnio et al 2012). In addition it was estimated that occasionally the local wood combustion emissions caused an addition of even 10-15 µg/m^3 to the daily mean concentration of $PM_{2.5}$ while the average addition to the daily concentrations of $PM_{2.5}$ was about 1-3 µg/m^3.

Wood combustion in suburban small house areas

The measured concentrations of benzo(a)pyrene have been at the same level in an urban background site at least since year 2007 (Table 1). It seems that local traffic does not have an effect on the concentrations of benzo(a)pyrene because the concentration levels are equal with the urban background and street canyon sites. The highest benzo(a)pyrene concentrations are measured in the suburban small house areas where local wood burning exists. It seems that there is quite large spatial variation between different suburban small house areas. The EU's target value for benzo(a)pyrene (1 ng/m^3) is exceeded in some suburban small house areas clearly when in some other areas the concentrations are well below the target value .

Table 1. The concentrations of benzo(a)pyrene in an urban background, different street canyons and suburban small house areas .

	Concentration of Benzo(a)pyrene (ng/m^3)		
Year	Urban background	Street canyons	Small house areas
2007	0.3	0.3	
2008	0.2		1.1
2009	0.3		0.5
2010	0.3	0.3	0.5
2011	0.3		1.2

Black carbon (BC) concentrations in year 2009 were measured in the suburban small house area (the annual BC concentration was 0.8 µg/m^3) and in year 2010 in one of the most polluted street canyon (the annual BC concentration 2,6 µg/m^3) in the Helsinki Metropolitan Area. The strong effect of local sources can be clearly seen in variation of BC concentrations between day of week and time of day (Figure 2). In the busy street canyon the concentrations were the highest during morning rush hours in weekdays while in the suburban small house areas the BC concentrations were highest on Saturday evenings. Also on Wednesday evenings the BC concentrations were elevated in the small house areas. This can be explained by the fact that Wednesday and Saturday are the days when sauna stoves are traditionally heated in Finland.

The annual $PM_{2.5}$ concentration was 8.1 µg/m^3 so it can be estimated that 11 % of total $PM_{2.5}$ concentration was caused by BC in the suburban small house area.

Correlations between the concentrations of levoglucosan and benzo(a)pyrene in an urban background site and suburban small house areas are also studied.

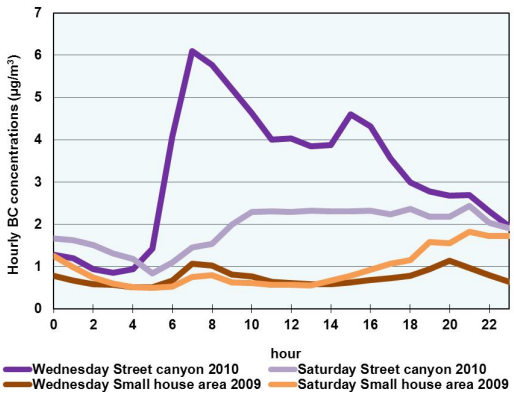

Figure 2. Daily variation of BC concentration in the street canyon and suburban small house area.

This study was partly funded by MMEA Programme (Measurement, Monitoring and Environmental Assessment). MMEA is supported by Tekes (the Finnish Funding Agency for Technology and Innovation) and coordinated by the Finnish energy and environment cluster - CLEEN Ltd.

Overview of the impact of wood burning emissions on carbonaceous aerosols and PM in the Alpine region

H. Herich[1], M.F.D. Gianini[1], Ch. Piot[2,3], J. Cozic[2], J.L. Jaffrezo[2] , J.L. Besombes[3], A.S.H. Prevot[4], and Ch. Hueglin[1]

Wood burning for domestic heating is an important source of carbonaceous aerosols and ambient particulate matter (PM). The importance of wood burning as a source of particulate air pollutants has been shown in many studies carried out in different countries. At locations in the Alpine region during the cold season, wood burning can be the dominating source of carbonaceous aerosols and PM (Szidat *et al.*, 2007; Gilardoni *et al.*, 2011; Piot, 2011).

During the past years, implemented measures for the reduction of PM emissions have been focused in many European countries on road traffic emissions. Conversely, much less attention has been paid to emissions from domestic wood burning. As shown recently by Gianini *et al.* (2012), average road traffic contributions to PM10 have in Switzerland declined during the past ten years, whereas the contributions from wood burning remained unchanged. As a consequence, the contribution of wood burning to PM10 is today comparable to (or even higher than) the contributions from road traffic on annual average at many locations in Switzerland. Same results are observed in France by Piot (2011).

This presentation provides an overview of the impact of wood burning emissions on carbonaceous aerosols and PM in the Alpine region. The overview is based on results of recently published studies using different methods, such as multivariate statistical models (Positive Matrix Factorization, PMF), Chemical Mass Balance (CMB), ^{14}C-method and evaluation of the wavelength dependence of the optical aerosol absorption (Aethalometer model). In addition, available data of specific wood combustion tracers such as levoglucosan are used together with published source emission ratios and PMF-derived emission ratios in macro-tracer analyses to estimate contributions of wood burning emissions to carbonaceous aerosols and PM.

As an example, Fig. 1 shows average wood burning contributions to PM10 as derived by PMF versus average concentrations of levoglucosan at sites in Switzerland and the Lombardy region (Northern Italy; data from Piazzalunga et al., 2011). The content of levoglucosan in PM10 from wood burning is constant for the Swiss sites that are located north of the Alps (Bern, Zurich, Payerne; levo/$PM10_{WB}$ = 0.045) and clearly lower than at the Swiss site south of the Alps (Magadino; levo/$PM10_{WB}$ = 0.069) and the average of the sites in Northern Italy (Piazzalunga et al., 2011; levo/$PM10_{WB}$ = 0.059). These and other PMF-derived emission ratios are used for estimation of wood burning impacts on particulate air pollutants and for comparison with results obtained by other source apportionment approaches.

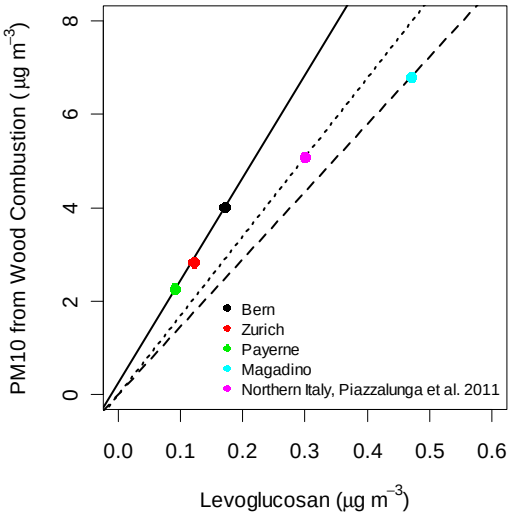

Figure 1. PMF-derived average contribution of PM10 from wood combustion versus average concentration of levoglucosan at sites in Switzerland and Northern Italy.

Indoor-outdoor relationships of airborne particles and nitrogen dioxide inside Parisian buses

R. Molle[1,2], E. Géhin[2], S. Mazoué[1] and A. Ionescu[2]

[1]RATP, Paris Public Transport, Paris, 75012, France
[2]Université Paris-Est Créteil, CERTES, 61 avenue du Général de Gaulle, 94010,Créteil

Keywords: Ambient air pollution, PM2.5, Cars, Diesel exhaust
Presenting author email: romain.molle@ratp.fr

Studies measuring air pollutants in the living areas determine the city-dwellers' exposure to urban air pollution. In 2008, measures were made in Paris on the passengers' exposure to traffic air pollution inside the main modes of transport during rush hour periods by Delaunay et al. (2010). The results have revealed that passengers travelling on bus line 91 are more exposed to fine particles and nitrogen dioxide compared to those using the bus line 56 in Paris.

New works were scheduled to confirm these preliminary results and to identify the sources and parameters determining the concentrations of pollutants measured inside the buses.

The regulated pollutants in the outdoor air were firstly selected, moreover pollutants from AIRPARIF data (the monitoring network of Paris and its suburbs) and 2008 measuring campaign were also selected for comparison. For all of the above reasons, NO_2 concentration, PM2.5 mass concentration and particle number concentration between 0.3 and 20 µm were measured in this study. Portable devices were used to measure simultaneously pollutants at the front, middle and rear positions inside buses in order to determine the spatial distribution and the most exposed position to these pollutants. This study evaluated passengers' exposure to traffic air pollution inside the buses of the line 91 in Paris during 10 working days in May, 2010 in the presence of passengers. Twenty buses were studied on 32 routes of 40 minutes each from 8 a.m. to 9 a.m. and from 4 p.m. to 5 p.m., time periods corresponding to the peak traffic and travellers.

Results

According to the results, the NO_2 and PM2.5 exposure is greater inside the instrumented buses in comparison to the outside air.

In 2010, the nitrogen dioxide concentration average obtained inside the instrumented buses is 203±21µg.m^{-3} therefore lower compared to air monitoring stations means range from 58±3 to 128±4 µg.m^{-3}. The conclusions are the same for in-cabin PM2.5 mass concentrations with 82±4 µg.m^{-3} against 46±7 µg.m^{-3} for air monitoring station. Moreover, the particle number concentration (0.3-20 µm) inside buses is variable and depends on the sampling date.

This experiment reveals the negligible role of the sampling position in the bus to PM2.5 mass concentration and for the particle number concentration (0.3-20 µm) thereby the levels are considered equal between the three sampling positions. However, in-cabin NO_2 concentrations increase when the sampling positions move from the front to the back of the bus.

The campaign confirmed the NO_2 levels found in 2008 therefore the NO_2 concentrations are repeatable and vary little if the factors (line, rolling stock, ventilation conditions, outdoor level) do not vary. The campaign confirmed also the PM2.5 levels despite fluctuations of PM2.5 concentrations measured by air monitoring station.

A correlation (Pearson, Spearman) is calculated with 2010 results to identify correlations between the in-cabin air and the outside air. These calculations have been made by comparing the average in-cabin concentration to air monitoring station concentration mean for each trip on identical time periods.

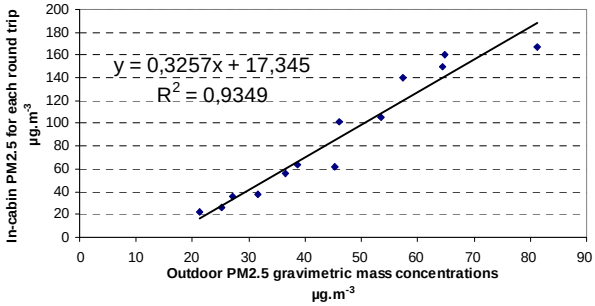

Figure 1. Linear regression between in-cabin PM2.5 and outdoor PM2.5.

The correlation coefficients between in-cabin and outdoor PM2.5 concentrations are highly correlated (greater than 0.9), despite the variability of PM2.5 mass concentrations inside the cabin.

However, it is still difficult to conclude. Indeed, the air monitoring stations are not present in the route of the studied bus line, the comparison between outside monitoring station data and in-cabin data are distorted.

Therefore the next campaign scheduled for autumn 2010 has included a laboratory vehicle in order to sample the air near the instrumented buses.

[3]Department of Plant Pathology and Microbiology, The Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Rehovot 76100, Israel.

Keywords: Health aspects of aerosols, fungal spores, particulate matter, allergens, biomarkers, ergosterol.

Presenting author email: naama.lang-yona@weizmann.ac.il

Airborne fungal spores are an important fraction of atmospheric particulate matter and are major causative agents of allergenic and infectious diseases. Predicting the variability and species of allergy-causing fungal spores requires detailed and reliable methods for identification and quantification. There are diverse methods for fungi detection in the atmosphere and in the indoor environments; yet, it is important to optimize suitable methods for their characterization in atmospheric samples.

In this study we sampled and characterized total and specific airborne fungal spores from PM10 samples collected in Rehovot, Israel over an entire year.

The total fungal spore concentrations vary throughout the year although the species variability was nearly the same (Figure 1).

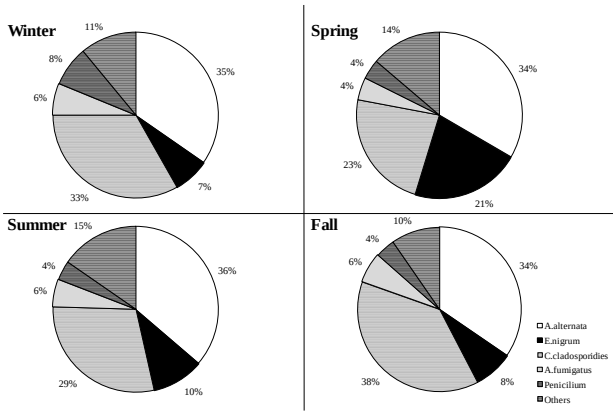

Figure 1: Seasonal distribution of selected allergy-inducing fungal species.

Seasonal equivalent spore concentrations analyzed by real-time quantitative-PCR-based methods were fall > winter > spring > summer. Reported concentrations based on ergosterol analysis for the same samples were fall > spring > winter > summer (Table 1, Burshtein, 2011).

Table 1: Seasonal correlation coefficients between Ergosterol and spore concentrations.*

Season	Ergosterol ng m^{-3}	Spore m^{-3}	Correlation coefficient, r	P-value
Winter	0.42±0.38	2044.6±2772.5	0.03±0.40	0.95
Spring	0.76±0.74	1380.6±2090.5	0.61±0.63	0.10
Summer	0.28±0.23	356.6±265.7	0.06±0.24	0.84
Fall	0.94±0.71	2896.9±2240.1	-0.15±0.72	0.55
Whole year	0.61±0.61	1873.8±2195.0	0.18±0.61	0.21

*Ergosterol and spore values are presented by the season mean value.

Correlation between the two analytical methods was found only for the spring season (Figure 2). These poor associations may be due to the per-spore ergosterol variations that arise from both varying production rates, as well as molecular degradation of ergosterol.

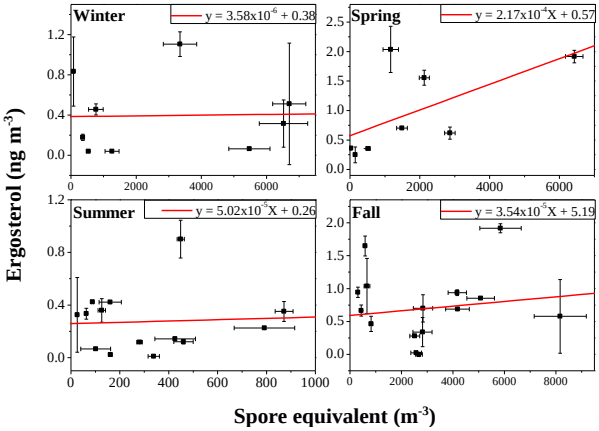

Figure 2: Seasonal correlation between equivalent total fungal spore concentrations analyzed from q-PCR measurements, and ergosterol mass concentrations (Burshtein 2011). The error bars represent the standard deviation of ergosterol (vertical) and fungi spore sampling replicates (horizontal).

While conversion of genome copies to spore concentration is not yet straightforward, the potential for improving this conversion and the ability of q-PCR to identify groups of fungi or specific species makes this method preferable for environmental spore quantification.

Identifying tools for establishing the relation between the presence of species and the actual ability to induce allergies is still needed in order to predict the effect on human health.

Comprehensive evaluation of dust cleaning in a subway indoor

W. R. Kim, H. W. Park, Y. M. Jo†

Department of Environmental Engineering, Kyung Hee University, Yongin, Gyeonggi-do, 446-701, Korea
Keywords: Indoor aerosol, Filtration, PM_x, IAQ, Subway
Presenting author email: woojoa@hanmail.net

Air quality of underground railway is of a critical interest in Seoul, Korea. The local government has paid a great attention to the IAQ(Indoor Air Quality) of metro-subway. In order to reduce the fine dust concentration of public indoor spaces, an integrated managing system including intelligent control network, on-line detects and double filters lay-out has been installed in a test field station. The effects of automatic operation of two stage filters: pre-filter and electret filter, were examined with a real-time analysis focusing on PM10 and PM2.5 at several points of the platform and tickets. The present study attempted to estimate the time-lag of conveyed air from the MVAC (Mechanical Ventilation Air Chamber) to the passengers' standing rooms.

Main purpose of this work is to provide the reasonable data for the integrated control program, which can give an order to operate the filtration system; individually or simultaneously. In order to meet an appropriate operation, an accurate estimation of the dust distribution inside is essential beforehand. Two particle monitors: Grimm-portable aerosol spectrometer 1.109(Germany) and HCT-PM sensor(Korea), were used to measure the quantitative analysis.

Table 1. Dust concentration of the flows at duct outlets from MVAC

[$\mu g/m^3$]

	Outdoor	Platform	Tickets	Filtration efficiency
PM10	56.3	10.9	12.4	78.3%
PM2.5	35.4	8.2	9.9	75.3%

Table 1 shows a typical tendency of dust levels just right after cleaning and conveying through long ducts. Filtration efficiency of the two stage filters including pre-filter and an electret filter screen was quite fair about 80% for fine dust aerosols. Nevertheless the supplied clean air from the MVAC would be combined with the ambient air insides of ticket waiting room and platforms. As can be seen in Fig. 1, therefore, the detected level of dust in ticket room and platform was quite high. Fig. 1 indicates the time delay of cleaning; for example of a certain day, the second electret filter in the MVAC initiated working at 9:00, but the cleaning effect on the internal spaces appeared at least one hour later. It implies that the artificial intelligence control system should consider the time delay as long as the predicted.

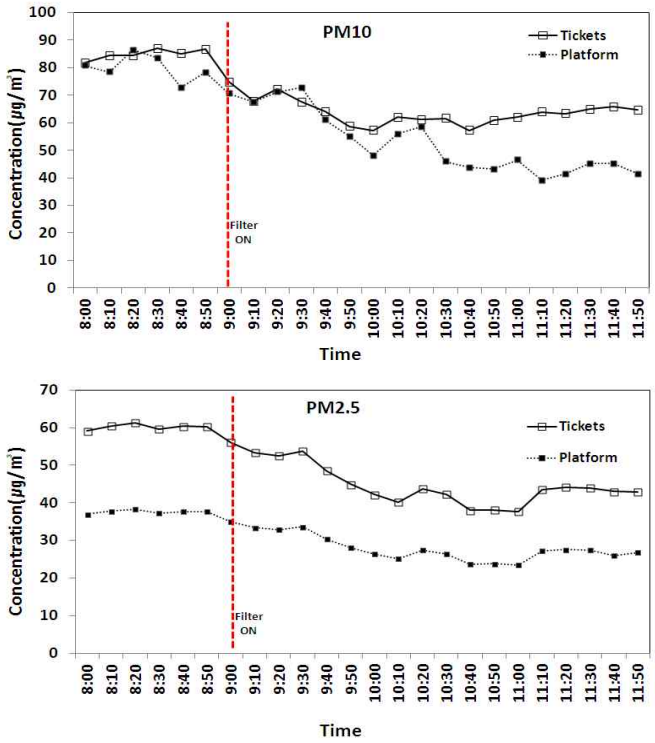

Figure 1. Dust concentration change with time at test indoor spaces.

Dust filtration of MVAC was more effective on platform than tickets because while the space of tickets was widely open to the external air, the standing corridors of platform in the second basement would be relatively isolated from the outdoor. In addition, the screen doors prevents inflowing the dust from the tunnel. In accordance, the platform composed of the limited air volume must be more effectively controlled by the central ventilation.

Introduction

A *review* is given of the results from the *second* Netherlands Research Program on Particulate Matter (BOP II). The BOP programs in the Netherlands are aimed at performing *policy-oriented* research on particulate matter, funded by the ministry of Infrastructure and the Environment. The BOP II framework was a co-operation between the institutes RIVM, ECN and TNO. The focus of BOP II addressed three main issues:

1. The concentrations of secondary inorganic aerosols (SIA) have been underestimated in the past in the Netherlands. BOP II provides an answer on 'how to continue' with analysis of models and measurements of SIAs.
2. PM_{10} and $PM_{2,5}$ are limited indicators to monitor the population based impact on health from the combustion aerosol. BOP II performed research in EC/OC on the local (city) scale and the more regional scale around Rotterdam. This to provide more insights in the contribution from sources within and outside of cities to the EC/OC concentrations in cities.
3. The first BOP program provided insights into the contribution of several sources to PM. However from the measurements performed in BOP it is difficult to determine whether the sources are originating from within or outside of the Netherlands. In BOP II this aspect will be investigated in more detail by means of model calculations which take into account source apportionment/labeling techniques.

Secondary inorganic aerosols

From the first BOP program it was concluded that the concentrations of SIAs had been underestimated by 50% in the Netherlands. In BOP II the mismatch between the old low-volume sampler (LVS) and the reference low volume sampler (Leckel) are further investigated: it was found that measurements as performed by the Leckel are more representative for ambient SIA concentrations than the ones measured with the old LVS method. Furthermore, fudge factors are derived in order to achieve comparability between the old LVS and recent Leckel annual values. Furthermore, depletion effects on the filters of the Leckel instrument were investigated: it was found that nitrate and chloride mass loss occurs on days with high temperature and low relative humidity.

Additionally, in BOP II new simulations were performed with the LOTOS-EUROS model which included new improved modules: height distribution of the emissions; cloud chemistry; implementation of compensation point approach for ammonia; improved dry deposition module for particles; implementation of new thermodynamic equilibrium module and including the formation of coarse nitrate mode. The underestimation of SIAs in the Netherlands in PM_{10} was reduced from 50% to 20% with the new simulations.

EC/OC

A measurement campaign was performed in Rotterdam from November 2010-November 2011. The campaign was focused on measurements of PM_{10}, $PM_{2.5}$ and EC/OC at urban background and kerbside locations. From this campaign it was shown that PM_{10} and $PM_{2.5}$ only partly reflect exposure to traffic-related PM. Contrary, EC showed elevation up to 100%, both near urban and motorway traffic.

Source apportionment

In BOP II source apportionment was implemented into the 3D chemistry-transport model LOTOS-EUROS (LE) model. With this new module in the LE model, one can now distinguish between national and foreign source contributions to the PM_{10} and $PM_{2.5}$ levels in the Netherlands. This information in both spatial and temporal variability of the source contribution to PM levels is a valuable tool for policy discussions.

Single molecule water catalysis of atmospheric OH oxidation reactions

Theo Kurtén[1], Ditte Linde Thomsen[2], Solvejg Jørgensen[2], Signe Baggesen[2], Cecilie Aalling[2], Henrik Kjærgaard[2]

[1]Laboratory of Physical Chemistry, University of Helsinki, P.O. BOX 55, FI-00014 Finland
[2]Department of Chemistry, University of Copenhagen, Universitetsparken 5, DK-2100 København Ø, Denmark
Keywords: aerosol chemistry, precursors, molecular clusters, amines
Presenting author email: theo.kurten@helsinki.fi

Atmospheric chemical reactions have traditionally been divided into gas-phase and condensed-phase reactions. Elementary gas-phase reactions are typically assumed to involve at most two reactant molecules, with possible third bodies only playing the role of inert collision partners. Recent computational and experimental evidence has begun to nuance this picture, as the clustering (complexation) of reactants with just one or two condensable trace gas molecules such as water or formic acid has been shown to catalyse several key reactions. From an aerosol perspective, the most important example is the SO_3+ H_2O => H_2SO_4 reaction, which is speeded up many orders of magnitude due to catalysis by one or more water molecules (Kolb et al, 1994).

Atmospheric new-particle formation from gas-to-liquid nucleation is believed to involve sulfuric acid, water, nitrogen-containing base molecules such as ammonia or amines, and oxygenated organic compounds such as diacids. Water catalysis is already known to be important for sulfuric acid formation, and may possibly play a role also in key oxidation reactions involving nitrogen- and carbon-containing aerosol precursors.

We have investigated the effect of a water molecule on hydrogen abstraction by OH radicals from the central carbon atoms of a series of substituted, saturated organic compounds of the type $HCY_{1...2}X$. The series includes both amines (X = NH_2), alcohols (X = OH) and aldehydes (X = O): all relevant functional groups for aerosol formation and growth processes.

For molecules containing polar functional groups such as those mentioned above, the transition states for the hydrogen abstraction reactions by OH typically resemble those shown on the left-hand side of Figure 1. Water molecules are able to stabilize the transition states (lower the activation energy of the reaction) by forming hydrogen bonds with both the OH hydrogen atom and the polar group, as shown on the right-hand side of Figure 1. Our calculations indicate that the magnitude of the stabilization is at most a few kcal/mol, implying an increase in the reaction rate by around one order of magnitude at room temperature.

Since simultaneous three-body collisions in the atmosphere are extremely improbable, a necessary precondition for water catalysis is that water is already complexed with either the molecule being oxidized, or with OH. Unfortunately, neither OH nor any of the studied organic compounds of type $CY_{1...2}XH$ (including for example methylamine) form strong enough complexes with water to be significantly hydrated at temperatures and humidities encoutered in the troposphere. For example at 298 K and 50% RH, computed equilibrium constants indicate that at less than 0.03% of any of the reactants will be complexed to water.

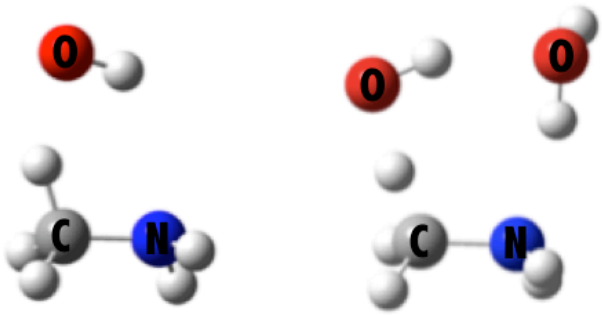

Figure 1. Transition states for the oxidation of methylamine by OH in the absence (left) and presence (right) of a water molecule.

Thus, despite the existence of a moderately strong *intrinsic* water catalysis effect (increase of the reaction rate when one of the reactants is complexed with water), the *net* catalytic effect of water on OH oxidation reactions in the atmosphere is likely to be quite small – certainly smaller than the typical error margins of reaction rate coefficients. The catalytic effects observed in the laboratory for OH oxidation reactions of, for example, acetaldehyde (Vöhringer-Martinez et al, 2007) were measured at very low temperatures and high absolute water concentrations – conditions unlikely to occur in the atmosphere. We therefore conclude that atmospheric chemistry models (for example, chemistry-transport models used in many types of aerosol modelling) do not need to include the effect of water catalysis on OH hydrogen abstractions from saturated organic compounds.

Calculations were performed at the B3LYP/aug-cc-pVTZ//CCSD(T)-F12/VDZ-F12 level using Gaussian 09 (Frisch et al, 2009) and Molpro 2010.1. (Werner et al, 2010). We thank the CSC IT Centre for Science in Espoo, Finland for computer time.

Sand and Dust Storm Warning Advisory and Assessment System (SDS-WAS) is a program of the World Meteorological Organization (WMO) with the mission to enhance the ability of countries to deliver timely and quality sand and dust storm forecasts, observations, information and knowledge to end users. The Regional Center for Northern Africa, Middle East and Europe, hosted by the Spanish State Meteorological Agency (AEMET) and the Barcelona Supercomputing Center (BSC-CNS), supports a network of research and operational partners implementing the objectives of the SDS-WAS program in the region.

A system to routinely exchange forecast model products has been established as the basis for a model intercomparison that includes common near real-time evaluation, verification, and generation of multimodel products. Six modelling systems: BSC-DREAM8b (Pérez et al., 2006), MACC-ECMWF (Morcrette et al, 200)), LMDzT-INCA (Schulz et al, 2009), DREAM8-MACC (Nickovic et al., 2001), CHIMERE (Menut et al., 2009) and NMMB/BSC-Dust (Pérez et al., 2011) provide daily dust forecast products (surface concentration and dust optical depth at 550 nm) for a reference area extending from 25ºW to 60ºE and from 0º to 65ºN with a 3-hourly basis until a lead time of 72 hours.

The forecasts of dust optical depth are compared with the total AOD provided by the AERONET network for 36 selected dust-prone stations. Version 2-Level 1.5 of AERONET products are used, that is, data that have been automatically cloud screened, but without the final calibrations applied. Since AERONET sun photometers do not yield AOD at 550 nm, it is calculated from AOD at 440, 675 and 870 nm and the Ångström exponent (AE) 440-870 using the Ångström law.

Bias error (BE) and root mean square error (rmse) are computed on a monthly basis. Because there might be other aerosol types not simulated by some of the participating models, negative BE could be expected. In order to minimize this source of error, it is intended to restrict the comparison to situations in which mineral dust is the dominant aerosol type. A threshold discrimination is made by discarding observations with AE higher than 0.6.

Multimodel products are generated from the values of the different prediction models. In order to produce them, the model outputs are bilinearly interpolated to a common grid mesh of 0.5 x 0.5 degrees. The median multimodel product could provide in principle a more reliable forecast than individual models. Its performance is assessed by comparing the respective verification scores. The range of variation of the models at every grid point is also displayed in order to evaluate the dispersion of the models and to allow identification of areas where there is a better match between the predictions of the different models.

Secondary organic aerosol formation during summer 2010 over Central Europe

B. Langmann[1], K. Sellegri[2] and E. Freney[2]

[1] Institute of Geophysics, University of Hamburg, KlimaCampus, Hamburg, Germany

Introduction

Until recently, atmospheric models systematically underestimated measured OC aerosol mass concentrations in the atmosphere by a factor of up to 10 and more. Jimenez et al. (2009) proposed the concept of aging of organic vapors, thereby producing less volatile and higher oxygenated organic vapors with atmospheric mass concentrations comparable to sulfate. Based on these ideas, Yu (2011) developed a promising modeling strategy where the aging of organic vapors is considered and in addition to the traditional two compound thermodynamical gas-particle partitioning a third low volatile organic vapor is formed which kinetically undergoes condensation on pre-existing particles.

Model description

Here we use the regional three-dimensional atmosphere-chemistry-aerosol model REMOTE (Langmann et al., 2008) with the aerosol dynamics and thermodynamics module M7 (Vignati et al., 2004). The standard M7 has been extended by Anntila et al. (2010) by a thermodynamical two compound SOC aerosol formation mechanism. This one was further extended based on Yu (2011). We consider three classes of organic vapors where the low-volatile one is formed by aging form the more volatile ones. The low-volatile organic vapor is assumed to condense kinetically on pre-existing particles, while for the medium- and semi-volatile organic vapors the thermodynamical approach of Anntila et al. (2010) is used.

Model results

REMOTE model results over Central Europe are compared with measurements from a campaign at Puy-de-Dome, France during June 2010. Sulfate and chlorine aerosol mass concentrations are very well captured in the model simulation results - finally also organic carbon aerosol mass concentration. For illustrating the sensitivity of OC model results on SOC parameterizations, Fig. 1 shows results for the original two compound thermodynamical approach for isoprene only by Anntila et al. (2010) (grey line) and model results with additional VOC precursor gases (yellow line). Taking into account the SOC gases as additional trace species in the model, which undergo transport and removal (green line) leads to a considerable, however still insufficient increase in comparison with the measurements. The red line shows results from the simulation where aging of the most volatile SOC gas to the semi volatile SOC gas has been considered, finally generating OC aerosol mass concentrations in the range of the measurements. Taken into account the aging of the semi volatile SOC gas to the low volatile SOC gas (black line) does not modify OC aerosol mass concentrations much in comparison to the first aging step.

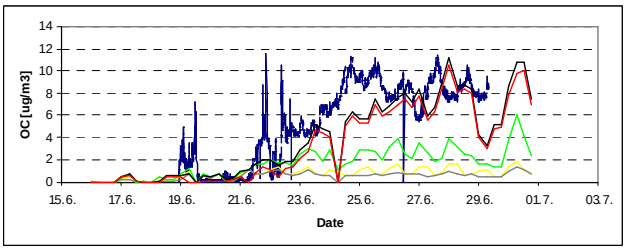

Fig. 1: AMS-measured (dark blue line) and modeled near surface OC mass concentration during June 2010 at Puy-de-Dome, France. Grey line: according to Anntila et al. (2010); yellow line: more VOC precursor gases; green line: SOC gas transport and removal; red line: 1. aging SOC gas; black line: 2. aging SOC gas - see text for more explanation

It should be noted however, that considerable differences in the aerosol size distribution are determined between the model simulations taking into account the first and second step of SOC gas aging. Due to kinetic condensation of the low volatile SOC gas, nucleation mode particles (up to 5 nm) grow into the aitken mode particle range (5 nm – 50 nm) which further grow into accumulation mode particle range (bigger than 50 nm).

This work was supported by the German and French Science Foundations DFG and CNRS within the joint project ATMOCHEM: Secondary organic aerosol production in the lower free troposphere over Western Europe.

Simulation and evaluation of ozone and its precursor gases over Indian region using the high resolution CHIMERE chemical transport model

Chinmay Jena, Sachin D. Ghude, G. Beig and D.M. Chate

This study presents annual simulations of ozone and its precursors made for the first time using CHIMERE regional chemistry transport model over the Indian domain. The model simulations are made using EDGAR emissions (v4.1) on 50 km by 50 km grid resolution for the year 2005. The model simulated ozone and its precursors are evaluated against ground-bashed and space-borne observations. The comparison of model results with seasonal variation of surface ozone observations from eleven sites and diurnal variation of ozone, CO and NO_X observations from two sites are presented. In addition, surface ozone measurements aboard 'Sagar Kanya' over the Bay of Bengal during 2009 are compared with the model simulations. The spatial and temporal variabilities of ozone, CO and NO_X are simulated very well by the model. The model in general compare well with the OMI observations during pre-monsoon and monsoon season, but underestimates tropospheric column NO_2 retrievals during post-monsoon and winter season. Model results indicate regional differences in surface ozone seasonality over Indian region. This study shows that CHIMERE model captures many important features of the observations and lends confidence to the use of model for understanding spatio-temporal variability of ozone over India. However, improvement of India emission inventories is also essential for accurately quantifying ozone production in this region.

Climate change impacts on atmospheric gas and particulate mercury levels and deposition rates

Presenting author email: athmegaritis@chemeng.upatras.gr

Despite its low concentration in the atmosphere, there is an increasing interest on atmospheric mercury (Hg) due to its ability to accumulate in the food chain in the form of methylmercury, a neurotoxin to living organisms and human beings (Satoh, 2000). In addition, atmospheric mercury is a global pollutant subject to long-range transport due to the long atmospheric lifetime of gaseous elemental mercury (0.5–2 years).

Recent studies have addressed the sensitivity of ozone and PM concentrations to climate change (Tagaris *et al*, 2007) pointing out that climate change could have an appreciable effect on future air quality. In this study, for the first time, we applied the global-regional climate-air pollution modeling system (GRE-CAPS) (Dawson *et al*, 2009) over the eastern United States to study the impact of climate change on concentration and deposition of atmospheric mercury in three distinct forms: gaseous elemental mercury (Hg^0), gaseous oxidized mercury (Hg^{2+}) and primary particulate mercury Hg(p).

The GRE-CAPS modeling system includes three models, spanning the global to the regional scale: the GISS II' GCM global CTM with online chemistry (Racherla and Adams, 2006), the MM5 regional meteorological model (Grell *et al*, 1994), and the PMCAMx regional CTM (Karydis *et al*, 2007) which was modified in order to simulate also mercury. A set of ten present-day Januaries and Julys was simulated using GRE-CAPS and the present-day model predictions (2000s) were compared to model predictions for a set of ten future Januaries and Julys. The future climate period studied was 2050s according to the Intergovernmental Panel on Climate Change A2 scenario.

Figure 1 shows the predicted changes in average July Hg^{2+} concentrations due to climate change. In most areas of the model domain, Hg^{2+} is predicted to increase in the future (3% on average), mainly due to increased temperature which favours the oxidation of Hg^0 and the subsequent formation of Hg^{2+}. The predicted increase was found to be highest in the Southeast (up to 25 pg m^{-3} or 35% in Florida). Similar results were predicted during January (5% increase on average) while Hg(p) was found to have a similar response to climate change as Hg^{2+}. On the contrary Hg^0 was not significantly changed, with a small decrease predicted in both periods.

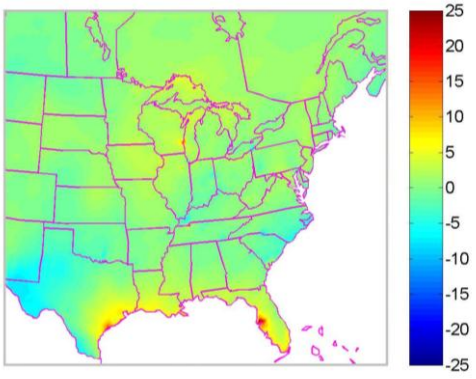

Figure 1. Changes (future-present) in average July Hg^{2+} concentrations (pg m^{-3})

Climate change has also a significant effect on mercury deposition. In both periods the response of mercury deposition to climate change varies spatially with an average increase of 3% during July and 5% during January to be predicted for the entire model domain. The predicted mercury deposition response is mainly explained from the changes in rainfall which largely affects mercury wet deposition.

Air Quality in Paris - A modeling study

A. G. Megaritis[1,2], K. Skyllakou[1,2], C. Fountoukis[2], and S. N. Pandis[1,2,3]

Large urban population centers, also known as Megacities (Gurjar and Lelieveld 2005) are substantial sources of anthropogenic pollutants having adverse effects on human health, visibility and ecosystems (Seinfeld and Pandis 2006). In order to improve air quality in a Megacity like Paris we need to understand what fraction of the pollution comes from local and regional sources and to determine the response of the system to emission controls. Three-dimensional chemical transport models (CTMs) are well suited to help address these source receptor questions since they model all the necessary processes that impact air pollution concentrations and transport in the domain.

In this study we applied PMCAMx-2008 (Fountoukis *et al* 2011) a detailed 3-D chemical transport model (CTM) to simulate the chemical composition and mass of the major PM components during a summer and a winter period. The PMCAMx-2008 model includes state-of-the-art organic and inorganic aerosol modules which make it well suited for the purpose of this study. We focused our analysis on the Paris metropolitan area evaluating the performance of the model against Aerosol Mass Spectrometer ground measurements taken from different sites (LHVP, SIRTA and GOLF) in the Paris greater area. In addition, the contribution of air pollution originating from local and regional sources was examined through sensitivity analysis.

The model performance against the AMS measurements is encouraging especially during summertime. For example, for the suburban site in SIRTA the model reproduces both the observed diurnal variation in PM_1 organic aerosol (OA) and the measured average levels (predicted average 1.9 μg m^{-3} compared to a measured average of 1.85 μg m^{-3}) (Figure 1). The model performance for OA was similar in other sites. In general, OA is predicted to be the dominant species in both periods, accounting for 25% of total PM_1.

In order to examine the contribution of local and regional emissions sources to Paris air quality we performed a sensitivity analysis applying different emissions scenarios (e.g. an "annihilation" scenario zeroing all anthropogenic emissions in Paris). The results showed that local emissions sources accounted for approximately 20% of total PM_1 within Paris during summertime while during winter their contribution on PM_1 levels is higher (more than 30%). The impact of local sources is even higher for BC levels (more than 45% in both periods). At the same time, Paris emissions do not influence only the local air quality, but their impacts extend to the surrounding regions up to an average distance of 200 km.

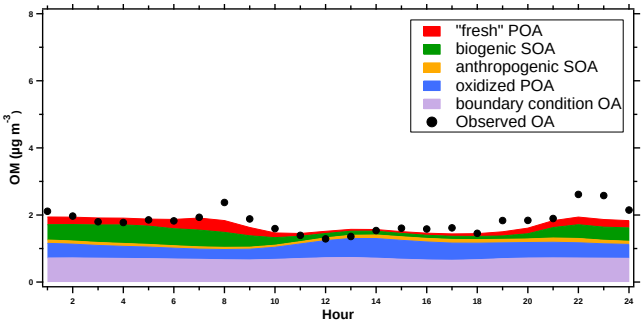

Figure 1. Summertime average diurnal profile of PM_1 organic aerosol and its component (in μg m^{-3}) in SIRTA.

In our study for the simulation of the contribution of different emissions source areas to Paris region we also utilized the Particulate Matter Source Apportionment Technology (PSAT) in PMCAMx-2008 to quantify the contributions from local emissions and short range, mid range and long range pollutant transport to Paris PM concentrations. The results of these simulations will be presented.

Clouds on Venus are formed of sulfuric acid aerosols. The clouds are optically very thick in the visible, inhibiting visual observation of the surface. The clouds are organized in three quite distinct layers with differing properties in terms of particle size distributions and possibly composition. Some early observations hint to the existence of other species in the clouds, but recent missions have not been able to verify their composition. The lowest cloud layers are very dynamic and the reason for the bi- and trimodal size distributions could be partly explained by mixing and distinct altitudes of nucleation. However, the possibility of mixed phase clouds and different chemical compositions of the droplets have not yet been evaluated.

Both the clouds of Venus and aerosols found in the Earth's stratosphere are composed of sulfuric acid droplets. On the Earth, the sulfur in the stratosphere originates from OCS, a long-lived sulfur species emitted at the surface and transported by the general circulation, and from volcanic eruptions that can inject material above the tropopause. It is thought that the water – sulfuric acid droplets form by binary homogeneous nucleation on both planets. However, the existence of condensation nuclei on Venus has not been ruled out.

We use a model developed for the sulfuric acid aerosols and polar stratospheric clouds (PSCs) in the terrestrial stratosphere (Jumelet et al., 2009; Larsen et al., 2000). The model describes several key microphysical processes, including nucleation via a parameterization for two-component nucleation (Vehkamäki et al., 2002) of water and sulfuric acid. This parameterization is in principle quite applicable for the Venusian atmosphere, but we discovered that the lower limit of relative humidity is still too high considering the extremely dry Venusian atmosphere. We are extending the parameterization of (Vehkamäki et al., 2002) to lower relative humidity (see another abstract by Määttänen et al., this conference). In addition to formation of droplets via nucleation, the model includes their subsequent growth by condensation, evaporation of droplets, coagulation, and sedimentation. The model describes explicitly the size distribution with 50 size bins. It can handle several particle modes described with a log-normal size distribution. In the future, we will explore simplifications of the fully size-resolved model in order to develop a moment model for coupling with a global atmospheric model (Lebonnois et al., 2010). We are planning to include the effects of (in)soluble condensation nuclei in the model at a later stage.

First tests of the model are carried out with a standard temperature profile from the Venus International Reference Atmosphere (VIRA, Kliore et al. 1986) and a compilation of water vapor and sulfuric acid concentration profiles, as in McGouldrick et al. (2007). Further sensitivity tests with profiles from the LMD Venus GCM (Lebonnois et al., 2010) are performed. Preliminary results will be evaluated against a range of cloud observations from Venus Express. The infrared channel of SPICAV instrument can scan the highest cloud levels and give profiles and microphysical properties, and for observations of the deeper cloud levels we will use the VIRTIS instrument.

We have developed an aerosol dynamics model for the Venusian clouds by adapting a model of terrestrial stratospheric aerosols and PSCs to the Venusian case. We will present the first results and some improvements included in the model during the development phase. The development is still ongoing, but we aim, after a full phase of testing, at developing a simplified version of the model for implementation into the LMD Venus GCM.

Aircraft pollutant emissions have been of concern since the beginning of commercial aviation. The continuing growth in air traffic and the increasing public awareness have made environmental considerations one of the most critical aspects of commercial aviation (Kurniawan, 2011). This effect of airports close to urban areas is of growing concern and current emission regulations have focused on local air quality in the vicinity of airports (ICAO, 1993; ICAO, 2007a; ICAO, 2007b).

Ca' Foscari University in collaboration with SAVE S.p.A., Are Tre S.p.A. and Ente Zona Industriale (EZI) started in 2009 a research project in order to understand the role of the airports in two particular areas: Venice and Treviso. The two areas represent two important hot spots in the study of air pollution impact: i)the Venice Marco Polo airport, for the presence of the lagoon, a very delicate ecosystem and; ii) the Treviso airport for its closeness to urban sites. The project involved both measurements and modelling studies to characterize principal pollutants dispersion (SO_2, PM_{10}, O_3, NO, NO_X NO_2, CO, methane and non-methane hydrocarbons). A characterization of both Venice and Treviso aircraft emissions were made adopting the EMEP/CORINAIR methodology (EMEP, 2009). A 3D Lagrangian particle dispersion model, SPRAY, (Tinarelli et al., 1994) was applied to assess the impact of aircrafts in both the study sites. Predicted data were correlated to measurements and to the other emission sources of the areas. Results presents a low impact of both the airports respect to the close urban and natural areas.

Nucleation studies with regional aerosol-climate model REMO-HAM

J.-P. Pietikäinen[1], S. Mikkonen[2] and A. Laaksonen[1]
[1]Finnish Meteorological Institute, P.O. Box 503, 00101 Helsinki, Finland
[2]Department of Applied Physics, University of Eastern Finland, P.O. Box 1627, 70211 Kuopio, Finland
Keywords: nucleation, climate models, statistical proxy.
Presenting author email: Joni-Pekka.Pietikainen@fmi.fi

Nucleation of aerosol particles is an important part of the climate system. It occurs around the world and has a potential to influence regional cloud condensation nuclei (CCN) concentrations (e.g. Kulmala *et al* (2004), Laaksonen *et al* (2005)). Different types of mechanisms for nucleation have been proposed in the past few years. It is still unkown which of the different mechanisms is the dominant one, or whether nucleation can be only explained with a combination of different mechanisms. In any case, sulfuric acid (H_2SO_4) is concidered to be the most important species contributing to nucleation. Moreover, many studies have also indicated the importance of organic compounds to nucleation and particle growth.

In this work, we have concentrated on the boundary layer activation nucleation. In this mechanism, the nucleation rate J_{nuc} is taken to be a function of gas phase sulfuric acid concentration $[H_2SO_4]$:

$$J_{\mathrm{nuc}} = A \times [H_2SO_4], \qquad (1)$$

where A is the activation coefficient. We have used this mechanism in a regional aerosol-climate model REMO-HAM (Pietikäinen *et al* (2012)). In REMO-HAM, the H_2SO_4 concentration mainly depends on the availability of sulfur dioxide (SO_2) and dimethyl sulfide (DMS), and the oxidative species OH (daytime chemistry, for SO_2 and DMS) and NO_3 (night-time chemistry, only for DMS) (Stier *et al* (2005)). For H_2SO_4 concentrations, SO_2 oxidation by OH during daytime is the most important process. The normal approach for determining the concentrations of the oxidative species in the model is to use monthly mean fields derived from the chemical transport model MOZART. In addition an artifical cosine based diurnal cycle has been applied for OH. This improves the treatment of OH inside the model, but does not link its concentrations directly to radiation (OH is known to be formed by photochemistry in the atmosphere). Therefore, reduction of radiation intensity below clouds does not affect the OH concentrations.

In order to improve the calculation of H_2SO_4 concentrations in REMO-HAM, we have implemented a statistics-based proxy for the OH concentrations. The proxy is a non-linear function of solar radiation intensity and is based on OH measurement data from Europe. In this way, the 3-D OH oxidation fields become radiation dependent, and are thus affected by the cloudiness inside the model. The improved representation of OH leads to more realistic H_2SO_4 concentrations. This is important, because in our previous studies we have shown that the model has too much sulfuric acid in the gas phase (Pietikäinen *et al* (2012)).

We have done series of detailed simulations for Europe with 50×50 km^2 horizontal resolution. The simulations included the the new OH proxy approach. In addition, we have tested a range of values for the activation nucleation coefficient. Fig. 1 shows the sulfuric acid concentrations from Hyytiälä and San Pietro Capofiume for both model versions. Measured daily maximum values at Hyytiälä are about $[2]\times10^7$ molec/cm^3 (data for the years 2003 and 2007), and about $[5]\times10^7$ molec/cm^3 at San Pietro Capofiume(data for the year 2009) (Mikkonen *et al* (2011)). As we can see from the Fig. 1, the new model version gives much more realistic results than the old one.

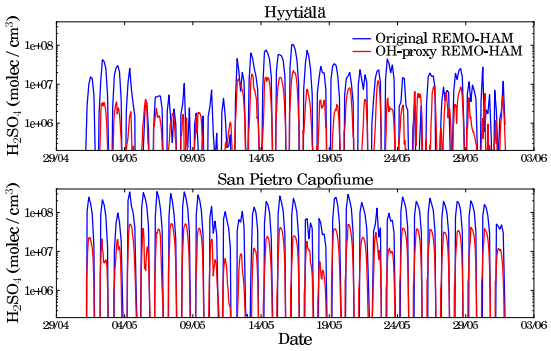

Figure 1: Original and OH-proxy REMO-HAM sulfuric acid conconcentrations from Hyytiälä and San Pietro Capofiume for May 2005.

If we consider $J_{\mathrm{nuc}} = 1.0$ cm^{-3} s^{-1} as a limit for nucleation event, we get slight overestimation for the number of event days. This naturally depends on the activation coefficient A. With $A = 4\times10^{-7}$ s^{-1}, we get for May 2005 at Hyytiälä 18 nucleation days (observations: 12), and at San Pietro Capifueme 28 days (observations: 22).

Research Needs Identified In a First-Generation Regional Air Quality Model for Polycyclic Aromatic Hydrocarbons

E. Galarneau[1], P.A. Makar [1], Q. Zheng[1], J. Zhang[1], and M.D. Moran[1]

[1]Air Quality Research Division, Environment Canada, Toronto, Ontario, M3H 5T4, Canada
Keywords: air quality model, chemical transport model, polycyclic aromatic hydrocarbons, PAHs
Presenting author email: elisabeth.galarneau@ec.gc.ca

AURAMS is a regional air quality model developed by Environment Canada to examine issues relating to ground-level ozone, size-resolved particulate matter, and acid deposition. The model has now been extended to simulate the atmospheric fate of polycyclic aromatic hydrocarbons (PAHs). Seven PAH species that span a range of volatilities and reactivities were selected for the first formal AURAMS-PAH simulation in order to examine interspecies differences in model performance.

The model was run for a full-year period (2002) using two alternate particle/gas partitioning schemes: Junge-Pankow adsorptive partitioning and Dachs-Eisenreich dual sorption partitioning. Model outputs were compared to ~5,000 PAH measurements from ~50 sites in southern Canada and the continental USA. Model performance was assessed for simulation accuracy of total (gas plus particle) PAH concentration, particle/gas partitioning, and particle size distribution. As a result of this first assessment, a list of research needs has been developed and is described below.

The first group of research needs relates to the PAH emissions that are used as model inputs (Galarneau et al., 2007). Model performance in predicting PAH concentrations was found to vary systematically by month of year (see Figure 1) and by day of week. This implies that the factors used to disaggregate annual emissions require adjustment. Extreme underestimation of anthracene concentrations near a large industrial facility in Canada led to the discovery that this commonly-reported species was excluded from mandatory reporting through the National Pollutant Release Inventory of facility emissions data in Canada. PAH particle sizes calculated with Dachs-Eisenreich partitioning were erroneously bimodal because of errors in a default emitted elemental carbon size distribution which have since been corrected.

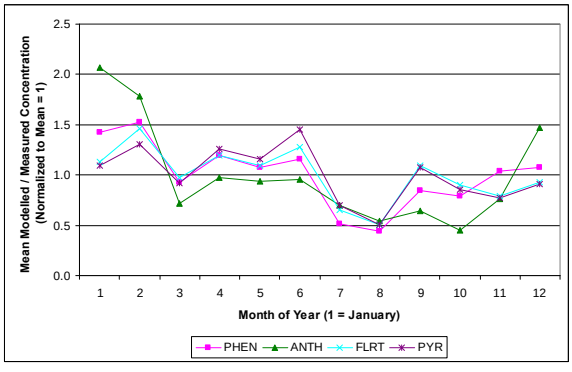

Figure 1: Concentration Simulation Variation by Month of Year for Four PAHs

The second group of research needs relates to physicochemical process representations in the model. The addition of PAH species to AURAMS required modifications to many existing model routines that handle reactivity, aqueous-phase chemistry, and deposition. Furthermore, a novel routine was added to calculate particle/gas partitioning according to the two aforementioned parametrisations thought to be relevant to PAHs. For the modified model to simulate PAH fate with reasonable accuracy, not only must the relevant processes be included but their associated physicochemical parameters must be also be correct.

Reactive particulate compounds such as benzo[a]pyrene (BaP) tended to be overestimated in the simulations; this may be due to the absence of particle-phase degradation in the model. However, no relationship was found between the degree of BaP overestimation and ozone concentration. Particle/gas partitioning was greatly biased toward the gas phase for volatile species but performance improved with decreasing volatility (increasing molecular weight). This behaviour was seen for both partitioning expressions and suggests that the physicochemical properties used in those expressions need adjustment. The simulated size distributions of all PAHs were identical because quantitative expressions to describe the inter-species differences observed in numerous field studies have not yet been developed and incorporated in the model.

The third and final group of research needs relates to shortcomings in the base AURAMS model that are not related to PAHs. For example, the total PM mass simulated by the model tends toward underestimation. As a result, the available pool of particle surface or mass available for partitioning of PAHs is not accurately represented. Improvements to PM accuracy in the model are expected to lead to improvements in the simulation of partitioning and particle size distribution of PAHs.

Observed inaccuracies in model simulations may be due to a combination of causes. For example, BaP overestimation may have contributions from both overestimated emissions and unrepresented reactions. Further analysis of these factors, including sensitivity of model results to their adjustment, will be conducted in order to prioritize research needs for the development to the second-generation version of AURAMS-PAH.

Modelling dust aerosol impacts on heating rate profiles over the Iberian Peninsula and Atlantic Ocean

D.Santos[1], M. J. Costa[1,2], R. Salgado[1,2] and A. M. Silva[1,2]

[1]Évora Geophysics Centre, University of Evora, R. Romão Ramalho, 59, 7000 Évora. Portugal
[2]Department of Physics, University of Evora, R. Romão Ramalho, 59, 7000 Évora. Portugal.
Keywords: Atmospheric Aerosol Modelling, Desert Dust radiative effects, Radiation
Presenting author email: dinas@uevora.pt

It is well known that the Sahara desert acts as the strongest source of mineral dust aerosol in the world.

Several studies have been dealing with estimation of direct effects associated with major aerosol types, especially mineral dust, and related changes of the radiative budget at the surface, top of atmosphere (TOA) and within the aerosol layer.

The effect of dust particles is very complex because of their capacity to interact both in the shortwave and longwave spectral ranges.

Over a given region, the desert dust radiative effects, occurring at different atmospheric levels (surface, TOA and within the aerosol layer), all contribute to a climatic response. Thus it is very important to understand how these effects can alter the earth energy budget at regional and/or global scales.

The Iberian Peninsula and surrounding Atlantic Ocean are affected by considerable mineral dust loadings able to significantly modify the regional radiative budget (Santos *et al* 2011).

The present study investigates the mineral dust potential impact in terms of heating rate profiles.

This work has been carried out by using the MesoNH meso-scale forecasting model (Lafore *et al* 1998) fully coupled with a dust production and transport model (Grini *et al* 2006), a radiation scheme and an explicit land surface model. The MesoNH model has then the ability of investigate how the aerosols have a direct radiative forcing upon the surface-atmosphere system.

Initialization and lateral boundary conditions of the domain used (10×10 km resolution) were taken from the ECMWF analysis. A case study for intense dust events occurring during May 2006, September 2007 and April 2011 is analysed.

Figure 1 present the simulated atmospheric heating rate at TOA level for 27 May 2006 (1200UTC).

From this Figure it is possible to observe the atmospheric heating rate changes due to the presence of desert dust in the atmosphere. An increase of the atmospheric heating rate is observed when the mineral dust layer is present in the atmosphere (probably due to the absorption of the incoming radiation).

For the other days under analysis the same situation occurs, being the warming more pronounced within the mineral dust layer.

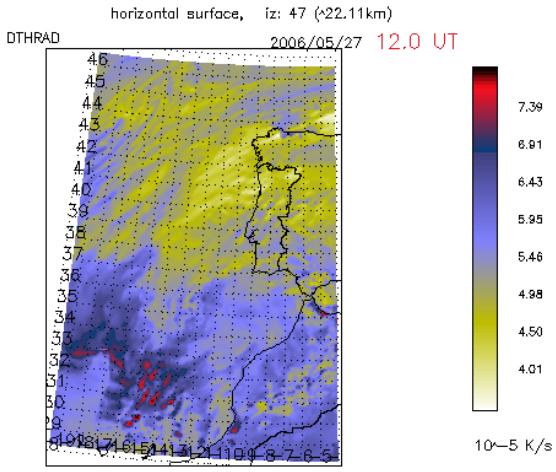

Figure 1. Simulated atmospheric heating rate for 27 May 2006 (1200UTC) at TOA level.

Modelling $PM_{2.5}$ chemical composition with CAMx in southwest Spain

C. Milford[1,2], N. Castell[3], C. Marrero[2], A. Sánchez de la Campa[1], R. Fernández-Camacho[1], S. Rodríguez[2,1], J. D. de la Rosa[1] and A. F. Stein[4]

Keywords: aerosol modelling, $PM_{2.5}$, chemical composition.
Presenting author email: cmilford@aemet.es

Background $PM_{2.5}$ concentrations (rural) are rather high in the southwest region of Spain (Andalusia). The region has high anthropogenic emissions including substantial industrial emissions (e.g. power plants, petrochemical refineries, fertiliser industry), on-road traffic, shipping traffic passing through the Gibraltar strait, agricultural emissions and also biogenic emissions. It also experiences a high frequency of African dust intrusions and its low rainfall, dry soils and high photochemical activity plus the availability of aerosol precursors all contribute to the enhanced concentration of atmospheric aerosols.

As a result of these factors the AER-REG project was initiated to study the formation and transport of atmospheric aerosol in western Andalusia. It involved intensive measurement campaigns at two rural sites and one urban site in 2008 and 2009. Chemically speciated $PM_{2.5}$ measurements of all major aerosol components (sulphate, nitrate, ammonium, total carbon, black carbon, sea-salt, dust) plus trace elements were made during daytime and nighttime with high volume samplers (30 m^3 h^{-1}) using quartz micro-fibre filters. In addition highly time resolved (15 minute mean) measurements of Black Carbon (BC) were made at one of the rural sites and the urban site using a Multi-Angle Absorption Photometer, see Fernández-Camacho *et al* (2010) for more details. Gaseous measurements of O_3, SO_2, NO and NO_2 were also conducted.

In parallel to the chemically speciated measurements the three-dimensional eulerian photochemical model CAMx v4.51 (Environ) was implemented to investigate the complex dynamics of aerosol formation and transport in this region and their spatial and temporal resolution. CAMx was run with three nested domains with 18 km, 6 km and 2 km resolution. The outer domain covers the Iberian Peninsula while the inner domain covers the southwest region of Spain (western Andalusia). The non-hydrostatic mesoscale meteorological model (MM5) v3.7 was used to drive the photochemical model.

Emissions in the inner domain are based on Castell *et al* (2010) and include industrial point and area sources; on-road and shipping traffic; NH_3 emissions from fertiliser application to agricultural land and biogenic sources of non-methane volatile organic compounds (NMVOC). Emissions in the outer domains are from EMEP plus biogenic NMVOC emissions.

The combination of the high quality chemically speciated measurement dataset and the modelling system is now being utilised to explore the seasonal differences in both primary and secondary chemically speciated aerosol. The model performs well for ammonium in both summer and winter periods (although tending to underestimate the magnitude of concentrations) while for sulphate the performance is better during the summer period. The highly resolved measurements of $PM_{2.5}$ BC and CAMx simulated $PM_{2.5}$ primary elemental carbon (PEC) at the urban site in Huelva in winter and summer (Fig. 1) show that the model captures the diurnal and seasonal variability of this primary aerosol. Peak concentrations are observed during a winter anticyclonic episode in the first half of the March campaign and these are well captured by the modelling system (Fig. 1a), although the model underestimates concentrations in the latter half of the campaign. During the summer campaign, concentrations are generally much lower reflecting enhanced dispersive conditions (Fig 1b).

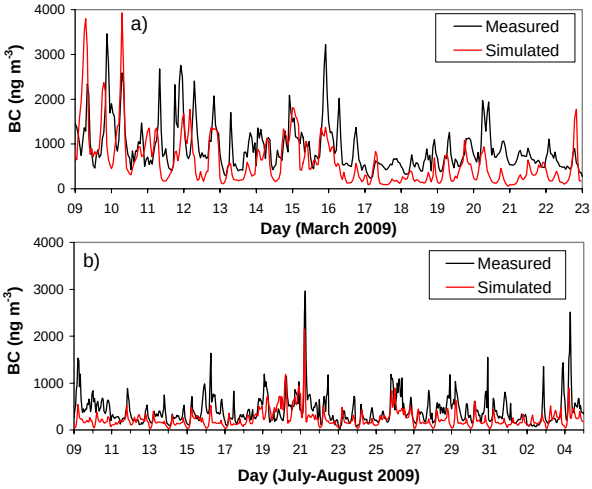

Figure 1. Measured BC ($PM_{2.5}$) and simulated $PM_{2.5}$ PEC concentrations at University Campus, Huelva.

Keywords: Modelling (regional), Asian dust, air pollution, megacity
Presenting author email: stefanie.schrader@kit.edu

Sand- and dust storms frequently occur in spring in Northern China causing very high geogenic particle mass concentrations in the atmosphere (Wu *et al.*, 2009). Dust particles can be transported over long distances towards the highly urbanized areas of Eastern China. These geogenic particles influence the state of the atmosphere and provide effective surfaces for heterogeneous chemical reactions (Huang *et al.*, 2010). In megacities like Beijing, the combined anthropogenic and geogenic aerosol loadings can lead to severe reduction of air quality and harm the human health (Chen *et al.*, 2011). Still, a lack of information exists about the impact of these geogenic particles on the urban atmosphere and aerosol pollution.

To investigate the contribution of geogenic particles on the urban particle loading in Beijing and their impact on the state of the atmosphere the comprehensive online coupled model system COSMO-ART (Vogel *et al.*, 2009) has been set up for Northern China. COSMO-ART consists of the meteorological weather forecast model COSMO of the German Weather Service (DWD) and ART for the treatment of aerosols and reactive trace gases. The model domain covers whole Northern China which allows the investigation of the influence of mineral dust from all Chinese desert areas to the particle loading in Beijing. COSMO-ART is applied for the spring season 2011 with a 28x28 km² horizontal resolution.

Model results are compared to $PM_{2.5}$ data measured by KIT. Daily measurements were conducted with two high volume samplers at one station in Beijing since June 2011. Meteorological data for model and measurement comparison is taken from the Beijing WMO official meteorological station.

COSMO-ART is applied for the Asian dust storm event that hit Beijing at April 30th in 2011 lasting for about 1 day. The Beijing meteorological station reported blowing sand conditions and wind speeds up to 20 m/s from north-western directions. There is also a rapid drop of relative humidity from 90 to 10% with arrival of the dust storm air masses. Observed $PM_{2.5}$ concentrations showed a sudden peak up to 100µg/m³. The simulated mass concentrations are reproducing the timing of this peak quite well. This confirms that the high particle concentrations observed in Beijing during this episode are of geogenic origin. In a next step we will also include in addition to the natural ones the anthropogenic emissions to quantify the contributions of each source category to PM_{10} in Beijing.

The horizontal distribution of simulated mass concentrations of mineral dust particles for April 30th 03h UTC is shown in figure 1. It can be seen that near surface wind is coming from north-western directions indicating that Gobi desert in Western Inner Mongolia is the main source of the geogenic particles transported to Greater Beijing. The fast decrease of relative humidity down to 10% is also supporting the assumption of the arrival of dry air masses from these desert areas.

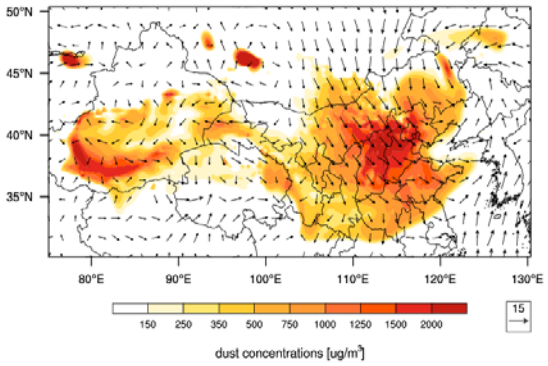

Figure 1. Simulated dust particle mass concentrations for April 30th 2011, 03h UTC and near surface wind conditions

In atmospheric modelling there are several applications where an aerosol microphysics module is coupled with a general circulation model. Many of these modules use a modal representation for aerosol distribution. For example, four modes can be used to cover the aerosol size range from nucleation to coarse mode. In 3D-transport model applications modes are often restricted to certain particle size ranges. If the larger edge of the mode grows over its set size limit, particles are moved, reallocated to the next mode (Binkowski and Roselle 2003).

When used in large scale models, modal modules reallocate the distribution to account for the changes in mode radius from microphysical processes and air mass mixing over a simulation step. The distributions before and after reallocation routine should describe the same physical situation (Figure 1). Nevertheless, in case of a rapid growth of one or several modes these two distributions can differ greatly. When the difference is in Aitken, accumulation and coarse mode size range, it affects the number of activated particles during cloud droplet formation when calculated from these modal representations. If the distributions before and after reallocation differ in accumulation and coarse mode size range, also the total extinction coefficient of aerosol particles can be clearly affected by the difference.

In this study we explore how the reallocation affects climate relevant model parameters such as cloud droplet number concentration (CDNC) and extinction coefficient. First, a base distribution is defined so that none of the modes exceed their size limit and there is no need for reallocation. Then the average radius and/or number concentration of a single mode is increased in small increments, creating a large set of distributions. When the mode grows enough, some of the particles will be reallocated to the next mode. Then the number of cloud droplets and the extinction coefficient are calculated before and after the reallocation routine. The number of cloud droplets is calculated by using a parametrization by Abdul-Razzak et al (2000) and the extinction coefficient by using libRadtran library.

From the CDNC and extinction coefficient we calculated the relative difference between the before and after reallocation cases. In our simulations we found out that the relative difference in CDNC and extinction coefficient can be from few to tens of percents.

Figures 1 and 2 are the results from a simulation where the accumulation mode properties were varied (average radius from 150 to 210 nm and number concentration from 10 to 1000 1/cm^3). Figure 1 shows the most "extreme" case where the overgrowth of the right most mode (accumulation mode) is the largest in the simulation, corresponding to the rightmost edge of Figure 2. In Figure 1, the number concentration of accumulation mode is 500 1/cm^3 before the reallocation. In Figure 2 the axes show the values of the diameter and number concentration of an accumulation mode through the simulation, and the colour describes the relative difference of the extinction coefficient. From Figure 2 we can see how strongly the difference between distributions affects the extinction coefficient.

An artificial data set was used in this simulation. The next step is to see if similar results can be obtained from the development of the real atmospheric aerosol distributions, for example in the case of a realistic nucleation event followed by growth of the aerosol particles.

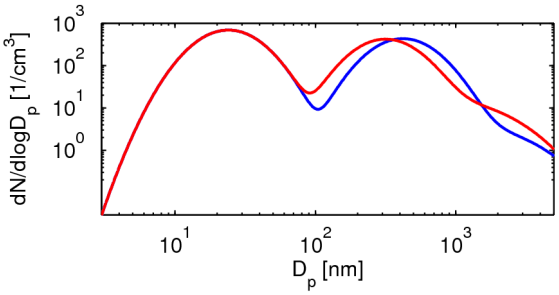

Figure 1. Distributions before (blue) and after (red) reallocation routine.

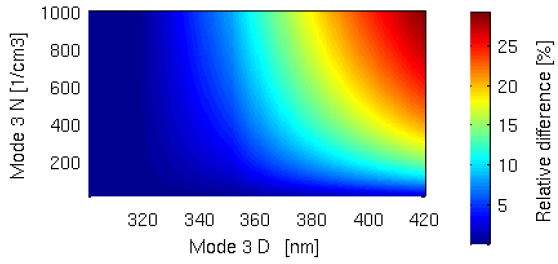

Figure 2. The relative difference of the extinction coefficient calculated before and after reallocation.

Summer 2007 was exceptionally hot for many parts of the southeastern Europe, the Balkans and particularly Greece. Comparisons with regional model projections showed that this summer can serve as a strong indicator of what eastern Mediterranean summers could resemble in future (Founda and Giannakopoulos, 2009). Since atmospheric chemistry is strongly dependent on temperature conditions, this episode has been selected for an air quality assessment over Greece, both by means of observations and regional modelling.

Observations utilised here include: PM_{10} measurements from the municipality networks of Athens and Thessaloniki, obtained and retrieved within the FP7 CITYZEN project. Aerosol optical depth (AOD at 550nm) measurements over Athens have been acquired using a Multi-Filter Rotating Shadowband Radiometer (Gerasopoulos et al., 2011). Finally, satellite derived AOD was obtained from the MODIS sensor onboard the Terra platform **(**Kaufman et al., 1998**).**

The numerical tool used is COSMO-ART (Vogel et al., 2009), which is established and applied for the first time in Greece. COSMO-ART is a regional chemistry transport model (ART stands for Aerosols and Reactive Trace gases) online-coupled to the COSMO weather prediction model (Baldauf et al. 2011). Simulations are performed between August 15 and September 15 with a horizontal resolution of 2.8 km and a vertical extend up to 20 km. The initial and boundary meteorological data are retrieved from a coarser COSMO simulation performed by the German Weather Service. The anthropogenic emission database used is the TNO/MACC (Kuenen et al. 2011), while biogenic and sea-salt emissions are calculated online.

A preliminary comparison between observations and measurements showed that PM_{10} predictions were significantly lower than observations. This was partly attributed to the unrealistically high $PM_{2.5}/PM_{10}$ values (higher than 90% for all sites), compared to the ratio measured during August (51%). This fraction was applied to predictions and the new results are presented in Table 1. Model performance has been improved approximately around 30% and is found optimal according to the metrics proposed by Boylan and Russell (2006) (MFB $\leq \pm$ 30%). Nevertheless, PM_{10} values are still underestimated. AOD is also investigated and found in a good correlation, especially concerning its spatial distribution and maximum values (Figure 1).

Current results are used for the optimization of COSMO-ART applications over Greece. In specific, local dust emissions will be incorporated. Then, the inorganic chemistry module will be modified so that sea-salt and dust particles are chemically active. Results will be presented during the conference.

Table 1. Comparison of daily average PM_{10} ($\mu g/m^3$) and AOD values between COSMO-ART predictions and measurements over Greece (17-24/08/2007).

Area/quantity	Measured	Predicted	MFB[1] (%)
Athens (7sites)/PM_{10}	41±14	22±12	-16
Thesaloniki (5 sites)/PM_{10}	53±16	34±14	-12
Athens (1 site)/AOD	0.21±0.11	0.13±0.04	-

[1]Mean fractional bias: normalize the bias by the average of the prediction and observation.

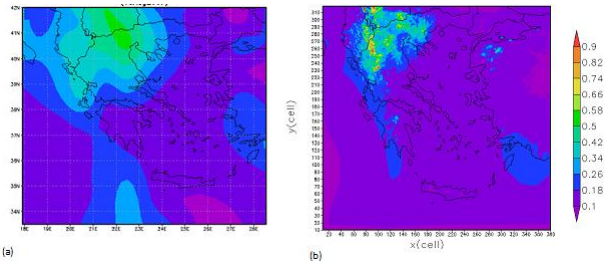

Figure 1. AOD (550nm) as measured by MODIS (a) and estimated by COSMO-ART (b) on 18/08/2007.

Application of a SOA parameterization for α-pinene and limonene photooxidation to different conditions

Manuel Santiago[1], Marta G. Vivanco[1] and Ariel F. Stein[2]

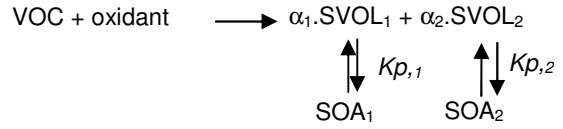
[1] *Atmospheric Pollution Divison. CIEMAT (Research Center for Energy, Environment and Technology). 28040 Madrid. SPAIN*

[2] *ERT on assignment of NOAA's Air Resources Laboratory, Silver Spring MD*

Presenting author email: manuel.santiago@ciemat.es

Secondary organic aerosol (SOA) is an atmospheric pollutant that has received increasing attention during the last decade. Because of its inclusion in environmental directives, 3-D air quality models are evolving to include SOA formation pathways in their code. However, due to the computational efforts needed by the models to perform mesoscale simulations, SOA treatment is still simple, being so a source of considerable uncertainty in air quality model predictions.

The two product model, first presented by Odum et al. (1996), represents an easy to implement parameterization used in several models. In the two product model, the oxidation of a certain volatile organic compound (VOC) drives to the formation of two semivolatile compounds ($SVOL_i$), that later partition to the particle phase to form individual SOA species (SOA_i). The formation and partition of the semivolatile compounds is governed by an stoichiometric coefficient (α_i) and a partitioning constant (Kp_i) respectively:



While this approach has the advantage of its straight-forward implementation in the model, it also represents a "black-box" conception of the overall process, as the parameters α_i and Kp_i are generally obtained empirically based on smog chamber experiments where the SOA formation potential of VOCs under certain experimental contitions are studied. Because of this, the application of a certain set α_i and Kp_i parameters to conditions different from which they were obtained may be difficult.

In this work, we present a evaluation of a two product model set of parameters obtained for the photooxidation of a 50:50 α-pinene:limonene mixture in a set of experiments performed in the EUPHORE smog chamber (EUropean PHOto-REactor, CEAM, Valencia) by the authors in a previous study (Santiago et al., 2011).

First, the parameterization is evaluated against some experiments performed by Li et al. (2007) for a similar α-pinene:limonene mixture in a different chamber (Figure 1). Based on the good simulation of the SOA growth curve obtained in an adapted version of CMAQv4.7 where the EUPHORE parameters were implemented, we have calculated the individual parameters for each of the components of the mixture and tested their ability to simulate the SOA yields (Y) obtained by other authors in different photooxidation experiments.

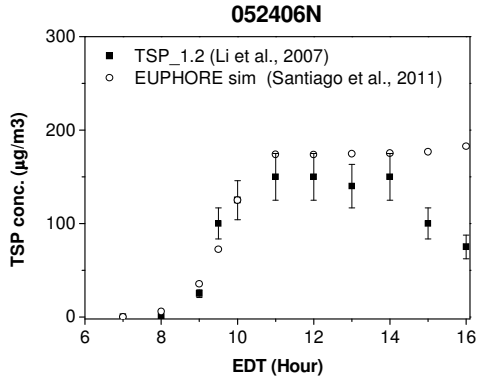


Figure 1. Simulation of the experiment 052406N by Li et al. (2007) using the EUPHORE parameters in an adapted version of CMAQv4.7

The results of this evaluation show that, while the parameters obtained in the EUPHORE chamber experiments generally represent a reasonable approximation of the experimental data from different studies, two product model parameters may present limitations when there is a change in experimental conditions such as the NOx level or the OH initiator.

This study has been financed by the Spanish Science and Innovation Ministry (CGL2008 02260/CLI) and the Spanish Ministry of Environment. We gratefully acknowledge all the EUPHORE team members.

PM modelling: old challenges and new possibilities

S. Tsyro[1], D. Simpson[1,2], H. Fagerli[1], W. Aas[3] and M. Schulz[1]

[1]Research and Development Department, Norwegian Meteorological Institute, Blindern, 0313, Oslo, Norway
[2]Chalmers University of Technology, Gothenburg, Sweden
[3]Norwegian Institute for Air Research, P.O. Box 100, N-2027, Kjeller, Norway
Keywords: regional modelling, PM10/PM2.5, aerosol chemical composition, AOD
Presenting author email: svetlana.tsyro@met.no

Model assessment of air pollution with Particulate Matter (PM) in Europe has started over a decade ago. Ever since, a sound model reproduction of PM_{10} and $PM_{2.5}$ fields and the temporal variation of concentrations has remained a challenging task.

Clearly, accurate PM calculations are essential for reliable assessment of the compliance with regulatory target values. Still, most of regional models tend to under-predict observed PM due to the underestimation of one or several PM components, or due to incomplete PM mass closure. Not less important is the model's ability of correct representation of PM chemical composition, which is necessary for trustworthy calculations of PM source allocation and the impact of emission reductions. Due to scarce observations, modelled PM chemical composition facilitates health effect studies of different PM components. Furthermore, in order to estimate the effects of climate change on PM levels, the models should be capable of reproducing meteorological dependencies of formation and depletion rates of different PM components.

The lack of appropriate observational data was for many years a serious obstacle to the improvement of models' results with respect to PM. However in the recent years, more measurements of PM_{10} and $PM_{2.5}$ mass closure and simultaneous measurements of several PM components have become available for models evaluation. In addition to surface in-situ measurements, aerosol observations from remote measurement systems have been more and more widely used for comparison with models, allowing model testing in the areas not covered with monitoring stations. Great possibilities for evaluating transport processes have been provided by LIDAR measurements of aerosol vertical profiles.

The EMEP model (Simpson et al., 2012) has recently undergone a substantial refinement aimed at improving the accuracy of PM_{10} and $PM_{2.5}$ calculations. Comparing model results with EMEP intensive measurements of PM mass closure in June 2006 and January 2007 (Aas, Tsyro et al., 2012) we have identified the most problematic PM components. Making extensive use of the size-segregated PM chemical composition data, as well as hourly measurements of Secondary Inorganic Aerosols (SIA) and gas-aerosol partitioning (Nemitz at el., 2012), the importance of different parameters and processes has been investigated and will be presented. Among the most important are the effect of cloud water acidity on sulphate production and gas-aerosol equilibrium calculation of ammonium nitrate and formation of coarse nitrate on sea salt and dust particles. The focus has been on completing the mass closure in modelled PM, which now includes SIA, EC, primary and secondary OC, sea salt, mineral dust and particle water (Fig. 1). The main features of geographical and seasonal variations of PM chemical composition and the ability of the model to reproduce those is discussed. We will also summarise the recent findings with respect to the effects of meteorological input and model resolution of PM results.

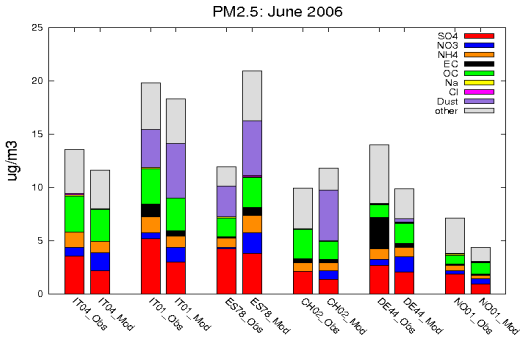

Figure 1. Measured and modelled chemical composition of $PM_{2.5}$. June 2006.

The performance improvement of the EMEP model for PM_{10} and $PM_{2.5}$ will be shown through comparison with EMEP and Airbase observations. Aerosol Optical Depth (AOD) data from satellites and AERONET sun-photometers within AEROCOM system (http://aerocom.met.no/) allows further model evaluation for extended areas (also on a global scale). Finally, first evaluation results will be presented of modelled aerosol vertical profiles, comparing 3D extinction coefficients from the EMEP model and the CALIOP LIDAR on board the CALIPSO satellite.

Modelling the microphysics of Martian CO_2 ice clouds

C. Listowski[1], A. Määttänen[2], F. Montmessin[2], F. Lefèvre[1]

[1]LATMOS, UPMC, Paris, France
[2]LATMOS, UVSQ, Guyancourt, France
Keywords: modelling, condensation, cloud microphysics, ice clouds, planetology
Presenting author email: constantino.listowski@latmos.ipsl.fr

The first unambiguous spectroscopic observation of CO2 ice clouds on Mars came from Montmessin *et al.* (2007), but observations have been reported for a decade now (Clancy *et al.* 2003). The CO2 ice clouds are a rare phenomenon in the Solar System, since 95% of the martian atmosphere consist of CO2 gas, and thus on Mars we are dealing with the condensation of the main component of the atmosphere. The condensation is moreover occuring in a rarefied atmosphere (large Knudsen numbers) that can have dramatic consequences on the crystal growth through the limiting effect of the heat transfer.

CO2 ice cloud modeling has turned out to be challenging : recent efforts (e.g. Colaprete *et al.* 2008) fail in explaining typical small sizes (80 nm-130 nm) observed in equatorial mesospheric ice clouds (Montmessin *et al.* 2006). Recent modelling studies suggest that the effect of the thermal tide in cooling the mesosphere is a prerequisite for the cloud formation (Gonzalez-Galindo *et al.* 2011), but other perturbations are required to attain the CO2 condensation temperatures. A recent study has shown a strong correlation between mesospheric ice cloud observations and the filtering of gravity waves through the atmosphere (Spiga *et al.* 2012). Those waves could create cold pockets in wich $T \leq T_{cond}$, and thus provoke a supersaturated environment in which the clouds can form. However, the nature of the key microphysical processes in the formation of CO2 ice clouds remains unclear, especially in the mesosphere.

We have adapted a microphysical model previously developed for water ice clouds formation on Mars (Montmessin *et al.* 2004) for modeling these CO2 ice clouds. The gas mixture considered here is CO2/N2, N2 being the second most abundant gas in the atmosphere. A hybrid radius grid is used and prevents numerical diffusion during crystal growth. We adopt classical nucleation theory assuming that nucleation is only heterogeneous, as it most probably is on Mars (Määttänen *et al.* 2005). The condensation and the sedimentation both use an implicit scheme for computing derivatives, which guarantees numerical stability whatever the chosen time step. To account for the free molecular regime a Fuchs and Sutugin (1971) correction is applied to the the heat conductivity of the mixture $K_{th,CO2+N2}$, and to the binary diffusion coefficient $D_{CO2/N2}$. Another approach would consist in using equations valid in both continuum and kinetic regimes as Wood (1999) did. It is however still not clear if one approach is better than the other one (see Colaprete *et al.* 2003) and we first aim at fully investigating the first option.

The model is used in a 1D mode with atmospheric pressure and temperature profiles taken from the European Mars Climate Database v.4.3 (Millour et al. 2008) that do not present any excursion below T_{cond} We simulate the presence of cold pockets, formed by gravity waves, by imposing a gaussian disturbance at the altitude where we wish to form a cloud (see Figure 1). We follow the evolution of the cloud during one or several daily cycles. We investigate the influence of different parameters and processes (see below) on the formation of the cloud, its evolution, and its microphysical parameters

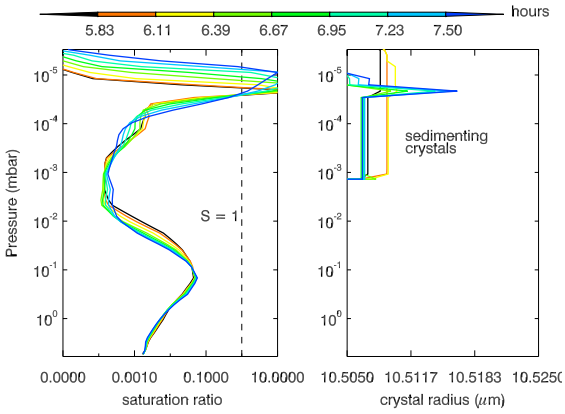

Figure 1. An ice cloud forming at an altitude >80km, in a cold pocket onto 10nm radius dust particles.

A companion abstract by Listowski et al. explains aspects of continuum equations that need to be considered when the major component of the atmosphere condenses (namely the Stefan flow, the thermal diffusion term and the Dufour effect). These processes could be part of the explanation for the small observed radii.

Presenting author email: zagaynov@cc.nifhi.ac.ru

Atmospheric aerosols significantly contribute towards physical and chemical properties of the ambient air. In fact atmospheric aerosol is a conclusive phase of atmospheric pollution, and the particle size distribution is a key problem of transport and kinetics of disperse media. Monitoring of atmospheric aerosols is related to (1) measurements of the particle size distribution and concentrations at various locations, and (2) analysis of data bases and modeling of the particle behavior. A very important part of analysis of substantially sized data arrays is selection of the procedure for rearrangement of the information in a way, convenient for following mathematical modeling. We propose a procedure based on employment of flicker noise spectroscopy (*Timashev et al, 2008*) enabling to convert the data base into an order very convenient for integration. This method uses autocorrelations $\sigma_i(\tau)$ and correlations $q_{ij}(\tau,\theta)$ between different parameters (particle size, concentration and so on) leading to the following mathematical expression:

$$\sigma_i(\tau) = (< (V_i(t) - V_i(t+\tau))^2 >)^{\frac{1}{2}} \qquad (1)$$

$$q_{ij}(\tau;\vartheta) = < \frac{(V_i(t) - V(t+\tau))(V_j(t+\vartheta_{ij}) - V(t+\vartheta_{ij}+\tau))}{\sqrt{2}\sigma_i \sqrt{2}\sigma_j} >$$

where τ – is time delay for autocorrelation, ϑ - time delay for correlation between two measured values, $V_i(t)$ – time dependant monitoring values.

The suggested approach allows refining important aerosol parameters from raw data sets, i.e. the information on particle growth rate or evaporation, particle generation and so on.

Then, the next step of mathematical modeling could be logically made. It is required for evaluation of time related evolution of dispersed phase and validation of the results against measured data. The modeling procedure could be based on the equation of aerosol kinetics written in the form:

$$\frac{\partial c_g}{\partial t} = I(g) + \frac{1}{2}\int_0^g K(g-n,n) c_{g-n} c_n dn + c_g \int_0^G K(g,n) c_n dn \qquad (2)$$

where c_g time dependant concentration of particles containing g monomers, $I(g)$ - source of particles, $K(g,n)$ – collision frequency between aerosol particle of various sizes with g and n monomers. This equation could be solved and the results obtained for a range of particle sizes. The procedure allows covering particle size range from 1 nm up to 10 micrometer by a number of specially selected size fractions. Direct integrations of equation (2) enables to get a set of N differential equations, which describes the particle evolution over time periods. To validate this approach and ensure that it is feasible to achieve accurate results, the equation (2) could be solved for the cases when K(g,n)=1, and K(g,n)=g+n. For this regime of particle collisions, the equation could be solved analytically and provide accurate solutions, which could be compared against the experimental data acquired for real collision regimes and different generation scenarios presented by the term I(g).

The results obtained by this procedure will be presented at the conference.

Evaluation of the hydrophobic SOA species estimated by the CHIMERE model considering experiments in a chamber

Marta G. Vivanco[1] and Manuel Santiago[1]

[1] *Atmospheric Pollution Divison. CIEMAT (Research Center for Energy, Environment and Technology). 28040 Madrid. SPAIN*

Keywords: secondary organic aerosols, modelling

Presenting author email: m.garcia@ciemat.es

Simulating secondary organic aerosol (SOA) formation presents a great number of uncertainties. Representative groups of aerosol species of the main oxidation products can be defined in different ways. For example, approaches based on two oxidation products (*Odum et al.*, 1996) are extensively used to determine the amount of aerosol formed from the oxidation of a specific volatile organic compound (VOC). Other approaches are based on the hydrophobic or hydrophilic characteristics of the aerosol species. In all of these approaches, mass stochiometric coefficients, vaporization enthalpies (Hv) and vapor pressures (Pv) for the aerosol species must be defined in order to estimate SOA concentration. In this paper we present an evaluation of the CHIMERE model performance when simulating some experiments in an outdoor chamber. These experiments were designed to study the oxidation of four VOCs assossiated to anthropogenic emissions: toluene (TOL), trimethylbenzene (TMB), o-xylene (OXYL) and octane (OCT). The experiments were carried out in the EUPHORE facility located in CEAM (Valencia, Spain) in 2008, 2009, 2010 and 2011 (*Vivanco et al.*, 2011). Experimental conditions are summarized in Table 1.

The CHIMERE model was applied to simulate 17 experiments. The model was first modified to reproduce EUPHORE conditions. In the model, SOA formation is governed by the production of a group of semivolatile compounds from the oxidation of biogenic and anthropogenic volatile organic compounds, that partition to the particle phase to form individual SOA species. According to the set of reactions included in the model AnBmP is the main SOA species formed from the oxidation of the precursors introduced into the chamber. This specie includes the hydrophobic aersosol compounds with a medium vapour pressure coming from the oxidation of anthropogenic VOCs. Pv and Hv values for this specie in 2011 CHIMERE version (2x10-3 Pa and 156kJ/mol respectively), do not produce organic aerosols. A lower Pv is required. Pv and Hv values proposed by Kim et al. (2011) for this specie (4x10-4 Pa and 88 kJ/mol, respectively) drove to an increase of aerosol formation Even lower Pv values taken from Jordan (2000) (4.8x10-5) drove to better results. This reference was used as according to SOA CHIMERE scheme, AnBmP is the only product coming from octane oxidation and thus thermodynamic properties of octane oxidation products could be assigned to AnBmP specie. Moreover, Hv value in the 2011 CHIMERE version (156 kJ/mol) leads to an unrealistic temporal behaviour. Other enthalpies, such as that in CMAQ (around 40 kJ/mol) improved model results. Nevertheless, an overall overestimation is found in most of the experiments (Figure 1).

We present and discuss a novel approach for modelling the dispersion of aerosols emitted by mobile sources in an urban environment using k-ε model with varying the Schmidt number in order to model the dispersion intensity of PM_{10} in the urban canyons. The study area, Lisbon downtown, is frequently surpassing the air quality limits, mainly in the main avenue of Lisbon: "Avenida da Liberdade". The main factors influencing this bad air quality are the high emissions and low dispersion due to atmospheric stability, urban structure (buildings and trees) and wind speed and direction. The integral modelling approach includes the emission estimation using fine traffic data, modelling the flow field through the urban canopy and the dispersion of the pollutants and the concentration of PM_{10} at pedestrian height. Dispersion is computed by both eulerian and lagrangian approaches. In the eulerian dispersion, one evaluates the influence of the Schmidt number upon the concentration field modelled. These results are compared with those obtained by the lagrangian approach and with the measurements available through the local air quality network. Results are in agreement with those published in the literature (Hagler et al., 2011; Tominaga & Stathopoulos, 2007). The influence of the Schmidt number is an important parameterization for any eulerian model and is being somehow addressed as a fine tuning for fitting the experimental measurements (Buccolieri, Sandberg, & Di Sabatino, 2010; Hang, Li, Buccolieri, Sandberg, & Di Sabatino, 2012).

Most modelling applications in the literature parameterize Schmidt number as a single value in the range 0.2-1.3 (Tominaga & Stathopoulos, 2007). However, there are studies that concluded that a Schmidt value of 0.04 can produce better results in specific conditions, namely when the wind direction is perpendicular to the street canyon axis (Di Sabatino, Buccolieri, Pulvirenti, & Britter, 2008).

We review the main physics behind Schmidt number and its importance for eulerian modelling based on the significant study of (Konrad, 2000) who studied the vertical profile of Schmidt number and thus reveals that the use of a single/uniform value for modelling domain is physically false. In our study we used a vertical Shmidt number vertical profile based on Konrad results, fitted as:

$$Sc = \begin{cases} 0.3 & if \quad \frac{z}{\delta} < 0.05 \\ -10.2\left(\frac{z}{\delta}\right)^4 + 25.161\left(\frac{z}{\delta}\right)^3 - 22.667\left(\frac{z}{\delta}\right)^2 + 8.1597\left(\frac{z}{\delta}\right) - 0.043 & if \\ 0.05 \le \left(\frac{z}{\delta}\right) \le 1 & \\ 0.4 & if \quad \frac{z}{\delta} > 1 \end{cases}$$

The influence of ion-induced nucleation on atmospheric aerosols based on data from the CERN CLOUD experiment

E.M. Dunne[1], K.S. Carslaw[1], J. Almeida[2,], and the CLOUD collaboration[3]

[1]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK
[2]CERN, Geneva, Switzerland
[3]Refer to author list of Kirkby *et al.,* (2011)
Keywords: aerosol modelling, ion-induced nucleation.
Presenting author email: E.Dunne@leeds.ac.uk

A range of observations support a connection between cosmic ray intensity and the Earth's climate, on time-scales from days (Pudovkin and Veretenenko, 1995) to centuries (Eichler *et al*, 2010) to millennia (Bond *et al*, 2001). Away from the surface, ion concentrations are controlled by cosmic-ray induced ionization. One likely candidate for the mechanism connecting cosmic rays and the climate is the ion-induced nucleation of aerosol.

Because ions stabilise sub-critical nuclei, ion-induced nucleation is likely to act as a nucleation pathway in remote regions with low concentrations of precursor vapours. When determining the impact of this phenomenon on the climate, a global aerosol microphysics model is a vital tool due to its inclusion of the various processes which affect particle growth and deposition.

The CERN CLOUD experiment is designed to accurately measure both ion-induced and neutral nucleation rates in unprecedented detail, as described in (Kirkby *et al.*, 2011) and its online Methods and Supplementary Materials. The experiment has found that the presence of both ions and ammonia enhance nucleation rates beyond the binary neutral, but that inorganic precursor vapours are not sufficient to reproduce atmospheric observations of new particle formation events.

Using the GLOMAP aerosol microphysics model, we quantify the contribution of ion-induced nucleation to global aerosol based on new results from the CLOUD experiment at CERN. We will present the results of the implementation within a global model of the first parametrisation of ion-induced nucleation based on experimental observations rather than theoretical predictions. This parametrisation is the result of work in the ternary H_2SO_4-NH_3-H_2O system by the CLOUD collaboration at CERN. Low-temperature measurements have been used to extend the region of validity of the parametrisation below 250 K.

The simulations have been compared with other simulations which used binary homogeneous nucleation and an activation-based boundary-layer nucleation mechanism. Changes in aerosol concentrations over a solar cycle have also been evaluated.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. The development of emission inventories relies on the laboratory emission testing. Numerous experimental results have indicated that particle emission measurements are sensitive to how dilution is conducted. The objective of our study is to investigate the effect of dilution process in fabricated dilution systems on particle emission measurement. An environmental turbulent reacting flow model, the Comprehensive Turbulent Aerosol Dynamics and Gas Chemistry (*CTAG*), developed by Energy and Environment Research Laboratory (*EERL*) in Cornell University, is employed to simulate the coupling of aerosol dynamics and turbulent mixing processes inside different types of diluters.

We first investigate the aerosol dynamics during the dilution process inside two dilution tunnels, one is a variation of the T-mixing Caltech lab dilution tunnel (noted as lab tunnel), and the other is a portable *CMU* field dilution tunnel (noted as field tunnel) with a type of coaxial mixing. The highly turbulent dilution process inside the dilution tunnels is simulated using the Large Eddy Simulation (*LES*) model, which is coupled with aerosol dynamical processes. Simulation result of particle size distribution *(PSD)* shows a reasonable agreement with the experimental data for the dilution of diesel exhaust (Lipsky and Robinson, 2005), illustrated in Figure 1. Our results indicate that nucleation has a strong relationship with the mixing rate, which is determined by the configuration of the dilution tunnel (especially the mixing type of the exhaust and dilution gas), dilution ratio *(DR)* and the turbulence level of the incoming dilution gas. The T-mixing lab tunnel tends to favor the formation of the ultrafine particles due to the faster mixing rate, shown in Figure 2. The process of aerosol dynamics inside the dilution tunnel is also affected by the property of dilution gas (e.g., temperature, relative humidity) and exhaust (e.g., the level of sulfuric acid), of which the sensitivity analysis have been conducted.

Furthermore, the turbulent flow field and aerosol dynamics inside several widely used sampling diluters (e.g., the ejector diluter and the porous diluter used in "Particulates" research program of EU (Ronkko *et al*, 2006)) are studied to characterize the different dilution processes, shown in Figure 3. The numerical study inside diluters can help understanding the dilution process and its effect on aerosol dynamics, and can provide useful information for the development of a harmonized sampling methodology.

Water bus emission factor model in Venice area

E. Pecorari[1], G. Rampazzo[1], A. Ferrari[2], G. Cuzzolin[2]

[1]Department of Environmental Science Informatics and Statistics, University Ca' Foscari, Dorsoduro 2137, I-30123 Venezia, Italy

Presenting author email: eliana.pecorari@unive.it

Human activities in urban areas strongly affect air quality. In order to characterize the main sources, emission inventories are requested by legislation. The water cities, in particular, need an appropriate regulation that take into account boats and ships for inland waters. The general concern for the impact of air pollutant emissions on the environment has led to the introduction of numerous regulations targeting land based emission sources. In contrast, marine emissions to the air from ships have largely been exempt from this development. Over the past decades, however, the air emissions from shipping have been the subject of increasing attention. Research and development efforts have focused on characterizing the problem at hand (Lloyd's Register Engineering Services, 1995; Cooper et al., 1996; EMEP, 2009) and offering suitable abatement solutions (Swedish Maritime Administration, 1994; Cooper and Andreasso, 1999). In the wake of these advances, regulatory work on a global scale is being dealt with by the International Maritime Organisation (IMO, 2002). Despite this some specific scenarios could not be considered because of their peculiarity. Venice, as a *water town* in its historical part, is a very distinctive case where transport is supplied by marine systems. In the historical center the canals serves as roads and beyond the road/rail land entrances at the northern edge of the town, transportation within it remains entirely on water or on foot. Venice is the largest urban car-free area of Europe. The main transportation means are motorized public and private boats. In order to better investigate on the impact of these vehicles on the Venice area, an emission factor model was implemented: *Water Bus Emission factor Model (WATERBUS)*. The WATERBUS model was developed using a bottom-up approach and tested on the public ACTV boats that furnished the data. The preliminary results were obtained and compared with local measurements.

Figure 1. Water bus transport plan (ACTV).

Presenting author email: yong@ewha.ac.kr

In this study, the emission inventories of NOx, which is a major air pollutant of South Korea were compared and analyzed.

The two bottom-up emission inventories, Regional Emission inventory for ASia (REAS) (Ohara et al., 2007) and Clean Air Policy Support System (CAPSS) (NIER, 2009), which are the latest emission inventories about the air pollutant emissions about South Korea were compared to find out the trend of NOx emission from the past to the present. Also, these two emission inventories compared to the top down NOx estimation by inverse modeling to estimate the accurate amount of NOx emitted from South Korea.

The total NOx emission trends, sectoral and regional comparisons were carried out. In total NOx emissions, REAS was bigger than CAPSS about 3.0E+05 ton per year.

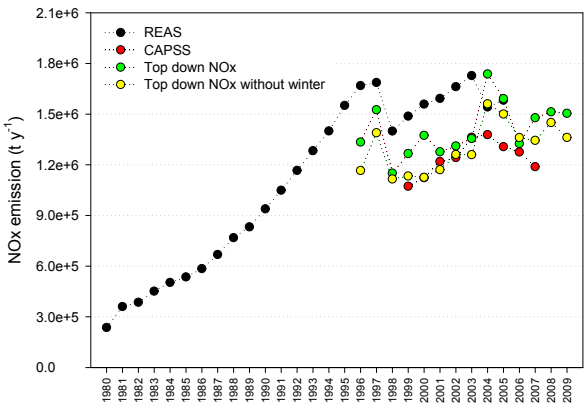

Figure 1. Trends and absolute values of NOx emissions of REAS, CAPSS, and top down NOx.

This difference was mainly caused by the difference in Transport sector, especially emissions from diesel buses (REAS was bigger than CAPSS about 2.5E+05 ton per year) and diesel cars (REAS was bigger than CAPSS about 5E+05 ton per year).

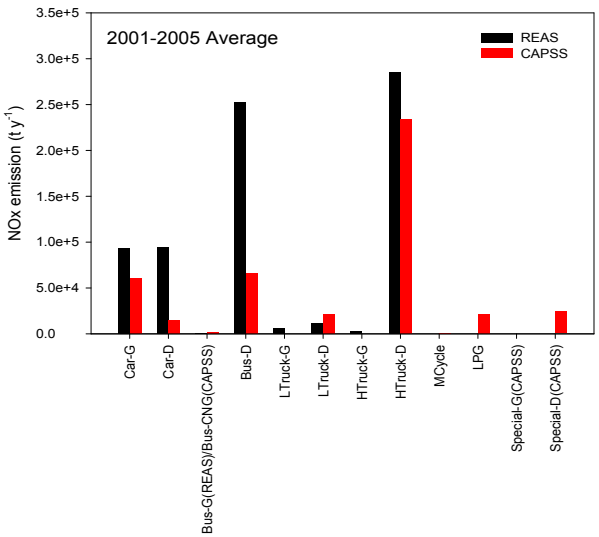

Figure 2. NOx emissions according to the types of vehicles.

The NOx emission of REAS was bigger than that of CAPSS in Seoul and Busan. On the other hand, the NOx emission of REAS was smaller than that of CAPSS in North and South area in Korea. These differences could be explained by the difference in Vehicle Kilometers Travelled (VKT) and emission factors (EF) used in REAS and CAPSS. REAS used longer VKT in Busan, Seoul, and Incheon than CAPSS. Also, REAS used bigger EF than CAPSS for diesel buses and diesel cars (5.01 times bigger for Diesel Buses, and 3.85 times bigger for diesel cars).

For the problems in the estimation of absolute amount of NOx emission, spatial distributions in bottom up inventories, inverse modeling could be a powerful method that solves the problems.

INTRODUCTION

The lack of information about aerosol chemical and physical properties in modelling systems is a critical step to enhance the emission reduction policies and the knowledge about aerosol impacts over radiative forcing and health.

Since heterogeneous reactivity experiments are conducted in our laboratory, we would like to add measured parameters and mechanisms in the air quality models. Such simulations can be useful to determine how the heterogeneous processes are important in the chemical balance of the main tropospheric oxidants or the evolution of chemical composition of aerosols. To achieve this goal, WRF-Chem has been chosen as the most suitable model because of the KPP module (Kinetic Pre-Processor) which permits to simulate the reactivity of new chemical families.

METHODOLOGY

The first step is to create software to generate emissions. At the same time, in order to improve the accuracy of air quality monitoring, we have adapted the USEPA chemical speciation profiles to a CORINAIR based emission inventory. A data processing system, EMEP2WRF, has been developed to generate chemical information which is compatible with the WRF-Chem specificities from any emission inventory based on CORINAIR architecture and methodology.

Using the RADM2 mechanism, we converted "emission species" into "model species" using the SAPRC methodology. An aerosol chemical speciation profile processing completes EMEP2WRF. Coming from the adaptation of US EPA $PM_{2.5}$ profiles (Borge et al. 2007), those data separate the unspeciated $PM_{2.5}$ emission into five chemical families: sulfate, nitrate, elemental carbon, organic aerosol and unspeciated particulate matter.

RESULTS

EMEP2WRF 1.0 has been created mixing SMOKE and CORINAIR methodologies. The EMEP2WRF 1.0 code has been developed using the Python programming language and PostgreSQL database system in order to evaluate their respective performances. Algorithms defining the EMEP, regional inventory and WRF-Chem projections maps and grids have been coded to adapt the program to any European domain and resolution. Since $PM_{2.5}$ speciation modelling has never been evaluated in Europe, we will statistically compare the simulated values with the measured ones in order to validate the chemical speciation of anthropogenic particles on a regional scale. A HR-ToF-AMS has been deployed over 2 measurements areas (Dunkerque and Douai), the first one is an urban station and the second one is an industrially influenced urban station. The measurements have been done during winter and summer seasons on both sites over about 20-day periods. From those measurements, we obtain hourly profiles of the mass of each chemical class for the ultrafine particles. Both measurements and simulations have the same information levels, this makes it possible to evaluate the new emission speciation methodology and chemical mechanism part developed in this work. EMEP2WRF 1.0 will be operational and available on poqair.univ-lille1.fr.

New method for estimating cigarette smoke emissions

Victoria Agranovski

Air Quality Sciences, Department of Environment and Resource Management, Brisbane, 4001, Australia
Keywords: Air pollution modelling, emissions, inventory, cigarette smoke
Presenting author email: victoria.agranovski@derm.qld.gov.au

Environmental Tobacco Smoke (ETS) emissions are the complex mixture of gases and fine particles, with thousands of individual toxic air contaminants (Daisey et al, 1998) emitted by the burning of tobacco products (cigarettes, cigars, and pipes) and from smoke exhaled by the smokers.

The composition of ETS emissions vary depending on the tobacco content, additives present and the type of paper and filter material used. Among other tobacco products, cigarettes are the principal source of ETS emissions in Australia (ABS, 2000). The environmental and health impacts of ETS emissions from cigarettes are therefore of concern to regulatory agencies.

There has been an increasing interest in developing emission inventories as a tool for air quality management. Accurate inventory development is however a difficult, time-consuming task due to diversity and large number of individual emission sources. Development of simplified techniques for estimating emissions using readily available activity data will facilitate the process and thus is highly desirable. The simplified techniques can be based on the typical, average emission rates derived from the analysis of relevant data specific to a particular geographical area. Such data can subsequently be used as the default input parameters for developing national emission inventories.

The purpose of this research was developing per smoker emission rates (PSER) for ETS emissions as a cost-effective mean for modeling emissions over large geographic areas containing numerous pollution sources.

The PSER, were estimated from the annual levels of pollutants emitted during smoking cigarettes divided by the number of cigarette smokers in a particular base year. The total annual ETS emissions were estimated using smoking prevalence data from the Australian national tobacco consumption surveys, coupled with cigarette sales figures gathered from the manufacturers.

For the purposes of this study, the emission rates were derived from the emissions factors (µg/cigarette) specific to Australian conditions. Specifically, they were based on the latest data available for cigarette brand variants manufactured and sold in Australia.

A selection of the default per smoker emission rates derived from this research is presented in Table 1. These figures are the mean values of relevant data over period 2000-2007 years.

The default PSER values were developed under assumption that the Australian adult smokers (older than 15 years) consume on average approximately 5150 cigarettes annually, based on the data from the Australian national surveys conducted over the last decade.

Table 1. Per smoker emission rates (PSER) for selected pollutants from cigarette smoke.

Compound	PSER (κg/smoker/yr)	
	Mean	SD
1,3 Butadiene	2.06E+00	8.67E-02
Acetaldehyde	9.60E+00	4.04E-01

Effect of the Lagrangian integral time scale estimation on particle deposition

G. Lecrivain[1], T. Barth[1] and U. Hampel[1]

[1]Institute of Fluid Dynamics, Helmholtz-Zentrum Dresden-Rossendorf, Dresden, 01328, Germany
Keywords: nuclear aerosols, deposition velocity, numerical simulation, CFD.
Presenting author email: g.lecrivain@hzdr.de

In a high temperature pebble-bed reactor, carbonaceous dust is conveyed by the cooling carrier phase and eventually deposits in the primary circuit of the reactor (Moorman, 2008). In hypothetical severe accident, a dose of radioactive graphite dust may escape the system boundaries. The accurate prediction of transport and deposition of graphite particles is therefore a key primary safety issue.

The numerical dispersion and deposition of aerosol particles in a turbulent flow involving Reynolds-averaged Navier-Stokes simulations frequently make use of the Lagrangian integral time scale T_L. It is the correlation of successive velocities along a particle path throughout the duration of particle travel. Each component T_{Li} of the time scale T_L is defined as:

$$T_{Li} = \int_0^{t_\infty} \frac{\overline{u_i(t) \cdot u_i(t+\tau)}}{u_i(t) \cdot u_i(t)} d\tau$$

where the subscript $i = 1,2,3$ denotes the streamwise, the wall normal and the spanwise component respectively, t_∞ is a long period of time and u_i is the instantaneous fluid velocity seen by the particle. T_L as seen by the moving particle is difficult to obtain, especially in the turbulent boundary layer. Multiple estimations of T_L were derived in homogeneous turbulence, and yet very scarce literature data are available on accurate estimations of T_L in the inhomogeneous and anisotropic turbulent viscous sublayer. Bocksell and Loth (2006) performed a Direct Numerical Simulation (DNS) in which thousands of fluid tracer particles were released within the boundary layer. At the wall most sample values of the wall normal component T_{L2}^+ were found to lie in the interval [2-5]. T_L^+ denotes here the non-dimensional counterpart of T_L. Luo et al (2010) reported the average value at the wall $T_{L2}^+ = 4$, thus supporting the results numerically determined by his predecessors. T_{L2}^+ values at the wall of up to 10 were also estimated in some other literature sources.

The effect of T_{L2} estimation in the near wall region on the numerical prediction of particle deposition is here investigated. The stochastic continuous random walk model is used. It correlates the velocity fluctuation u_i' from the previous time-step through a Markov chain, with the inclusion of a zero mean, unit variance distributed random number $N(0,1)$. The following first order approximation of the normalised Langevin equation which accounts for inhomogeneous turbulence is implemented in the OpenFOAM code:

$$u_i'(t+\Delta t) = u_i'(t) \cdot (1 - \frac{\Delta t}{T_{Li}}) + u_i^{rms} \cdot \sqrt{2\frac{\Delta t}{T_{Li}}} \cdot N(0,1)$$

where Δt is the simulation time step and u_i^{rms} the root mean square local fluctuation velocity taken from DNS data in the near wall region. The mean velocity field and its corresponding turbulence field are derived from a numerical simulation carried out with a Reynolds stress turbulence model. The turbulent flow is simulated in a vertical square duct flow (gravity in the flow direction) at Reynolds Number $Re = 42000$. The diameter of the particles is varied from 0.01 μm to 50 μm to cover the particle size range experimentally observed in a high temperature reactor. T_{L2} is varied as follows:

$y^+ < 5$	T_{L2}^+ =3, 4, 6 and 10
$5 < y^+ < 100$	T_{L2}^+ fitted value to DNS data
$y^+ > 100$	$T_{L2} = C \cdot \frac{k}{\varepsilon}$

The effect T_{L2} has on the particle deposition velocity can be seen in Figure 1. Findings form this study show that $T_{L2}^+ = 3$ at the wall results in an accurate match with particle deposition velocities previously determined. The "V-shape" variation of the deposition velocity is accurately reproduced. The deposition velocity seems very sensitive to T_{L2}^+ near the wall. A slight overestimation will produce large errors.

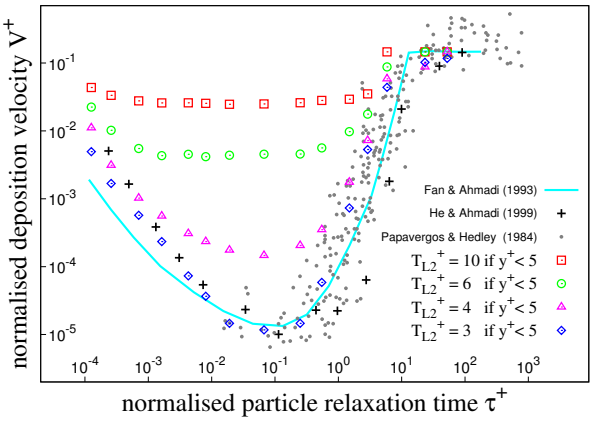

Figure 1: Effect of T_{L2}^+ on aerosol particle deposition.

Sulphuric Acid Aerosols in Industrial Processes – Simulation, Estimation of Coagulation and CPC measurement

L. Brachert[1], S. Sinanis[1] and K. Schaber[1]

[1]Institute for Technical Thermodynamics and Refrigeration, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany

Keywords: Absorption, Coagulation, CPC, Homogeneous nucleation, Industrial aerosols

Presenting author email: leonie.brachert@kit.edu

The formation of sulphuric acid aerosols is a phenomenon which emerges frequently in industrial processes such as absorption, mixing and cooling. An important domain is for example the absorption-based flue gas cleaning in power plants using fossil fuels. It is crucial to be able to predict the number concentrations and droplet diameters which will emerge in industrial applications in order to improve and facilitate the design of precipitation systems.

The simulation tool AerCoDe has been developed at the Institute of Technical Thermodynamics and Refrigeration to predict aerosol formation initiated by heterogeneous (Wix, 2008) as well as homogeneous nucleation (Wix *et al*, 2010). In sulphuric acid – water systems homogeneous nucleation has to be considered. The reason for this is the occurrence of high supersaturations as a result of the extreme phase equilibrium of this binary system. The simulation yields small aerosols (<200 nm) and high number concentrations up to 10^{10} 1/cm³ (Wix *et al*, 2010). The number concentration is slightly lower when the parameterisation of Vehkamäki et al (2003) is used to take the formation of hydrate clusters into account (Figure 1).

For heterogeneous nucleation the simulation tool has been validated by experiments with the systems H_2O-HBr and H_2O-HCl in the past (Wix, 2008). The validation of the homogeneous nucleation model is currently conducted at the semi-industrial flue gas cleaning facility at the institute. Therefore the number concentration of the aerosol is measured by means of a condensation particle counter (CPC) in combination with a dilution cascade. The measurements show high number concentrations of $>10^8$ 1/cm³ within the entire concentration range of H_2SO_4 in the flue gas (Figure 1). The measured concentration is slightly decreasing at smaller inlet concentrations of H_2SO_4.

Two competing depletion mechanisms of supersaturation affect the resulting number concentration: nucleation and growth. At low inlet concentrations, the binary system H_2SO_4-H_2O reveals a steep descent of the saturation pressure with increasing concentrations of H_2SO_4 (and subsequently high supersaturations). Hence, at low inlet concentrations the driving force for nucleation is high, whereas there is not much substance in the gas phase which would enforce growth. As a consequence, the resulting number concentration is high even for low inlet concentrations of H_2SO_4 combined with small diameters of the aerosol. The higher the inlet concentration, the higher the driving force for growth. However, the number concentration does not increase significantly as the supersaturation does not augment in the same manner. The simulation reveals even decreasing number concentration at higher inlet concentrations.

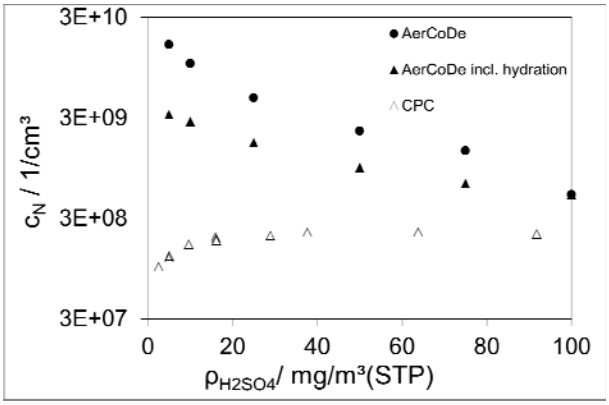

Figure 1. Total number concentration in the absorption column outlet as a function of the H_2SO_4 inlet concentration from AerCoDe and CPC measurement

For the homogeneous nucleation no coagulation model is implemented in AerCoDe so far because it is computationally expensive as a polydisperse model has to be used. It can be seen in Figure 1 that high number concentrations are obtained and coagulation has to be considered in order to compare simulation and experiments. This is essential at low inlet concentrations in particular because the prevalent small diameters increase the effect of coagulation. As a consequence, several approaches for coagulation (monodisperse as well as polydisperse) are investigated and will be presented at the conference.

The aim of the investigation is to provide information about the sulphuric acid aerosol formed during flue gas cleaning and thus provide a base for the improvement of absorption processes in industrial applications.

Microscopic observation of aerosol particle deposition in turbulent channel flows

T. Barth, G. Lécrivain, J. Preuß and A. Lehmann

Institut für Fluiddynamik, Helmholtz-Zentrum Dresden-Rossendorf,
Bautzner Landstraße 400, 01328 Dresden, Germany

Keywords: Turbulent flow, particle deposition, microscopic observation, isokinetic sampling, spectrometry
Presenting author email: t.barth@hzdr.de

The transport behaviour of carbonaceous dust in the primary circuit of a High Temperature Reactor (HTR) plays an important role in the safety assessment during a Design Basis Accident (DBA). Carbonaceous dust is formed mainly due to friction between graphite fuel elements (Kissane, 2009). In a pebble bed reactor the dust forms due to abrasion of graphite material between the pebbles. During reactor operation it is a safety issue to precisely predict the dust deposition and the corresponding resuspension rate of particles released into the containment during a DBA.

Deposition of aerosol particles has been investigated e.g. by Sippola & Nazaroff (2004). These experiments have been performed in steel ducts at Reynolds numbers and with particle relaxation times observed in a HTR. Their results follow the "v-shaped" curve of the non-dimensional deposition velocity against particle relaxation time and show a dependency on flow speed, particle size and orientation of the duct.

More recently, an Euler-Lagrange CFD simulation of particle deposition in a turbulent square duct flow has been performed by Lecrivain (2012). It was found that the friction velocity significantly influences the particle deposition velocities.

Deposition experiments of liquid and solid particles in a fully developed horizontal turbulent square duct flow are performed to further study the deposition behaviour of aerosol particles. The oil liquid particles (DEHS) are generated by a condensational aerosol generator (TOPAS, SLG 270). The aerodynamic particle size distribution and the particle number concentration of the suspended particles are determined by isokinetic sampling using an Aerodynamic Particle Sizer Spectrometer (TSI. APS 3321). The particle size distributions are fairly monodisperse for particles with $d_{aero} = [1.5, 2.5, 3.5, 4.5]\ \mu m$. The solid aerosol particles are microspheres (AkzoNobel, Expancel DU, $d_{50} = 6.5\ \mu m$) and are injected into the flow field by means of a solid aerosol generator (TOPAS, SAG 410). The particle mass flow rate and the particle concentration are precisely adjusted by the feed rate of the SAG. The particle size distribution of the airborne particles is measured by means of Scanning Electron Microscopy (SEM). The size distributions gained by the APS and the SEM analysis are used to calibrate the size distributions obtained by an optical microscope.

A commercial light microscope equipped with a CMOS camera is mounted underneath the test section of the channel. It is focused on the inside surface of the channel floor which consists of a glass plate coated with indium tin oxide to remove electrostatic charges. This allows a time-resolved *in situ* observation of the particle deposition processes. A standard LED light source illuminates the microscope's *6 x 4 mm²* field of view and the CMOS camera records the scatter light of the wall deposited particles. The measurement uncertainty for particles larger than *2 µm* is assumed to be *24%*.

Figure 1 illustrates the time averaged deposition velocities for varying friction velocities. The CFD results of Lecrivain (2012) and Sipolla & Nazaroff (2004) are also plotted for comparison purposes. In the particle relaxation time range $\tau^+ = 0.001..10$ the deposition velocity increases with decreasing friction velocity. which is also observed elsewhere. It is assumed that the effect of gravitational settling leads to an increase of deposition velocity for decreasing flow speed. The results of this study also capture this tendency. Nevertheless, the scatter in the data has to be further investigated.

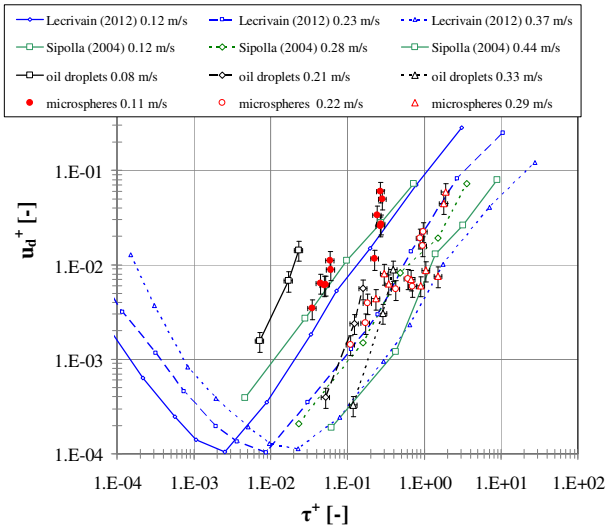

Figure 1. deposition velocity against relaxation time with respect to different friction velocities

Experimental and Numerical Investigation of Hygroscopic Aerosols Transport, Kinetics and Deposition in an Enclosure

M.A. Zatevakhin[1], A.A. Ignatiev[1],
Y.N.Vashlyaev[2], A.A. Zaitsev[2], A.A. Lukyanov[2], A.S.Mikheev[2], D.V.Sumin[2], O.V.Supotnitskaya[2]

[1] JSC SPAEP, 9/2a, 2nd Sovetskaya street, 191036, Saint Petersburg, Russia
[2] SSC RF-IPPE named after A.I.Leypunsky, 1 Bondarenko Sq., 249033, Obninsk, Russia

Keywords: aerosol dynamics, CFD, deposition, diffusiophoresis, hygroscopicity

Hygroscopic aerosols behaviour in an enclosure at certain thermohydraulic conditions was studied. Processes of aerosol transport, kinetics and deposition were modelled simultaneously under conditions of air-steam atmosphere. The soluble NaCl (sodium chloride) aerosol particles with size on the order of 1–2 μm were used. Experiments were conducted at the VKM test facility located in the SSC RF-IPPE territory (Obninsk). The scheme of the VKM is showed in figure 1. The volume of the vessel is 9 m^3.

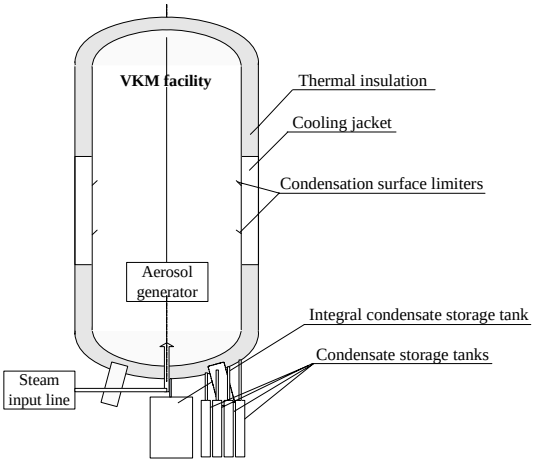

Figure 1. Scheme of the VKM test facility.

The experiments were carried out at 350 kPa pressure and 410 K temperature. Water steam was supplied into vessel containing some amount of air and condensed on vessel walls. Following parameters were measured during experiments:
- pressure;
- temperatures of gas and walls;
- volume of condensate at special wall collectors and vessel bottom;
- concentration of dissolved sodium chloride.

Hydrodynamic code integrated with aerosol block was used for numerical simulation. The code was based on Reynolds averaged hydrodynamic equations solution. To simulate the transport of low-inertia particles in turbulent flow Eulerian diffusion-inertia model (Zaichik et al. 2010) was employed. Boundary conditions at walls were set with taking into account gravitational settling, Brownian diffusion, thermophoresis and deposition by Stefan flow (diffusiophoresis).

Kinetic block was based on numerical solution of condensation/coagulation kinetic equations. Sodium chloride solubility and its influence on vapor pressure at particle surface were taking into account.

Simulation results showed that Stefan flow totally determines deposition onto lateral walls. Equilibrium between incoming and condensing water vapor was achieved at relative humidity of the order of 99.3%. Appreciable growth of water droplets on soluble NaCl nuclei occurs at this humidity level. These droplets deposit onto bottom of the vessel due to gravity sedimentation. This process provides good agreement between simulation results and experimental data. Meanwhile, results obtained without taking into account solubility differs considerably from described above and experimental data. It can be clearly seen in figure 2.

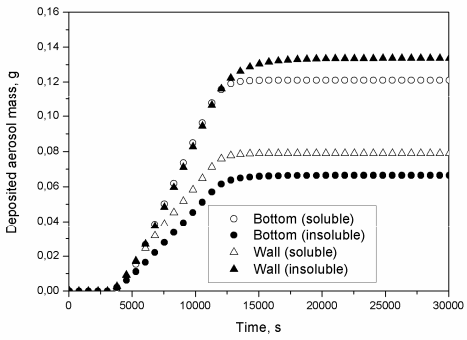

Figure 2. Deposited aerosol masses.

Mathematical study of inhalable fraction in low velocity conditions

A.K. Gilfanov, I.T. Mukhametzanov, S.K. Zaripov

Kazan Federal University, Kazan, Russia, 420008

Keywords: inhalable fraction, sampler, calm air, CFD
Presenting author email: artur.gilfanov@ksu.ru

The CFD model and parametrical investigations of the particle inhalable fraction for the human manikin in low velocity air including a calm air case are presented. Obtained dependences of the inhalable fraction on the particle size are compared with experimental data and the aspiration efficiency of a spherical sampler.

The particle inhalability for a realistic human head was studied numerically for low air velocity by Antony&Flynn (2006). Presently, there is little information regarding the human inhalability under calm air condition (Dai et al., 2006). In the present work a realistic digital model of human head and an idealized spherical sampler facing the wind are used to calculate the inhalable fraction of coarse dust particles up to very low velocity values including the calm air case.

In the first model the velocity field of the air flow is found by numerical solution of the Navier-Stokes equations of viscous flow of incompressible fluid using the FLUENT code. To describe the gas flow for the spherical sampler the potential flow model developed by Galeev&Zaripov (2003) is used. The particle motion equations are integrated in the velocity field, which is found numerically or analytically.

In the undisturbed air flow far from the human head and sampler particles move with the velocity $\bar{U}_1 = \bar{U}_0 + \bar{V}_s$, where $\bar{U}_0$ is the air velocity, $\bar{V}_s = \tau \bar{g}$ is the settling velocity, $\tau = \rho_p d^2 / 18\mu$ is the relaxation time, ρ_p and d are the particle density and diameter, μ is the air viscosity. Breathing is simulated by an stationary air suction through the elliptical mouth orifice. On the base of calculating particle trajectories the tube of limiting trajectories is calculated, which divides the sampled particles from the unsampled ones. The cross section area S_p of the tube of limiting trajectories far from the manikin allows to calculate the aspiration efficiency (inhalable fraction) by the formula

$$A = \frac{U_1 S_p}{Q} = \frac{S_p \sqrt{U_0^2 + V_s^2}}{S_m U_a},$$

where $Q = S_m U_a$ is air flow rate through mouth with area S_m, $\bar{U}_0$ is the aspiration velocity.

Some trajectories of particles in the vicinity of the human head at two values of wind velocity are shown in fig.1. The shape and size of the area S_p depends on the ratio of the wind and sampling velocities and the particle diameter. In the calm air case the human head screens a part of particles that could be aspirated. The aspiration efficiency as a particle diameter function is shown in fig.2. The obtained values of aspiration efficiency for moving air agree well with experimental data of Kennedy&Hinds (2002) and the theoretical curve of Anthony&Flynn (2006). Comparison with the criterion for inhalable particulate mass (IPM) aerosol samplers is given. The aspiration efficiency of the spherical sampler in moving air also agrees well with mentioned curves. Thus the model of an idealized spherical sampler can be used to estimate the inhalable fraction in low velocity environment.

Background of the Joaquin project

Air pollution and health effects has been the subject of extensive research for many years (Brunekreef and Holgate, 2002). Although air quality has improved considerably in Europe in recent decades (EEA, 2011), airborne fine particles still have a significant impact on our health and life expentancy (Amman *et al*., 2005).

Recent research shows that other pollutants, such as the smaller ultra fine particles (UFP) and "Elemental Carbon (EC)" are more likely to be linked to health problems, than the current parameters of NO_2 (nitrogen dioxide) and PM_{10} (PM with a diameter less than 10μm) (Sioutas *et al*., 2005, Janssen *et al.*, 2011). At present there is no clear understanding of the presence of these particles, especially at local and regional level. Furthermore, the links between air quality research and policy are missing (Morawska *et al*., 2008). Air pollution, especially of the current parameters, is by its nature a truly transnational problem, e.g. emissions of air pollutants in one region can have a detrimental effect on the air quality of other regions and vice versa. A jointly identified and implemented transnational approach is therefore an essential requirement for a successful reduction of air pollution.

The aim of the Joaquin project is to support health-oriented air quality policies in the Northwest European Region (NWE). To achieve this, the project is broken up in three work packages. The first work package consists of capacity building, in which innovative knowledge will be gained by e.g. setting up a novel monitoring infrastructure for UFP and EC. In the second work package, measures are assessed to identify, pilot and evaluate the most efficient and cost-effective measures to reduce exposure. In the third work package, communication is set-up between the involved policy levels, stakeholder groups and the general public.

Transnational assessment

Within the second work package, is a transnational assessment of health relevant parameters will be conducted. Currently there is no insight in the relative importance of health relevant pollutants across the NWE region and no maps of UFP and EC emissions and concentrations exist.

The first part of this action is the comparison of four currently used regional models with regard to EC (and UFP) concentrations, i.e. Lotos-Euros, BelEuros, Chimere and Aurora (EEA Model Documentation System). The results of this exercise will be validated with the measurements carried out in work package one of the project.

Secondly, the Lotos-Euros and BelEuros model will be used to assess the contribution of emissions from surrounding regions to the air quality in one region. To this aim, the NWE region will be divided in 10-15 regions. In the BELEuros model de contribution of one region to the other regions will be assessed based on emission reductions of the concerned region. In the Lotos-Euros model, emission data of each region are labelled and their distribution over the regions is tracked.

In the third part, local models are extended for UFP modelling. For this purpose, the high resolution bigaussian IFDM model and the TREDM model (EEA Model Documentation System) will be used.

The last part of this action involves the assessment of different measures on yearly average PM_{10}, $PM_{2.5}$, NO_x EC and UFP concentrations for 2020. The impact of several measures with regard to traffic (permanent speed reduction, greening of the car park), energy use (e.g. shift from oil fuel to natural gas or biomass) and agriculture (ammonia emission reductions) on air quality will be assessed.

This work was supported by the European Union through the Interreg IV-B NWE program.

Development of a workflow for integration of fresh slaughterhouse porcine lungs into an active lung simulation

K. Stiglbrunner[1], M. Forjan[1], Z. Bureš[2,3] and A. Drauschke[1]

[1]Institute for Biomedical Engineering, University of Applied Sciences Technikum Wien, Vienna, Austria

Working place safety is an important topic of recent discussions. Different institutions, like companies or R&D laboratories, are interested in enhanced research, containing environmental factors at the workplace, leading to knowledge of local particle distributions in the human lung. (Ruzer and Harley, 2005) Using measurements of the actual particle number entering the respiratory system, the possible effects or hazards of the inhaled aerosols can thereby be evaluated. The amount of particles is of interest as well as the local distribution on a cellular basis. Making this observation as realistic as possible, an anatomically realistic model, such as an isolated porcine lung, should be used, as well as an integrated circulatory system. The main advantage of the fresh slaughterhouse porcine lung in combination with the developed lung simulator (the i-Lung) is the possibility to use the setup as an alternative to animal testing, which will be necessary due to legal provisions. (European Commission, 1976)

The lung simulator has been developed and measurements have verified the functionality of both, physiological and pathological breathing patterns. (Forjan *et al*, 2011)

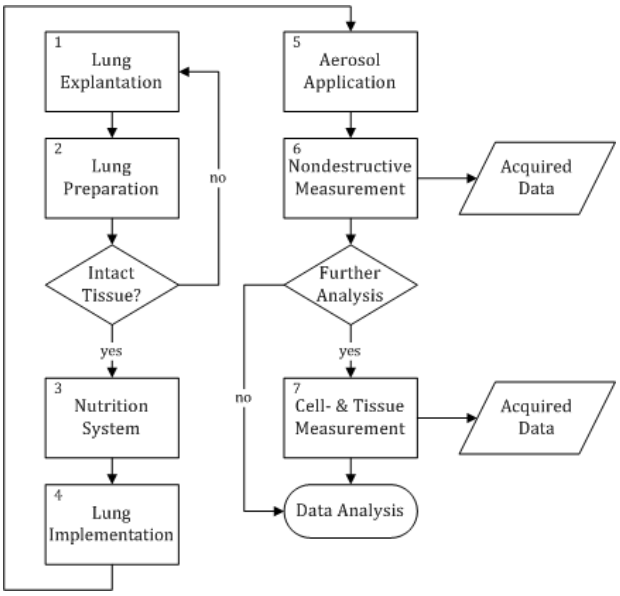

Figure 1. Workflow diagram of the measurement setup.

The workflow starts with the explantation of a porcine lung, (1) in Figure 1, during a common slaughtering process. In addition, prepared porcine lungs or other lung equivalents are used in aerosol measurements. The next step is the preparation and usage of the fresh porcine lung (2). If the tissue of the lung and the pharyngeal area is intact for the integration into the lung simulator, the nutrition system of the circulatory system has to be connected (3). Afterwards the porcine lung is implemented into the i-Lung (4). In combination with the either actively breathing or passively ventilated lung simulator, the aerosols are applied to the completed setup (5). The acquired data from the non-destructive aerosol concentration measurements of the porcine lung (6) is the basis for further analysis on a cellular level (7). The entire system is therefore designed to allow work place aerosol inhalation measurements with an anatomically correct model and to provide information about local particle distribution within the lung tissue.

The active lung simulator i-Lung is used as core element for this workflow. With either lung equivalent, aerosol concentration measurements have been performed and showed a significant degree of separation of inhaled particles using a porcine lung. (Forjan et al, 2012) In addition cooperation has been established for elaborating adequate slaughterhouse process integrated explantation techniques for porcine lungs. Furthermore the use of porcine lung tissue provides an anatomically and physiologically realistic model, comparable to a human lung. (Stiglbrunner, 2011) The next steps in this workflow development include the decision for a proper tissue preparation and nutrition solution. A further goal is the integration of a nutrition circulatory module for tissue life prolongation into the i-Lung system. In a last step the cell- & tissue measurement techniques for the workflow have to be defined and integrated.

Ion-induced vs. base-induced sulfuric acid nucleation

O. Kupiainen[1], T. Olenius[1], I.K. Ortega[1], T. Kurtén[2], and H. Vehkamäki[1]
[1]Department of Physics, University of Helsinki, Gustaf Hällströmin katu 2 A, P.O. Box 64, FI-00014 Finland

Keywords: Sulfuric acid, Molecular clusters, Modeling, Ion-induced nucleation.
Presenting author email: oona.kupiainen@helsinki.fi

A large fraction of atmospheric aerosols are formed in the atmosphere by gas-to-particle nucleation, but their birth-mechanism remains unclear. Sulfuric acid is believed to have a major role, but the observed new-particle formation rates cannot be explained by homogeneous nucleation of sulfuric acid and water alone. Instead, some additional compound is needed to stabilize the small sulfuric acid clusters and enable them to grow into particles.

Since acids and bases bind strongly together, bases are likely to enhance sulfuric acid cluster formation. We have studied the role of ammonia, which is a weak base and abundant in the atmosphere, and dimethylamine (DMA), which is a stronger base but has a lower concentration.

Nucleation can also be enhanced by ions through several mechanisms. Firstly, ions attract polar and polarizable molecules and clusters, which leads to higher collision rates compared to neutral cluster formation. Secondly, ionic clusters are more strongly bound, leading to lower evaporation rates. Finally, the recombination of oppositely charged clusters may enable the formation of neutral clusters even in conditions where purely neutral nucleation would be negligible.

We have computed formation Gibbs free energies of neutral and negatively and positively charged sulfuric acid – ammonia – DMA clusters up to four acids and four bases using a multi-step quantum chemistry method (Ortega *et al*, 2012). These energies were used to calculate evaporation rates of the clusters, assuming classical collision rates and barrierless reactions. Cluster formation was then studied using the Atmospheric Cluster Dynamics Code, ACDC (McGrath *et al*, 2011).

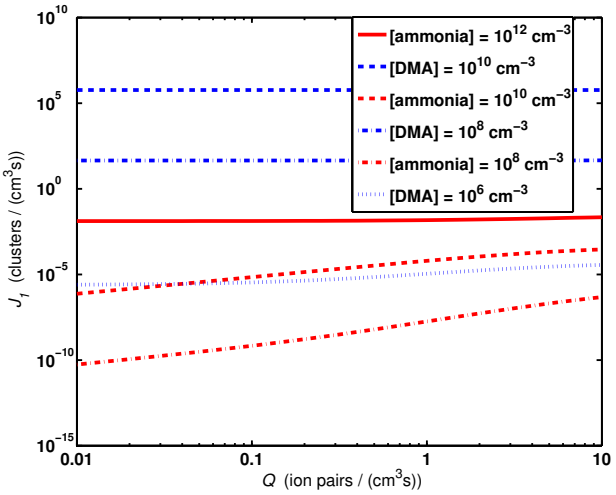

Figure 1: Formation rate of 1 nm clusters as a function of ion pair formation rate at a sulfuric acid concentration of 10^6 cm^{-3} and different ammonia and dimethylamine concentrations.

We have found that the charged clusters are overall more stable than neutrals, although the optimal acid-base ratio varies depending on the charge. In all charging states, DMA stabilizes the clusters more effectively than ammonia. On the other hand, ammonia concentrations in the atmosphere are typically a few orders of magnitude higher than amine concentrations, resulting in more frequent collisions with sulfuric acid molecules and clusters.

We have simulated the formation and growth of clusters at various concentrations of sulfuric acid, ammonia and DMA, and different ion formation rates. We have also compared our cluster formation rates with results from chamber experiments and field measurements, and studied the effect of charge in different conditions.

Figure 1 shows the effect of ions on our simulated cluster formation rate at a sulfuric acid concentration of 10^6 cm^{-3} and different ammonia and dimethylamine concentrations. It can be seen that DMA enhances cluster formation much more strongly than ammonia. For both bases, ion-induced nucleation may play a major role when the base concentration is low, but neutral cluster formation dominates at higher base concentrations.

Our results indicate that the first steps of atmospheric new-particle formation could be explained by the formation of sulfuric acid – amine clusters, whereas ammonia and charge may play a larger role in the absence of amines.

Presenting author email: anni.maattanen@latmos.ipsl.fr

We have extended the Vehkamäki et al. (2002) two-component nucleation parameterization for sulfuric acid and water in stratospheric conditions to very low relative humidities where nucleation of pure sulfuric acid becomes possible. Our motivation for this work was an application to the extremely dry atmosphere of Venus, where relative humidities can fall below the lowest limit of the Vehkamäki et al. (2002) parameterization, RH=0,01%.

According to observations, sulfuric acid aerosols are the main component forming the clouds on Venus. The clouds are optically thick in the visible wavelengths masking the surface of the planet from visual observation. The clouds are organized in three quite distinct layers with differing droplet size distributions and probably differing composition. Hints from early observations on possible existence of other species than sulfuric acid in the clouds have not yet been confirmed by recent missions.

It is thought that the water – sulfuric acid droplets form by binary homogeneous nucleation in both the Earth's stratosphere and the atmosphere of Venus. In this study we focus on homogeneous nucleation only. However, the existence of condensation nuclei on Venus cannot be ruled out in lack of observational evidence.

We have used the thermodynamically consistent version of the Classical Nucleation Theory (Noppel et al., 2002). The 2002 model was improved by deriving analytical formulae for the second derivatives of the formation free energy, since the numerical derivatives were unstable at the limit of one-component system.

Instead of the cluster distribution based on the dihydrate used in the 2002 model, we have used the self-consistent distribution of Wilemski and Wyslouzil (1995, hereafter WW95), which reduces to the one-component distribution at the one-component limit. We have studied analytically the one-component limit of the kinetic part of the two-component model, which differs from a one-component kinetic model, and verified that the numerical models behave as predicted by the analytical studies. In developing the parameterization, for continuity and consistency, the two-component model is used also at the one-component limit at the extremely low relative humidities that enable pure sulfuric acid nucleation. The data were calculated for the temperature range of 150-400 K, relative humidities ranging from 1e-6 to 100%, and sulfuric acid concentrations of 1e4 to 1e17 m^{-3}.

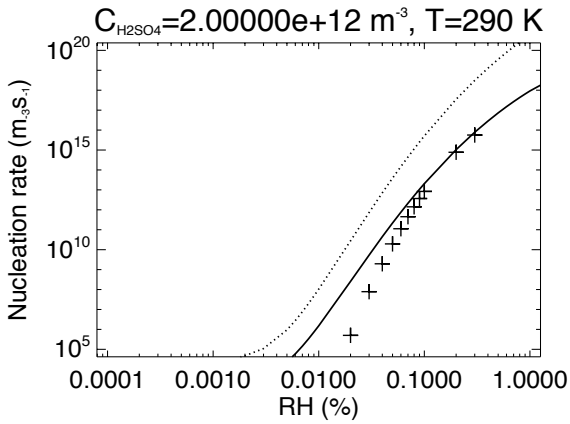

Figure 1. Example of the difference in nucleation rate between the old parameterization (+), old data (solid line, Noppel et al. 2002 hydrate distribution), and new data (dotted line, WW95 hydrate distribution). Validity range of the old parameterization goes down to RH=0.01%

Figure 1 presents a comparison of the old parameterization and the data calculated using the hydrate distributions of the 2002 model and WW95. The large difference between the solid line (Noppel distribution) and the dotted line (WW95 distribution) comes from the difference in cluster distributions. This example also illustrates that the old parameterization and the old data may differ by an order of magnitude or more in certain conditions.

The parameterization has been developed mainly for the needs of a Venus cloud model (see another abstract by Määttänen et al. in this conference), but it can naturally be applied to other, for example stratospheric, conditions as well.

First modelling study on new particle formation and growth in Southern African savannah environment

R. Gierens[1], L. Laakso[1,2,3], V. Vakkari[1], D. Mogensen[1], and M. Boy[1]

Presenting author email: rosa.gierens@helsinki.fi

Africa is one of the least studied continents in respect to atmospheric aerosols. In this study measurements from a relatively clean savannah environment in South Africa were used to model new particle formation and growth. There are already some combined long-term measurements of trace gas concentrations together with aerosol and meteorological variables available (Laakso *et al.*, 2008), but to our knowledge this is the first time detailed simulations, that include all the main processes relevant to particle formation, were done.

MALTE (Model to predict new Aerosol formation in the Lower TroposphereE) is a one-dimensional model, which includes modules for boundary layer meteorology, emissions from the canopy as well as aerosol dynamical and chemical processes (Boy *et al.*, 2006, Lauros *et al.*, 2011). The aerosol dynamic processes are simulated with UHMA (University of Helsinki Multicomponent aerosol model) using two different nucleation approaches, the kinetic nucleation and organic induced nucleation. Previous studies indicate that this model is able to predict new particle formation events at the surface (Boy *et al.*, 2006 and Lauros *et al.*, 2011) and in the boundary layer with good agreement compared with measurements.

The measurements utilized in this study were done at a relatively clean background savannah site in central southern Africa (Laakso *et al.*, 2008). The location is characterized with relatively low pollutant concentrations with occasional polluted air masses from the industrial areas 100-300 km to the east. New particle formation at the site has been found to take place during most of the sunny days, 69 % of the days showing clear nucleation with additional 14 % of the days with non-growing nucleation mode (Vakkari *et al.*, 2011). The measurements include meteorological variables (temperature, relative humidity, wind speed and direction, precipitation, and radiation), trace gas concentrations (SO_2, NO_x, CO, and O_3), aerosol number size distribution, and concentrations of volatile organic compounds.

The observational data was used for input and comparisons with the simulations. We selected a couple of days of continuous data and varying conditions of clean and polluted background air. Figure 1 shows the measured and modelled particle size distributions for one day (the 10th of October 2007), during which a relatively polluted air mass was advected on the site. The model was able to reproduce the nucleation event and the growth of the particles, but the particles grow to the detected size, which is shown in the figure with a white line, later than observed. For this day the kinetic nucleation approach also underestimated the number concentrations.

The frequent new particle formation events and particle growth for the simulated days was evaluated in detail. We were able to simulate the aerosol number concentrations of newly formed particles with a reasonable good agreement with the measurements. This work will present new model results to give a better understanding on the new particle formation process in South Africa and discuss the reasons for high frequency of nucleation episodes observed.

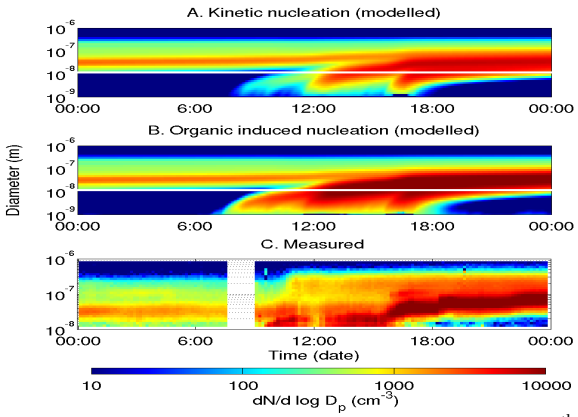

Figure 1. Particle number size distribution on the 10th of Oct assuming a) kinetic nucleation and b) organic induced nucleation in the simulation, and c) from the measurements. The white line in a and b show the detection limit of the instrument at 10nm.

Comparing simulated and experimental molecular cluster distributions

T. Olenius[1], I.K. Ortega[1], O. Kupiainen[1], T. Kurtén[2], S. Schobesberger[1] and H. Vehkamäki[1]

[1]Department of Physics, University of Helsinki, Gustaf Hällströmin katu 2 A, P.O. Box 64, FI-00014 Finland
[2]Department of Chemistry, University of Helsinki, A.I. Virtasen aukio 1, P.O. Box 55, FI-00014 Finland
Keywords: molecular clusters, sulfuric acid, modelling, nucleation.
Presenting author email: tinja.olenius@helsinki.fi

The first step in the formation of secondary atmospheric aerosols involves nucleation of gas phase molecules into small molecular clusters. Today high-resolution mass spectroscopy enables the detection and unambiguous chemical characterization of electrically charged clusters from molecular scale upward, but experimental observation of electrically neutral clusters smaller than 1 nm in diameter still remains impossible. This results in a need for theoretical methods able to link the observed concentrations of charged clusters with the concentrations of neutral clusters.

We have used the kinetic code ACDC (Atmospheric Cluster Dynamics Code) (McGrath *et al*., 2011) to simulate a set of small molecular clusters containing sulfuric acid and ammonia molecules. As an input for the code we have used formation free energies of the clusters calculated with quantum chemical methods (Ortega *et al*., 2012). The code solves the birth-death equations of the clusters by using evaporation rates derived from the formation free energies. In this way we have examined the steady-state cluster distributions in different conditions, and compared the results to the concentrations measured in CLOUD experiments at CERN (Kirkby *et al*., 2011). We have included in the simulation both neutral clusters and negatively and positively charged cluster ions that contain up to four sulfuric acid and four ammonia molecules. The set of clusters was chosen based on the relative stability of the clusters, and therefore the unstable charged clusters were left out.

We have studied how the ratio between the concentrations of charged pure sulfuric acid clusters of different sizes varies with sulfuric acid and ammonia concentrations. Figure 1 shows the ratio of tetramer and trimer concentrations as a function of sulfuric acid concentration. According to the simulations the effect of ammonia becomes more important as the temperature decreases. At 278.65 K lines with different ammonia concentration are clearly separated, whereas at 292.15 K they fall on top of each other. The modelled ratios are qualitatively consistent with experimental observations.

We have shown that ACDC is capable of qualitatively reproducing the results measured in CLOUD. ACDC can also be used to simulate the distribution of neutral clusters that cannot be experimentally observed, leading to a better understanding of atmospheric cluster formation and nucleation mechanisms.

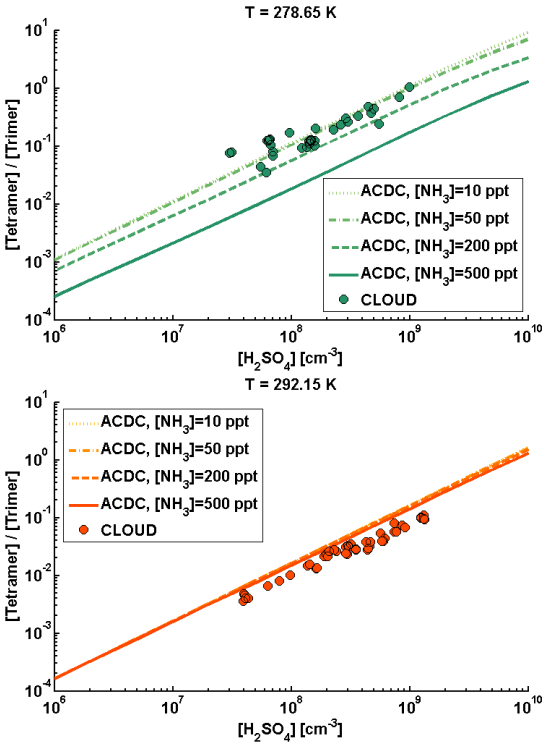

Figure 1. The simulated and experimental ratios between sulfuric acid tetramer and trimer concentrations versus sulfuric acid concentration for different temperatures and ammonia concentrations. The ammonia concentration in the experimental data points is uncertain and is estimated to vary between 0-500 ppt.

Simulation of Aerosol Nucleation Bursts: A Case Study

J. Salm, A. Luts, U. Hõrrak, M. Vana and H. Tammet

Institute of Physics, University of Tartu, Tartu, 50090, Estonia
Keywords: tropospheric aerosols, nucleation bursts, nanoparticles, simulation.
Presenting author email: jaan.salm@ut.ee

Tammet and Kulmala (2005, 2007) have developed a numerical tool for the simulation of atmospheric aerosol nucleation bursts. The tool takes into account a number of various processes and relationships, which probably affect the generation and growth of aerosol particles in the atmosphere. This report presents a development of the preliminary attempt by Salm (2007) to simulate a measured nucleation burst.

Complex measurements were performed at SMEAR II Station, Hyytiälä, Southern Finland (61 51'N, 24 17'E, 170 m above sea level), from March 20 to April 20, 2000, at the annual maximum of the new particle burst occurrence (Salm, 2007). The main novel apparatus was a set of two identical DMPS with different pre-charging conditions. One of these DMPS operated at the very customary mode: the aerosol particles were charged in a bipolar charger. Another DMPS was identical, but without the charger; thus it measured only naturally charged aerosol particles. In both DMPS, negatively charged particles were analyzed.

The same nucleation burst of April 8, 2000, as previously (Salm, 2007), was chosen for an advanced study. In the previous study, the output graphs of the simulator calculations were visually compared with the measurement graphs. In the present study, one of the authors compiled a special shell, which links the initial data of a simulation and the simulation results with MS Excel tables, and enables automation of the calculations.

From measurements, we have the concentrations of negative nanoparticles in the size interval of 2.8–8.6 nm, the concentrations of neutral nanoparticles in the same size interval, and the concentrations of negative cluster ions recorded as average values for successive 30 min intervals. The particular nucleation burst began about 09:00 of LST and dropped about 14:30 LST. The time series of these three concentrations serve as targets for simulation (see Figure 1).

The simulation tool has 61 physical input parameters. Several parameters are kept as in the previous study, e.g., the electric mobility of cluster ions, the recombination coefficient of cluster ions etc. The meteorological and the background aerosol parameters are taken from the measurements. 44 parameters were varied in the process of calculations by means of the abovementioned shell using random number function. Thus every trial of calculations had an independent set of input parameters. The accuracy of every individual trial was rated through the sum of the squares of deviations between simulated values and measured values of the concentrations. The realization of about 1000 trials gives us a high probability that a satisfactorily simulated nucleation burst has been found (see Figure 1).

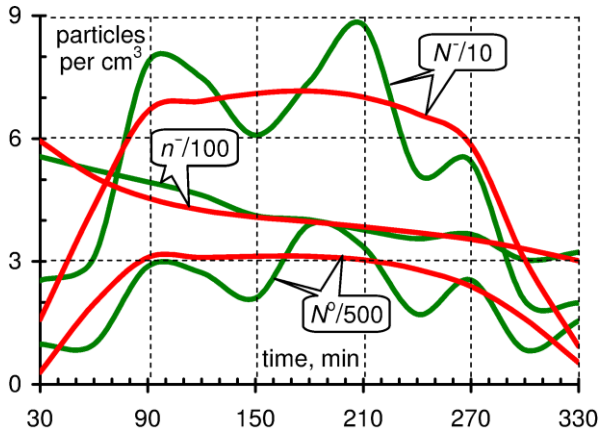

Figure 1. Simulation results for the fraction concentrations of charged and neutral aerosol particles and of cluster ions. n^- is the concentration of negative cluster ions, N^- and N^o are the concentrations of negative, and neutral particles in the diameter interval of 2.8–8.6 nm. Green lines represent the measured values and red lines the simulations.

The majority of obtained parameter values are comparable with the results of (Salm, 2007). However, several values turned out to be different, e.g.

- initial ionization rate 3.0 $cm^{-3}s^{-1}$
- halftime ionization rate 2.6 $cm^{-3}s^{-1}$
- final ionization rate 4.9 $cm^{-3}s^{-1}$
- max nucleation rate for + particles 0.06 $cm^{-3}s^{-1}$
- max nucleation rate for – particles 0.07 $cm^{-3}s^{-1}$
- max nucleation rate for neutral particles
  0.8 in free air and 1.1 $cm^{-3}s^{-1}$ in forest
- the time of steady nucleation activity 240 min
- the birth size of particles 1.0 nm.

A special calculation showed that the birth size of particles is a sensitive parameter, i.e. its increase or decrease rapidly worsens the accuracy of simulation.

Two condensing substances were considered. The initial, halftime and final growth rate of particles was 2.2–3.7 nm/h for both the substances.

This work was supported by the Estonian Science Foundation through grants 8342 and 8779, and the Estonian Research Council Project SF0180043s08.

Efficient second-order time-integration for simulation of single-species aerosol dynamics

C. Winkelmann[1,*], M. Nordlund[1], A. Kuczaj[1], S. Stolz[2] and B.J. Geurts[2,3]

[1]Philip Morris International R&D, Philip Morris Products SA, 2000 Neuchâtel, Switzerland
[2]Department of Applied Mathematics, University of Twente, 7500 AE Enschede, The Netherlands
[3]Department of Applied Physics, Eindhoven University of Technology, 5600 MB Eindhoven, The Netherlands
Keywords: CFD, aerosol formation, aerosol dynamics, time integration.
[*]Presenting author email: christoph.winkelmann@pmi.com

The dynamics of a single-species aerosol composed of water droplets in air is described in terms of nucleation, evaporation and condensation processes. Fast nucleation bursts that initiate formation of aerosol droplets co-exist with comparably slow condensation, which is responsible for the subsequent growth of the droplets. In order to accurately represent the dynamical consequences of the fast nucleation process, while retaining numerical efficiency, a new time-integration method for the nucleation, evaporation and condensation terms is proposed.

The new time-integration method is second-order accurate in time also in the general case of solution-dependent transport coefficients. The computational costs per time step were found to be increased by less than 50% compared to the reference Euler forward method. For a spatially homogeneous model system, a speed-up with a factor of up to several hundred was observed in selected cases.

The second order method is also applied in spatially varying situations involving convection-diffusion transport of the aerosol forming vapor inside a pipe geometry. We employ first order upwinding for the spatial discretization to capture sharp spatial variations, e.g., in the aerosol number density. Comparison with the Euler forward method allows identifying physical and numerical parameters for which the benefits of the new method, in terms of both accuracy and efficiency, are significant.

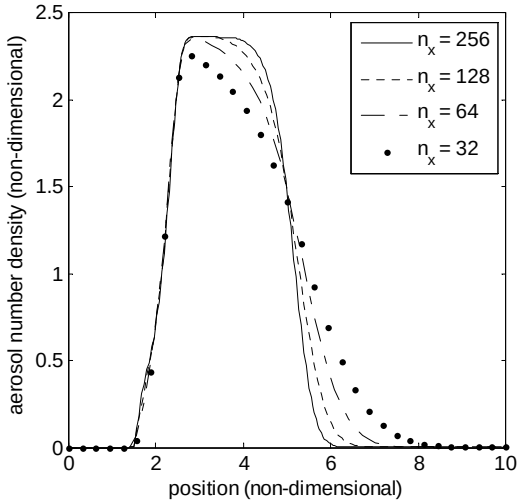

Figure 1: Convergence of aerosol number density with refinement of spatial discretization (n_x). Shown is the solution at the characteristic dimensionless time *t=5* at which a nucleation burst clearly developed.

We concentrate on the development of a front of rapid nucleation. In Figure 1, we observe the aerosol number density at a characteristic time for several spatial resolutions. A clear convergence is observed towards a sharp profile. The convergence with respect to a reduction of time step is illustrated in Figure 2. In the case shown, the Euler forward method is about a factor of 10 less accurate at equal time step. Conversely, at given desired accuracy level, the computational cost is reduced by a factor of up to 10 by the proposed scheme, even though only first order convergence is achieved in view of the selected spatial discretization.

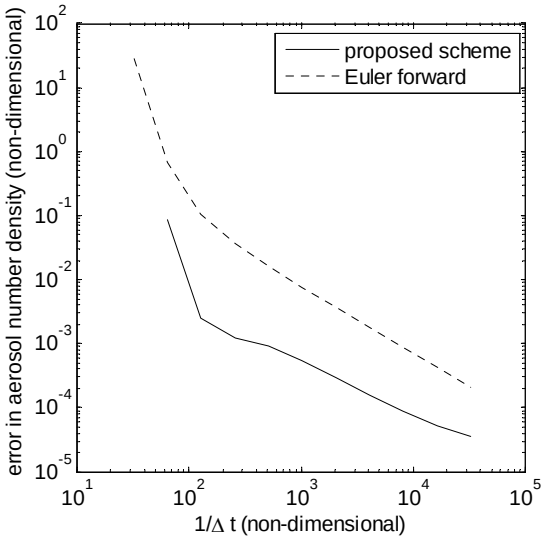

Figure 2: Convergence of aerosol number density with refinement of time discretization.

A complete overview and analysis of the new method for a range of physically realistic parameters will be presented at the conference. Extension to multi-dimensional nucleation fronts is subject of current research.

The mechanism in force of tearing-off of daughter droplets is a base of the theory of parent drop shattering in gas flows. It was shown earlier that hydrodynamic instability of "gradient instability" type describes adequately the known features of the process for weak-viscosity liquids. It is grounded on the concept of quasi-continuous high-frequency periodic dispersion of daughter droplets from unstable part $\varphi_{cr}<\varphi<\pi/2$ of parent drop surface due to action of gradient instability in conjugated boundary layers with due regard to changing of velocity profile across the boundary layers. In speedy flows, when the criterion of gradient instability $\mathrm{GI}\equiv \mathrm{We_d}\,\mathrm{Re_d^{-0.5}} \gg \mathrm{GI_{cr}} \approx 0.3$, values of polar angle of critical point are small: $\varphi_{cr} \ll \pi$, so, most part of drop surface generates a mist of droplets. This mechanism differs from that of Kelvine – Helmholtz type and it is caused by a large enough velocity gradient inside liquid boundary layer.

The foundations of drop breakup theory for speedy flows were laid in (Girin, 2011, a, b, c), where the application of approximative analytical approach, based on gradient instability mechanism, allowed to derive the governing differential equations of shattering process: of drop mass efflux (ablation law) and of torn-off droplets quantity together with the characteristic scales for their sizes and quantity. These equations demand simultaneous solution of drop motion equation in order to determine relative velocity, and of equation for transient critical conditions of instability – to determine $\varphi_{cr}(\tau)$. Their integration provides all the necessary relations of the theory of shattering process.

For speedy flows and spherical shape of drop we have obtained by integration the law of drop ablation $M(\tau)=\left(1-A\left(\tau-\alpha^{1/2}X_{\mathrm{d}}(\tau)\right)/3\right)^3$, that indicates the direct influence of drop motion law $X_{\mathrm{d}}(\tau)$. Then at approximation of experimental data for drop velocity versus time in the form $W=1-\exp(-H\tau)$, or $\alpha^{1/2}X_{\mathrm{d}}(\tau)=\tau-(1-\exp(-H\tau))/H$, we have integrated the equation of drop mass efflux and have obtained the drop mass history: $M=\left(1-h(1-\exp(-H\tau))\right)^3$ (here $h=A/3H$ is the ratio of initial mass efflux rate $A=0.46\left(1+(\alpha\mu)^{1/3}\right)^{-1}\left(\mu^2/\alpha\right)^{1/6}$ to the rate $H=2\alpha^{1/2}$ of relaxational decreasing of relative velocity of shattering drop and gas flow, $\alpha=\rho_{\mathrm{g}}/\rho_l$ and $\mu=\mu_{\mathrm{g}}/\mu_l$ are density and viscosity ratios of gas and liquid).

The distribution function $f_{\mathrm{n}}(r,\tau)$ was then obtained by integrating the equation of torn droplets quantity and the distributions $\Delta n(\tilde{r})=f_{\mathrm{n}}(r)\Delta r$ for various h, Re_∞ were calculated. Formula for $f_{\mathrm{n}}(r,\tau)$ allows to calculate intermediate distribution of droplets torn-off to arbitrary time moment. The analysis showed, that values of h slightly higher than $h=1$ are inherent to flows behind shock and detonation waves, the values $h>4$ correspond to ablation of liquid meteoroids and the case $h<1$ – to incomplete shattering of viscous drops. When $h>1$, the entire drop is dispersed to the moment $\tau_{\mathrm{b}}=H^{-1}\ln\left(h/(h-1)\right)$. When $h<1$ dispersing terminates before the drop is completely shattered, because of quick reducing of main reason of dispersing – relative velocity.

In view of lack of empirical data about laws of drop motion for various gas-droplets systems the main relations of shattering drop kinetics were obtained again, but on reliable ground of theoretical laws. They were found analytically as solutions of a system of non-linear differential equations of drop motion, drop mass efflux and quantity of torn droplets in a speedy uniform gas stream at neglecting by drop deformation influence. The two approaches of determination of drop motion law, which are based on empirical and theoretical methods, have lead eventually to similar distribution functions, but theoretical approach has the advantage being independent from lack of empirical data, so obtained formula is applicable to any gas – droplets system.

Obtained theoretically main regularities of shattering process: distribution function of torn daughter droplets by sizes, law of motion of shattering in gas stream parent drop and law of parent drop mass ablation give the opportunity to build mathematical model for further processes of rapid acceleration and evaporation of the mist of stripped daughter droplets in a wake of shattering parent drop.

Fugitive emissions pose problems both for general air quality as well as for the operational management of facilities. Harbours activities such as loading, unloading and transport of dusty materials, are important sources of particles fugitive emissions. Therefore, harmful health effects of atmospheric particles in harbours may be originated by the handling of huge amounts of pulverulent raw material (including hazardous chemicals) that are managed in harbours (Gupta *et al*, 2002; Lucialli *et al*, 2007 and Gómez-Ollés *et al*, 2007).

The aim of this study was: 1) to characterize particulate matter emitted during unloading operations of fertilizer, phosphorite from Syria, phosphorite from Morocco, and sugar; 2) to compile an inventory of the main characteristics of $PM_{2.5}$ and $PM_{2.5-10}$, and; 3) to determine the emissions factors associated with these activities.

Results showed that manipulation of materials during harbour operations produced high emissions of particles, especially from the coarse fraction ($PM_{2.5-10}$). Figure 1 shows that the highest average concentrations were registered for phosphorite provided from Syria followed by phosphorite provided from Morocco. The lowest concentrations were measured during the handling of fertilizer and sugar.

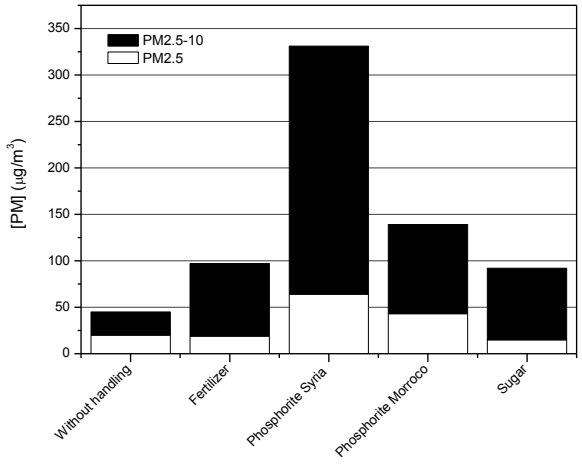

Figure 1. PM average concentrations measured in the harbour during the bulk materials handling (values in $\mu g.m^{-3}$).

PM10 concentrations discriminated by wind direction confirmed that the location of the sampling stations in relation to the wind direction is essential to evaluate the impact of fugitive emissions.

Emission estimations are usually based on emission factors provided by classical handbooks, U. S. Environmental Protection Agency reports labeled as AP-42 available at the EPA web page (http://www.epa.gov/ttn/chief/ap42/index.html) for different bulk handling and batch drop operations. Unfortunately, there are not specific harbour operation emission factors which take into account the unique conditions that exist in these coastal places.

This study processed experimental data to estimate the emission rate variation during the experiments, and the emission factors from each handling operations. This was done by applying a reverse dispersion modeling technique applying a high resolution Lagrangian puff model. This approach uses particulate matter concentration measured values and the atmospheric conditions to estimate emission rates, assuming that the contribution of a source to the concentration at a receptor is the product of the source emission rate and an atmospheric dispersion factor (Henry *et al* (1984). Crossing results with the quantities of handled material, for each period of time, provided specific emission factors.

Finally the comprehensive analysis of measured values and modeling results allowed to better characterize fugitive emissions in harbours and to develop specific emission factors from the handling operations, considering different types of raw material.

Detailed understanding of the partitioning of biogenic hydrocarbons to the aerosol phase is important when trying to quantify their aerosol forming potential. Several different processes can be associated with secondary organic aerosol (SOA) and information is required about the forming mechanisms of low- and semi-volatile organics. For example, semi-volatile compounds can either be locked in the condensed phase or be present in both the gas and particle phase. Modeling-based studies suffer from the lack of quantitative information of different partitioning processes and therefore, aerosol (smog) chamber data is needed to offer an optimal platform for both model verification and development.

The dynamical model applied in this study is SALSA (Kokkola *et al*, 2008) which includes subroutines for aerosol condensational growth, coagulation and nucleation, as well as for aerosol size distribution and its time-dependent behaviour. SALSA model running time was 8 hours and nucleation was handled by inserting measured data for the first two bins in the model. Next, the particle number concentration time evolution predicted by SALSA was compared to the chamber measurement data and first model run results can be seen in Figure 1.

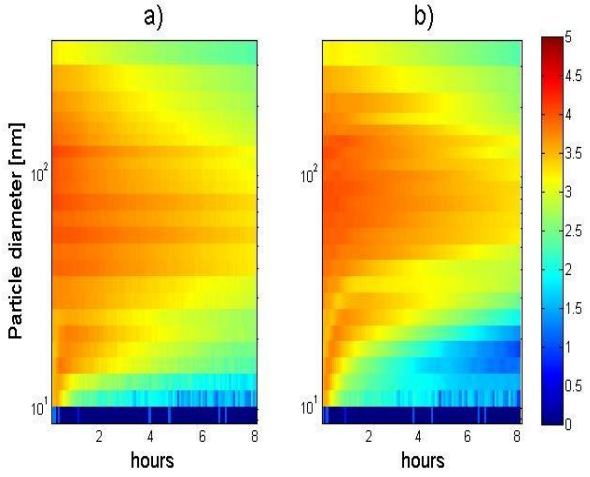

Figure 1. Left: the measured particle number concentration (cm^{-3}) as a function of time (h) and diameter (nm). Right: simulated particle number concentration. The particle number concentration is presented in a logarithmic scale with a maximum of 10^5 cm^{-3}.

For the condensing species, a basic two – product model was applied (for example, see Bowman *et al* (1999). In addition, wall loss of the gases was included in the calculations. The simple precursor gas – phase chemistry was based on the reaction between ozone and alpha-pinene that was similar to the measurement. Aerosol wall deposition rate was determined by fitting a first-order wall loss curve for each size class (by using data 4.5 hours after the outset of the measurement) and by combining the fit results to obtain a wall loss function for polydisperse aerosol population (see Figure 2). Measurement was performed in a Teflon coated chamber with a volume of 5.8 m^3; details of the chamber can be found in Hao *et al* (2009).

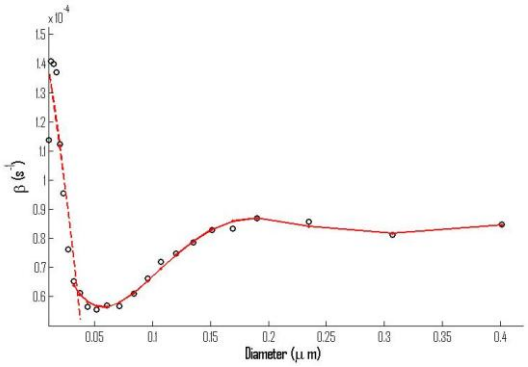

Figure 2. Particle wall deposition rate (s^{-1}) as a function of the particle diameter (μm). Two separate fits were performed (for small and for larger particles) and the results were combined to obtain a polydisperse wall loss function.

Oxidation of SO_2 by $O_2^-(H_2O)_n$ molecular clusters – a density functional theory study

N.T. Tsona[1], N. Bork[1,2] and H. Vehkamäki[1]

[1]Department of Physics, University of Helsinki, Helsinki, 00014, Finland

Keywords: Ion-induced nucleation, aerosol catalysis, charged particles, molecular clusters.
Presenting author email: narcisse.tsonatchinda@helsinki.fi

One of the most active areas of atmospheric chemistry is related to understanding cloud formation. The first step in this mechanism is known as nucleation, and despite much research dedicated exclusively to this process, it is still not properly understood.

Although clouds are mainly composed of water, it is well known that at least one other particle or chemical is needed to initiate the nucleation. In numerous studies sulphuric acid has been identified as the primary candidate for this (Kulmala *et al.* (2004)).

The most important mechanism of H_2SO_4 formation is the well known UV induced oxidation of SO_2. It follows a neutral pathway.

$$OH + SO_2 + M \rightarrow HSO_3 + M \quad (R1)$$
$$HSO_3 + O_2 \rightarrow SO_3 + HO_2 \quad (R2)$$
$$SO_3 + H_2O \rightarrow H_2SO_4 \quad (R3)$$

Currently, the properties of atmospheric ions are receiving increased attention from both theoretical, field based, and chamber studies. It has thus firmly been established that ions increase nucleation rates and hence aid cloud formation. However, the underlying mechanism is currently unknown. Several possible mechanisms may be responsible but since ionic chemistry also opens a mechanism for formation of sulphuric acid this might explain the observations.

It is well known that the majority of atmospheric ions originate from cosmic ray impacts, producing free electrons and a variety of cations. A free electron may easily attach to O_2 with an energy gain of ca. 40 kJ/mol. The resulting ion has been found to form stable clusters with at least 5 water molecules (Bork *et al.* (2011)).

Few chemical properties of $O_2^-(H_2O)_n$ clusters have been investigated but experiments have shown that

$$O_2^-(H_2O)_n + SO_2 \rightarrow SO_4^-(H_2O)_n \quad (R4)$$

for n = 1 and 2. Further, it has been shown that the reaction is fast at ambient temperatures (Möhler *et al* (1992)). Also in recent field measurements SO_4^- has been observed (Ehn *et al* (2010)). SO_4^- is hence known to be stable and it seems plausible that SO_4^- may react further to H_2SO_4 or a related species and thereby contribute to nucleation and cloud formation. This confirms the need to understand the origin of SO_4^-.

However, neither the structures, the reaction mechanism, nor the possible catalytic effects of water molecules are properly understood.

The main goal of this research is to provide a plausible mechanism and reaction rates for the formation of SO_4^-. We have used density functional theory calculations and basis sets successfully used in previous studies.

Since it is known that the reactants are containing at least 5 water molecules, we have included that amount in our studies. We model the entire reaction from the initial collision and clustering, over intermediate structures (see Figure 1) to products.

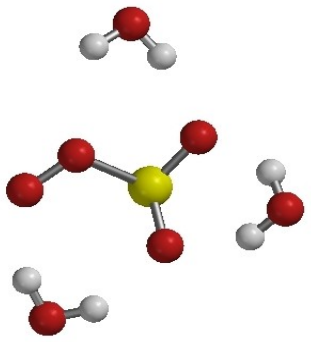

Figure 1. Stable configuration of the $SO_2O_2^-(H_2O)_3$ cluster. Sulphur (yellow), oxygen (red) and hydrogen (white). The cluster is stabilized by hydrogen bonds.

The following results will be reported and analysed:

- the structures of hydrated clusters
- the thermodynamics of the reactions
- the cluster populations at varying conditions
- the dynamics of the reactions
- the kinetics of the reactions
- comparison to experimental results and field studies
- the atmospheric relevance of the reaction

Presenting author email: kai.ruusuvuori@helsinki.fi

Understanding the birth and interaction mechanisms of atmospheric aerosols is essential if we are to understand e.g. climate change and the health effects of aerosols.

Our aim is to study the absolute values of proton affinities using quantum chemical methods. These methods will be applied to several molecular ion species that have been observed by Ehn *et al.* (2010). Proton affinity is a measure of gas-phase basicity and is an important thermodynamic quantity. However, absolute gas-phase proton affinities are hard to measure, which makes theoretical methods a valuable tool in determining these absolute values.

We have begun our study by a series of benchmark calculations, where several different computational methods have been used to calculate the proton affinities of ammonia (NH_3) and pyridine (C_5H_5N). The obtained values have been compared to results listed in the National Institute of Standards and Technology (NIST) database. For the case of ammonia and pyridine, the NIST values for the proton affinity are from a review article by Hunter and Lias (1998) and are theoretical values calculated at the G2 level of theory.

Quantum chemical calculations of proton affinity have been performed using Gaussian 09 and Turbomole 6.3 quantum chemistry programs at the following levels of theory: G2MP2, G2, G3, G4, CBS-QB3, CBS-APNO, W1BD and B3LYP/6-31++G(2df,2pd)//RI-MP2-F12/cc-pVDZ-F12. Due to computational limitations, the W1BD method has only been used for ammonia. The resulting proton affinities are listed in Table1.

Table 1. Proton affinities in kcal/mol for the reactions $NH_3 + H^+ \rightarrow NH_4^+$ and $C_5H_5N + H^+ \rightarrow C_5H_6N^+$ calculated from standard enthalpies (1 atm, 298.15K).

Method	PA(NH_3) [kcal/mol]	PA(C_5H_5N) [kcal/mol]
G2MP2	204.008	222.238
G2	204.040	222.232
G3	204.619	222.407
G4	204.363	222.505
CBS-QB3	204.186	221.600
CBS-APNO	204.420	222.366
W1BD	204.062	-
A*	202.540	219.605
NIST(G2)	204.015	222.275

*B3LYP/6-31++G(2df,2pd)//RI-MP2-F12/cc-pVDZ-F12

The results of the benchmark calculations show that only results obtained with the B3LYP/6-31++G(2df,2pd)//RI-MP2-F12/cc-pVDZ-F12 method differ from the NIST values by more than 1 kcal/mol. Out of all the listed methods, the W1BD method should, at least in principle, provide the most accurate results. The W1BD is also the most demanding computationally and computational resources will not permit its use in the remaining part of our study. All the CBS-methods proved to be quite similar to each other in performance as did the different G-methods. In addition, comparison between the CBS- and G-methods shows that similar accuracy is obtained. Since the CBS-QB3 method should be significantly faster than the G-methods and is also available for second row atoms in Gaussian 09, whereas the CBS-APNO is available only for first row atoms, it would make a good choice for the remaining proton affinity calculations. However, the benchmark calculations of CBS-4M are still underway and since the Gaussian 09 manual recommends it for new studies over the CBS-QB3, our final choice of method is still at the moment undetermined.

Once the CBS-4M results are obtained and the choice of theoretical method made, we will proceed to calculate the proton affinities of positively charged ions observed by Ehn *et al*. (2010).

Particle generation in electric arc: experiment and modelling

V.A. Zagaynov[1], E.V. Zhukova[1], A.A. Lushnikov[1], Yu.G. Biryukov[1], I.E. Agranovsky[1,2], V.V. Maksimenko[1]

Keywords: electric field, particle generation, modelling
Presenting author email: zagaynov@cc.nifhi.ac.ru

Particle generation in atmospheric and laboratory conditions is very important part of aerosol dynamics. The matter of fact, very often the particles of different sizes are generated in electric arc and electric discharges. There are great experimental data on the particle generation in these conditions; at the same time till now the corrected theory on this subject is absent. During electric discharge there are several physical processes, which can lead to particle generation and to extract most important is hard problem. The flow of free electrons and ions collide with metal surface, they knock out electrons, selected atoms, and molecular clusters. The temperature in this local space exceeds several thousand degrees, and when this vapor finds themselves in cold air, it begins to create aerosol particles of different sizes. At the same time metal molecular clusters and particles, which were kicked out from metal surface. At high temperatures they become liquid and take spherical form. This picture was found under electron microscope after sampling particles from arc discharge.

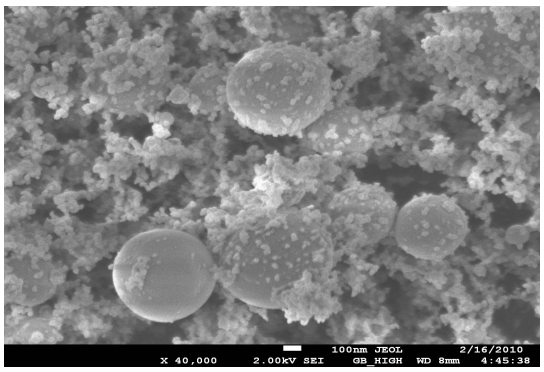

Figure 1. Photo image, obtained under electron microscope of silver particles, created in arc discharge.

It may be seen from this picture, that two mode particle size distributions was formed. There are large particles, which size is in the range between 300 and 700 nm, and small particles which size in the range between 10 and 30 nm. It may explain by two processes which responsible for particle generation. First of all large particle were kicked out from metal surface as molecular or atomic clusters, at large temperatures they become liquid and take spherical form, as may be seen from the picture. They have not enough time to be evaporated and after cooling save their spherical form. Secondly, there are many small particles, which were formed by volume condensation of metal vapors.

To control particle generation diffusion aerosol spectrometer and SMPS were used. They showed the same results. To get more information on particle generation in these conditions the computer modeling was involved. To this end the kinetic equation of particle coagulation was written:

$$\frac{\partial c_g}{\partial t} = I(g) + \frac{1}{2}\int_0^g K(g-n,n)c_{g-n}c_n dn + c_g \int_0^G K(g,n)c_n dn$$

here c_g –concentration of the particles, which composed of g monomers, $I(g)$ – source power of particles, consisted of g monomers, $K(g,n)$ – collision frequency between particles consisted of g and n monomers. To adjust it to computer calculations the axis of particle sizes was divided into fractions by logarithmic scale (Zagaynov and Lushnikov, 1988). It allowed to cover particle size range between 1 nm and 10 micrometers. To approach modelling results to reality the random factor was used (Lushnikov and Zagaynov, 1989).

The results allowed to clear up processes of particle generation.

Presenting author email: cfountoukis@iceht.forth.gr

Three dimensional Eulerian Chemical Transport Models (CTMs) are often used for the design and assessment of air pollution mitigation policies. Grid resolution is a critical factor for these models since a large model grid size cannot capture inhomogeneities in emission rates, meteorology and land cover while a very small grid size makes the simulation inefficient due to the large computational cost. The lack of adequate resolution limits also the ability of the model to accurately simulate individual processes and their interactions.

In this work, we use the regional CTM PMCAMx (Fountoukis et al., 2011) in a two-way nesting configuration to study the impact of different grid resolutions on fine particulate matter predictions at two domains, the North Eastern United States and Western Europe during a summer and winter period. In the US domain we use model grids of 36 and 12 km and PM measurements taken by the IMPROVE and STN monitoring networks, while for the European domain high time resolution AMS measurements were used to evaluate the performance of the model at 36 km and 4 km grids. For the US nested subdomain the model interpolates the input emission data from the coarse grid while for the European nested grid high resolution (~ 1 × 1 km) emissions are used.

During the July 2001 period use of both grid resolutions results in very similar predictions for $PM_{2.5}$ sulfate and organics over the Eastern US. The higher resolution slightly improves predictions of OA for the mostly rural (IMPROVE) sites, while for the mostly urban (STN) sites the model underpredicts both major $PM_{2.5}$ components with either the 36- or the 12-km grid spacing with roughly the same magnitude. During the January 2002 period there is a clearer improvement in the model predictions in both monitoring networks mainly for fine organic aerosol and elemental carbon.

In an effort to stress more the differences between the two model grid configurations we combined high resolution emissions (1 × 1 km) with AMS measurement data and applied an even higher model grid resolution (4-km) over a Megacity in Europe. For particulate sulfate, the model predicts negligible differences in the two simulations at all sites (both urban and suburban) even on an hour-by-hour basis during both the July 2009 and the January 2010 period. Similarly to the Eastern US domain, the differences between the two grid simulation results in the Paris area are, on average, small for all species during the summer period. During the winter period there are some significant differences in model predictions of mainly primary organics (Fig. 1) and black carbon. The major differences are seen for the maximum (morning peak) values in the two most polluted sites (LHVP and GOLF). The 4-km grid simulation captures the average diurnal concentration of fine organic aerosol better than the coarse grid.

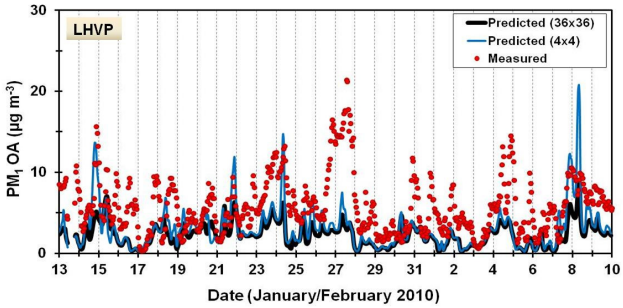

Figure 1. Timeseries comparison of predicted vs. observed PM_1 OA concentration in Paris center (LHVP station) during winter 2010.

Overall, the improvement in model predictions with the fine grid is modest during the summer and somewhat more significant during wintertime at both domains. The use of very high resolution emissions in the Megacity of Paris does not reveal a significant improvement in the predictions of the fine grid simulation. These results suggest that the major reasons for the discrepancies between the model predictions and observations in both seasons and at both domains are not due to the grid size used, but to other problems (e.g. emissions, process description, and meteorology).

This work was funded by the European Community's 7th Framework Programme EU project PEGASOS.

In this study, a mechanistically complete and time-dependent model, Observation-BAsed Model for Ambient Particulates (OBAMAP), is developed for resolving chemistry processes, thermodynamic equilibriums and size distribution of secondary inorganic aerosols (SIA) in an urban atmosphere. OBAMAP uses in-situ atmospheric and meteorological observations to determine the sensitivity of sulfate and nitrate concentrations to changes in their precursors (i.e., volatile organic compounds, nitrogen oxides and sulfur dioxide). OBAMAP is relatively easy and inexpensive to operate and makes use of data that are increasingly available in China and other developing countries, thereby offering a cost-effective tool for the analysis of SIA-precursor relationships in an urban atmosphere.

To demonstrate the applicability of OBAMAP, we first compare the simulation results of hydroxyl radicals with ambient observations. The OBAMAP is then applied on a wintertime pollution episode in Hong Kong to gain insight into relevant physical and chemical processes of SIA formations and to shed light on ways of effective control strategy formulation in Hong Kong. The results suggest local processes contrite more significantly on ambient NO_3^- and SO_4^{2-} levels during the episode period than the normal period. The major pathway responsible for the production of NO_3^- is the reaction of OH and NO_2 in the gas phase, while the aqueous phase oxidation of $S_{(IV)}$ by NO_2 shows the most significant contributions on SO_4^{2-} production. Local processes contribute 78.4% enhancement of NO_3^- and 14.0% enhancement of SO_4^{2-} in the episode hours (hours with Air Pollution Index>100). Formation of $PM_{2.5}$ NO_3^- is somewhat more sensitive to the reduction of NO_x and anthropogenic volatile organic compounds (AVOC) concentration. For each percent reduction in NO_x and AVOC, a 0.53 and 0.66% reduction in mass of NO_3^- formation would result in, respectively. Reduction of SO_4^{2-} formation is most sensitive to reduction of SO_2 and it would become more effective when more SO_2 has been reduced.

Simulation of Droplet Nucleation and Growth in a Laminar Counterflow via the Quadrature Method of Moments

A.O. Alshaarawi, K. Zhou and F. Bisetti

The solution of the General Dynamic Equation (GDE) is an essential step for simulating multiphase flows. Applications include the study of soot formation, spray combustion and air pollution.

In the current study, the dynamics of the nucleation and growth of di-butyl-phthalate (DBP) droplets are simulated in a counterflow configuration. A cold stream of nitrogen mixes with a hot one saturated with DBP vapor. Near the stagnation plane, temperature drops and nano-size droplets of DBP nucleate and grow due to heterogeneous nucleation. As the number density of particles increases, coagulation affects the population balance.

The flow field is simulated with a stream-function formulation due to Kee et al. (1989). The GDE of the particle size distribution (PSD) is integrated to obtain transport equations for moments. The Quadrature Method of Moments (QMOM) (McGraw (1997)) is used for closure. Moments are transported using a second-order upwind scheme in space and an adaptive variable-order scheme in time. Homogeneous nucleation is described by classical Becker-Döring theory and heterogeneous nucleation is modelled using the generalization of Mason's formula due to Loyalka and Park (1988).

Realizability of the transported moments was treated carefully to ensure the existence of a corresponding PSD. For this purpose, Stieltjes conditions were monitored and shown to guarantee a physical solution.

Droplets start nucleating at the cold side (right side in Figure 1) of the stagnation plane. These droplets are then convected towards the stagnation plane where they diffuse to the hot side. As particles are convected, they grow in size due to heterogeneous nucleation and the volume-averaged diameter increases.

Mass diffusion of particles modifies the spatial distribution of each moment differently, making diffusion more significant for the moments of low order, such as the number density. Nucleating droplets have a diameter equal to the critical diameter (2.3 nm). Such small particles have a high diffusion coefficient corresponding to a Schmidt number $\sim \mathcal{O}(10)$.

On the other hand, large particles with a diameter of size $\sim \mathcal{O}(1\,\mu\mathrm{m})$ have a very low diffusion coefficient corresponding to a Schmidt number $\sim \mathcal{O}(10^6)$. For higher moments such as the volume fraction, the strong dependence of the mass diffusion coefficient on the particle size results in two flow regions: a hyperbolic convective-reactive zone away from the stagnation plane and a diffusive-convective-reactive zone near the stagnation plane, where velocity vanishes and diffusion dominates.

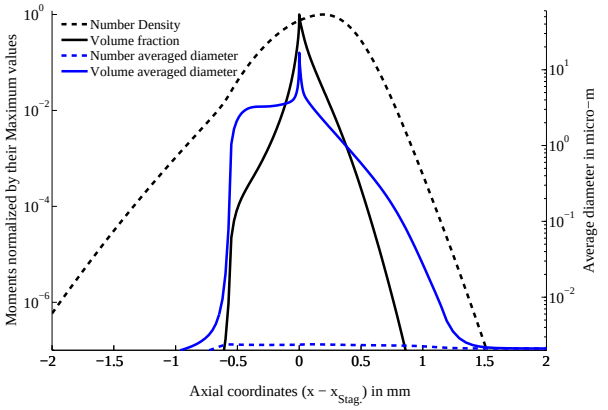

Figure 1: Distribution of different normalized Moments (in black), distribution of the number/volume averaged diameters (in blue). The flow has a nominal strain rate of 20 s^{-1} with boundaries at $T_c = 0\,^{\circ}\mathrm{C}$ and $T_h = 160\,^{\circ}\mathrm{C}$. DBP concentration at the hot inlet is 2600 ppm.

Vertical wind as the dominating factor for spatial-temporal distribution of stratospheric aerosol

V.I. Gryazin* and S.A. Beresnev

Aerosol Physics Laboratory, Ural Federal University, Ekaterinburg, 620083, Russia
Keywords: aerosol modelling, stratospheric aerosols, aerosol dynamics, vertical wind
Presenting author email*: Gryazin.Victor@mail.ru

This report continues and summarizes analysis and estimations of transport opportunities of the vertical wind in stratosphere. The developed method is based on the inclusion of the averaged fields of vertical wind retrieved from the assimilation global circulation model UKMO (http://badc.nerc.ac.uk) in the standard statistical atmospheric models. We are limited in analysis only to the monthly-averaged or annual-averaged profiles of a vertical wind (synoptic and global temporal scales for stratosphere). For the description of mechanical characteristics of motion of particles with different sizes and densities under action of gravity and vertical wind the gas-kinetic expression for resistance force, being by generalization of Millikan empirical formula, and well-worked in various problems of aerosol mechanics is used (Gryazin and Beresnev, 2011).

In this study the standard climatological analysis of vertical wind field in stratosphere over a period of a total solar cycle is presented, and surprising capabilities of the averaged vertical wind to the aerosol transport in comparison with other mechanisms (gravitational sedimentation and turbulent diffusion of particles) are demonstrated. High-altitude, temporal, and latitude dependences of zonal-mean averaged vertical wind velocity for the period of 1992-2006 from the UKMO atmospheric general circulation model are analysed. It is shown that monthly averaged amplitudes of the vertical wind are approximately ±5 mm/s, while annual averaged ones are ±1 mm/s (Beresnev et al, 2008). We have carried out the comparison of the received results with the NCEP-NCAR reanalysis data, and have found out their qualitative agreement.

The upward wind can provide the vertical lifting against gravity for sufficiently large (up to 3-5 μm) aerosol particles with a density up to 1.0-1.5 g/cm^3 at stratospheric and mesospheric altitudes. The vertical wind is a substantial factor for particles motion up to altitudes of 30-40 km, and can change essentially the sedimentation velocities and the residence times of stratospheric aerosols. The structure of the averaged fields of vertical wind supposes the opportunity of formation of dynamically stable aerosol layers in the middle stratosphere (Beresnev et al, 2009).

For the problem about action of a permanent source of monodisperse particles near the stratopause, it is shown that action of the averaged vertical wind along with the gravitational sedimentation and turbulent diffusion changes the standard vertical profiles of the relative concentration of particles cardinally. Estimations for the levitation heights for particles of different densities and sizes in the stratosphere under action of gravity and vertical wind are presented also (Gryazin and Beresnev, 2010).

Transport capabilities of the vertical wind will be especially noticeable for fractal-like particles (for example, soot particles and volcanic aerosol). It is possible that the proposed approach would allow clarifying mechanisms of accumulation of soot particles from the air transport and the ground-based biomass burning at altitudes of the lower and middle stratosphere.

The method of comparison of vertical motion characteristics for spherical and fractal-like aerosol particles in stationary atmosphere and in atmosphere under action of the averaged vertical wind is introduced. It is shown, that subsidence velocities of compact spherical and fractal-like particles can differ essentially in this case.

Thus, the advanced aerosol transport models should include with necessity the vertical wind factor for the correct analysis of post-volcanic or background stratospheric aerosol at rather long time scales. On one hand, the used database of high-altitude profiles of the averaged vertical wind contains extensive information on its latitudinal and seasonal variability for the period of 1993-2006 and useful not only for a convenient mathematical approximation, but also a rather simple parameterization of the vertical wind profiles for the following analysis. On the other hand, the question regarding the reliability and representativeness of this parameterization remains open because of the high variability of the circulation processes in the stratosphere, including the data for the vertical wind as well. We believe that this problem can be solved partly by comparing the results for several different databases, for example, the UKMO model used in this paper and the NCEP/NCAR reanalysis data.

We are grateful to the BADC which provided us with access to the UKMO Stratospheric Assimilated Data. Presents to the nearest neighbours: contribution of transboundary transport to the PM10 and PM2.5 concentrations in Central Europe with focus on NRW

Presenting author email: sabine.wurzler@lanuv.nrw.de

Despite a series of measures to improve air quality there still remains a rather high PM background concentration over highly industrialized and densely populated Central Europe. High particle concentrations pose a threat for health. Even though compliance to the EC air quality limit value for the annual average PM10 concentration (40 µg/m³) does no longer pose a major problem, the allowed number of exceedance days (35 days with daily average PM10 concentrations > 50 µg/m³), which is linked to the annual average PM10 concentration, still presents a challenge.

Source apportionments in North-Rhine Westphalia (NRW) for measurement sites with limit value exceedance show that about 75 % of the PM10 burden stems from background concentration. The background concentration is dominated by transboundary transport, especially in the western part of NRW (Fig. 1), owing to the main wind direction (west). Therefore, local measures alone are not sufficient to comply with the limit values, especially in years with adverse meteorological conditions like 2011. But how high is the contribution of the neighbouring countries to the background concentration – on their own and in comparison to the effect of a reduction of emissions until 2015?

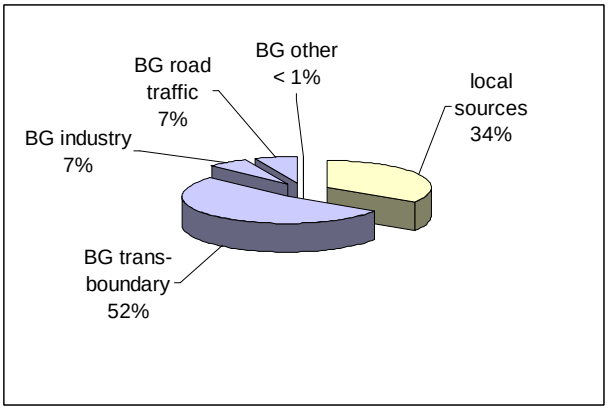

Figure 1: Source apportionment for PM10 at a curb site, Düsseldorf, Corneliusstraße, with focus on the background concentration (BG).

Scope of this paper is to estimate the contribution of Germany to the PM10 and PM2.5 loads of its neighbours downwind and the contribution that Germany, with focus on NRW, receives from its nearest neighbours upwind. For this reason simulations have been performed with the European Air Pollution Dispersion Model (EURAD, Memmesheimer et al., 2004). The EURAD model simulates the concentration due to emissions, transport, and chemical transformation. The meteorological data is computed with the dynamic model MM5. The atmospheric, transport model CTM2 solves the 3-D advection and diffusion equation together with the transformation of constituents through gas phase and heterogenous chemistry. Within CTM2 the Modal Aerosol Dynamics Model (MADE) is used to account for secondary aerosol generation (Schell et al., 2001). The EURAD model has been applied in a one-way nesting mode with two grids, spanning Europe in a horizontal resolution of 125 x 125 km² and a nested domain covering the area of Germany with 25 x 25 km². This allows the consideration of long-distance transport across Europe while retaining sufficient resolution in NRW to analyse regional changes.

Simulations were performed for the year 2009 with baseline emissions, without emissions from the Netherlands, and without emissions from Belgium and for the year 2006 without emissions from Germany. Additionally, a simulation with an emission forecast for the year 2015 was done.

For annual averages, the contributions from Germany, Belgium, and the Netherlands are of similar magnitude, though the effect from Belgium is more pronounced in the south western part of NRW, while the effect from the Netherlands is stronger in the north western part of NRW. Assuming a scenario without emissions from Belgium or the Netherlands leads to a reduction of annual average PM10 background concentration of about 5 to 10 µg/m³. The reduction in PM2.5 background concentration is smaller with up to 5 µg/m³. The contribution of Germany to the PM load in Poland and Czech Republic is of the same order.

The European wide reduction in emissions until 2015 leads to a reduction of about 5 µg/m³ PM10 and about the same for PM2.5 for all of Europe Thus, successful abatement of air pollutants is a European issue.

Some further analyses of special episodes and on further details are currently under way.

Aerosols and the uncertainty related to their climatic impact have gained increasing interest in recent years because of the on-going climate change. In order to study the effect of the aerosols on various processes of the atmosphere and on climate, modelling and different kind of observations are used. However, due to the complexity of the aerosol-climate coupling, such as the impact of aerosols on clouds and their feedback on climate, the results from the different models may show a great deviation. Thus, the comparison of different modelled aerosol properties with observational data is a useful method to improve the models and the understanding related to atmospheric processes affecting the aerosol fields.

In this work, the aerosol extinction vertical profiles achieved from the global circulation model ECHAM5-SALSA (Roeckner *et al* 2003, Kokkola *et al* 2008) are compared with the observations provided by European Aerosol Research Lidar Network (EARLINET) (Bösenberg *et al* 2003) at various stations. EARLINET is the first coordinated aerosol lidar network, established in 2000, with the main goal to provide a comprehensive, quantitative, and statistically significant database for the aerosol distribution on a continental scale. The locations of the measurement sites are shown in Fig.1. One of the main objectives of this network is to provide the necessary database for validating and improving numerical models describing the evolution of aerosol properties and their influence on climate and environmental conditions.

For the comparison in this study four EARLINET stations were selected on the basis of different predefined regions including central Europe (Leipzig), western Mediterranean (Granada), Central Mediterranean (Potenza) and East Mediterranean (Thessaloniki). The purpose of the comparison is to address two issues. First point is to study whether the model estimates the altitude of the aerosols correctly and if so, to investigate if their size distribution and composition are depicted properly in order to reproduce the observed extinction profiles. In the first stage, we study the seasonal variation and geographical distribution of aerosol over Europe. In addition, to study how the model performs in describing the different aerosol types the extinction profiles from the model are compared with the observations at different sites and regions.

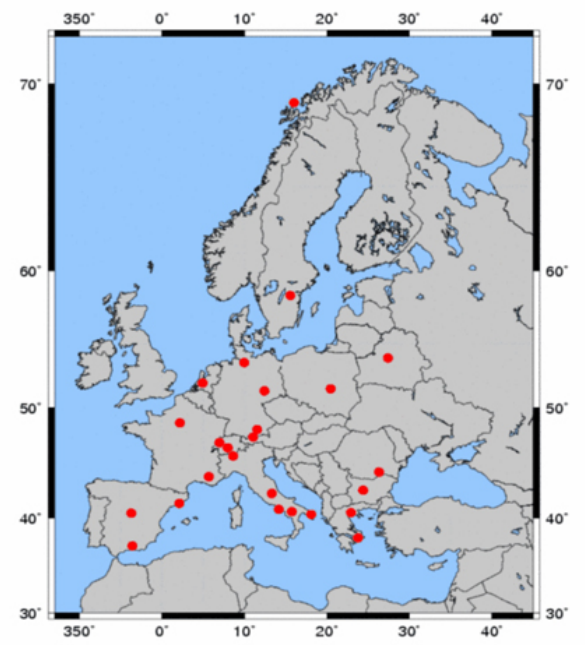

Figure 1: The locations of EARLINET measurement sites.

The results of the comparison in this study can be used to improve the representation of the emissions and removal processes in the ECHAM5-SALSA model.

The authors acknowledge EARLINET for providing aerosol lidar profiles available from the EARLINET database accessible at http://access.earlinet.org/.

Numerical simulations of mixing conditions and aerosol dynamics in the Cern CLOUD chamber

J. Voigtländer[1], J. Duplissy[2], L. Rondo[3], A. Kürten[3], F. Stratmann[1], and the CLOUD collaboration

[1]Leibniz Institute for Tropospheric Research, Leipzig, Germany
[2]CERN, PH Department, Geneva, Switzerland
[3]Institute for Atmospheric and Environmental Science, Goethe-University, Frankfurt/Main, Germany
Keywords: CLOUD, cloud chamber, modelling, mixing state, sulphuric acid, particle formation
Presenting author email: jensv@tropos.de

The Cosmics Leaving OUtdoor Droplets (CLOUD) project was established to investigate the effect of galactic cosmic rays on aerosols and clouds by studying the nucleation of sulphuric acid (H_2SO_4) particles and its dependence on ionizing radiation and additional other substances such as ammonia [Kirkby et al., 2011]. Experiments are carried out at a cylindrical electro polished stainless steel tank with a volume of 26.1 m^3, which is located at CERN (Switzerland). For the experiments it is necessary to attain spatial homogeneity regarding the prevailing thermodynamic conditions, gas concentrations and particle properties. To investigate the mixing state of the CLOUD chamber, numerical simulations were performed using a coupled computational fluid dynamics (CFD) – particle dynamics model, the so-called CLOUD-FPM [Voigtländer et al, 2011]. The model is the combination of the commercially available CFD code FLUENT (ANSYS Inc., Canonsburg, PA, USA) and the Fine Particle Model (FPM, Particle Dynamics GmbH, Leipzig, Germany). CLOUD-FPM is capable of handling the coupled fluid and particle dynamical processes taking place inside the CLOUD chamber as all relevant properties like velocity, temperature, pressure, turbulence parameters, wall losses of the condensable gas phase species and particle nucleation/growth are treated explicitly.

The flow field in the CLOUD chamber was investigated by adjusting the model to measured 1-D velocity profiles. With the adjusted model, the calculated temporal evolution of the H_2SO_4 concentration was found to be in good agreement with the experimental data. Time resolved calculations were also carried out to estimate time scales for mixing the tank's contents and to simulate nucleation and growth of H_2SO_4 particles. The simulations showed that two fans are necessary to mix the tank properly [Voigtländer et al., 2011].

Here, we present simulation results of the current set up of the CLOUD chamber in addition to prevailing measurements of the flow field, H_2SO_4 concentration and particle nucleation. These simulations are the consequent continuation of the previous investigations with the CLOUD-FPM model [Voigtländer et al., 2011]. Aim of the calculations is to evaluate the mixing conditions, controlled by fan speed and fan configuration, and their dependence on the ongoing modifications at the chamber. Calculated volume-to-surface exchange times were compared to internal mixing times. Thereby, internal mixing was simulated using a small regional source of a tracer species. The simulations show that the volume-to-surface exchange and therewith the wall loss of several trace gases increases with increasing fan speed. On the other hand the simulations indicate that at low fan speeds the exchange between lower and upper half of the tank decreases due to the low efficiency of the fan hoods and the resulting divergent flow field at low flow velocities. It can be concluded that sufficiently high fan speeds have to be used to ensure internally well mixed conditions in the CLOUD chamber.

Experimental Studies on Tin Oxide Dry Aerosol Deposition in Piping assembly under Flow and High Thermal Gradient conditions: Comparison with SOPHAEROS code

Rajni Modi[1], Arshad Khan[1], Sunil Ganju[2], Manish Joshi[1], Pallavi Khandare[1], B. K. Sapra[1] and Y. S. Mayya[1]

[1]Radiological Physics and Advisory Division, [2]Reactor Safety Division,
Bhabha Atomic Research Centre, Mumbai 400085, India
Keywords: Reactor accident, piping assembly, aerosol, deposition, SOPHAEROS.
Presenting author email: rajnimodi@gmail.com, rajnim@barc.gov.in

During a severe nuclear reactor accident involving core melt down condition, the deposition of fission product (FP) aerosols in the primary heat transport (PHT) system will lead to a reduction in the source term to the containment and subsequently to the environment.

This study aims to experimentally quantify the deposition in the PHT and to explore the capability of SOPHARERROS (a module of the Accident Source Term Evaluation Code (ASTEC) dealing with transport and retention of FP aerosols in the PHT of a reactor system) to reproduce the experimental results. In line with this, a small scale piping assembly has been fabricated and installed at Nuclear Aerosol Test Facility (NATF) at Bhabha Atomic Research Centre, India. This assembly, having a total length of 3m, consists of nine pipe sections, of which six are straight cylindrical sections and three are 90° bend sections. To simulate the reactor accident conditions, tin oxide aerosols have been generated using a plasma torch aerosol generator based on the evaporation-condensation technique (Sapra et al. 2008). The generated aerosols were transported to the assembly via a double walled water cooled plenum chamber using Argon carrier gas.

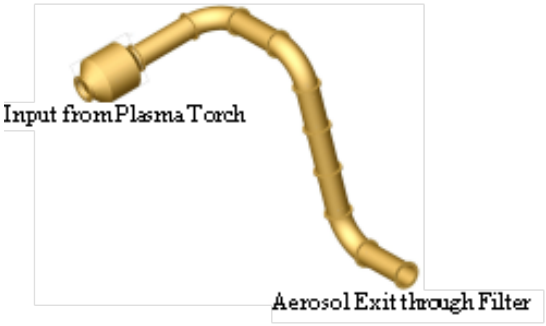

Figure1: Piping assembly

Experiments have been performed at two carrier flow rates of 135.5 lpm (laminar regime) and 237.5 lpm (Transition regime). The results showed that 47.36% and 40.75% deposition of tin oxide aerosols occurs in the whole system in experiment I and II respectively. However, a deposition of 17.40% and 15.50% was found in the piping system alone excluding the plenum chamber. SOPHAEROS results were within 7.96% and 17.51 % in case of experiment I and II respectively. The code predicted depositions of 76.48% and 23.16% due to thermophoresis and settling respectively in experiment I; while the respective depositions in experiment II were 88.19% and 11.38%. The increase in the thermophoretic deposition is attributed to increased thermal gradient in the latter experiment. Bend impaction and laminar diffusion did not play a significant role.

The XRD of deposited tin oxide particles confirms the formation of both SnO_2 and SnO.

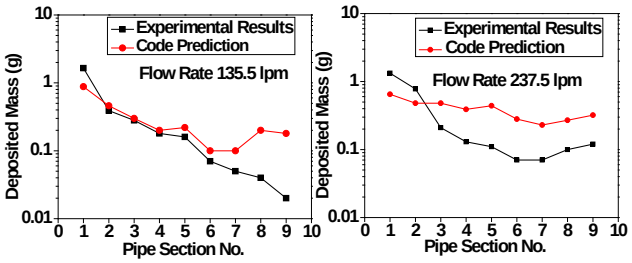

Figure 2. Comparison of experimental and code predicted results

Also, as analyzed by TEM pictures, primary particles showed a mode at around 15nm present in all pipe sections. Although some bigger particles in the size range of 50 to 100nm are also seen, it is difficult to say that the distribution is bimodal at this point.

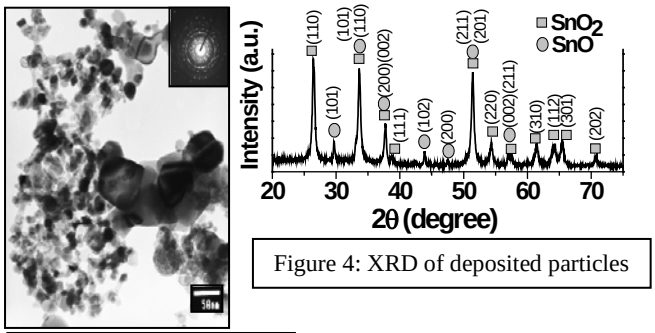

Figure 4: XRD of deposited particles

Figure 3: TEM of deposited particles

Evaluation of black carbon estimations by the regional aerosol-climate model REMO-HAM

A.I. Hienola, J.-P. Pietikäinen, A.-P. Hyvärinen, H. Lihavainen and A. Laaksonen
Finnish Meteorological Institute, Helsinki, FI-00101, Finland
Keywords: black carbon, regional modelling.
Presenting author email: anca.hienola@fmi.fi

Black carbon (BC), a product of incomplete combustion of fossil fuels and biofuels, is thought to contribute to global warming since pre-industrial times. When emitted into the atmosphere, BC directly warms the air by absorbing the incoming solar radiation and subsequently emitting thermal-infrared radiation into the surrounding space. Due to the complex mechanisms through which BC affects the radiation balance, estimating the impact of black carbon on climate change remains largely uncertain.

In this study, we evaluate black carbon model prediction from the regional aerosol-climate model REMO-HAM by comparing modeled data with available measurements from five remote sites in Finland (Hyytiälä, Pallas, Puijo, Virolähti and Ujö) for the year 2005 (Hyvärinen *et al.* (2011)), with focus on Hyytiälä station as a case study. The model-measurement comparison includes black carbon surface concentrations, the seasonal trends and black carbon concentrations in relation to some meteorological factors. We also used nonparametrical statistical tools for quantifying the agreement between the model and the observations.

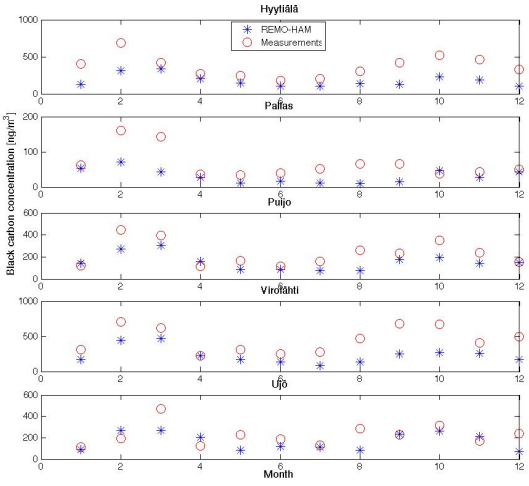

Figure 1: Monthly means of experimental (circles) and modeled (stars) black carbon concentrations in 5 Finnish stations for 2005.

The tool used in this study is the aerosol-climate model REMO-HAM, an improved version of the regional climate model REMO (Jacob(2001)), in which Pietikäinen *et al.* (2012) has recently implemented the aerosol module HAM-M7.

The monthly means of modeled and measured black carbon surface concentration for the 5 station are shown in Figure 1. A seasonal variation is detected for all stations, with a maxima in late winter/early spring and a second maxima in the autumn, potentially due in part to lower mixing height levels during this time of the year. The model reproduces to a certain extent the cycle. However, REMO-HAM agrees better with the measured values during the non-maxima period, while for the maxima periods the model underestimate is more evident.

The (dis)agreement between the model and the observation in can be accurately described by the overlap coefficient (OVL) of the probability distribution curves and the Mann-Whitney test (the Z-coefficient). The disadvantage of OVL is that its magnitude does not show where the common area is. As such, nonparametric density functions

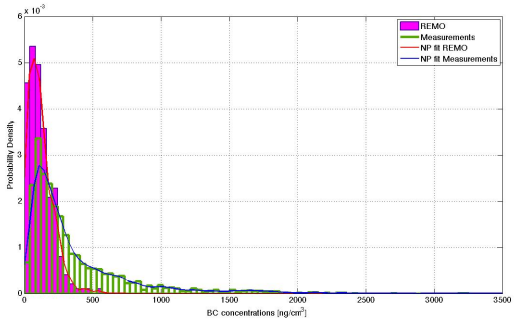

Figure 2: Histograms and nPDFs for black carbon concentrations - Hyytiälä 2005.

(nPDF) for the measured and computed 3-hourly resolution black carbon concentrations were used for Hyytiälä (Figure 2). The model fails in providing concentrations higher than 500 ng/m^3. This underestimation might be caused either by an excessive loss of black carbon in the model or by missing emissions during these periods of time. These hypothesis are discussed.

Effects of vapor properties on modelled particle growth in the model UHMA

A. Rusanen[1] and M. Boy[1]
[1]Department of Physics, University of Helsinki, Helsinki, Finland
Keywords: Organic aerosols, Particle growth, Aerosol modelling, Aerosol dynamics.
Presenting author email: anton.rusanen@helsinki.fi

The effect of changing the physical properties of a condensing vapor in a model run was tested and the effects on particle growth and composition were observed. The model used for this task was the University of Helsinki Multicomponent Aerosol model, abbreviated UHMA, which was first introduced in Korhonen *et al* (2004).The results were also compared with theory. The properties investigated were vapor density, surface tension and molar mass. In addition, effects of changes in ambient temperature and pressure, were tested.

Since the amount of possibly important organic compounds in the atmosphere is too large to simulate in most cases, we are currently using representative vapors. These sum up the contributions of several compounds into a single species. This results in the problem of determining appropriate physical properties for these representative vapors so that they can still accurately represent growth and particle composition.

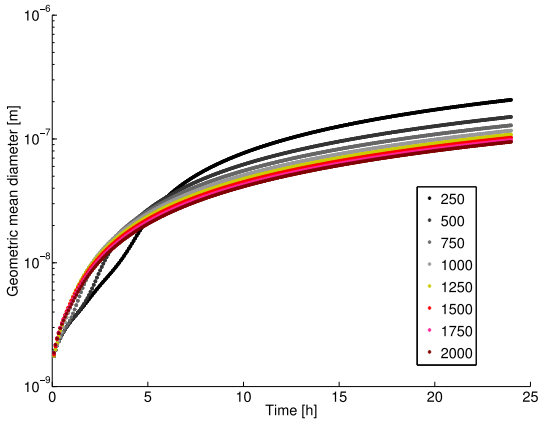

Figure 1: The geometric mean diameter of simulated particles with several different densities for one vapor. Vapor density is in units kg/m^3.

The simulation runs for these tests were done for identical conditions, only changing one parameter at a time. The runs had a single, initially monodisperse, peak that was allowed to grow for a day. Aerosol dynamics considered were coagulation and condensation. Three vapors were included, sulfuric acid with two generic organic compounds. Since only particle growth was investigated, constant vapor supersaturations for all vapors were chosen.

As an example of the results there are plots of geometric mean diameter and vapor volume fraction of a organic vapor for simulations with different vapor densities. The

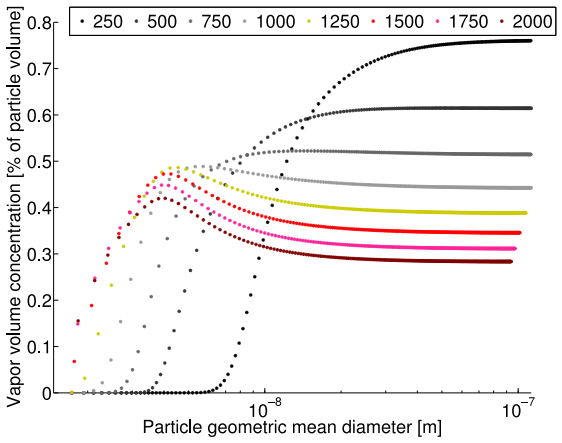

Figure 2: The volume fraction of the same simulated particles consisting of a specific vapor with several different densities for the vapor. Vapor density is in units kg/m^3.

simulation was of a initially monodisperse peak of pure sulfuric acid particles growing in constant vapor supersaturation. Initially growth is suppressed with decreasing density, but once the vapor starts condensing smaller densities result in more growth. In the volume fraction plot one can clearly see the kelvin effect in the delayed onset of vapor condensation.

While the study is limited to one model, the results are possibly useful in determining factors relevant to combining different organics into representative groups and determining which physical properties are important in a growing multicomponent aerosol system.

Introduction

SMPS (Scanning Mobility Particle Sizer) is the most widely used device to characterize particle sizes below 0.1 µm and it takes part in a large range of applications such as toxicology testing, indoor air quality measurement, etc.

Yet, a dimensional uncertainty on the size distribution isn't provided to SMPS users when the instrument operates under scanning mode. Since it has been proved that ultra-fine particles can pass through human barriers (lung, blood-brain barrier, etc.), assessing uncertainties on the estimated size distribution has become of primary interest. Present study aims at simulating SMPS measurements and at proposing a fast and accurate inversion technique to estimate the particle size distribution, as well as providing a sensitivity analysis to determine the influent parameters of the system. A 95% confidence region on the output size distribution is finally obtained by performing Monte-Carlo simulations.

Model and Inversion

Aerosol measurement using a SMPS is based on particle electrical mobility, that is defined as the ratio of the particles drift velocity to the magnitude of the electric field; particle electrical mobility is then linked to its mobility diameter d_p and electrical charge p. Once selected by DMA (Differential Mobility Analyser), particles are gathered into canals, enlarged and detected by a CPC (Condensation Particle Counter). Wang and Flagan (1990) developed the theory of particle classification when the instrument operates under scanning mode, and precision on the voltage ramp is given by Collins *et al.* (2004).

Raw data extracted from the SMPS represent a concentration over a certain class of mobility diameters. If we denote r_i as the concentration over the class i, n the size distribution, p the number of charges carried by a particle, $d_{1,i}$ and $d_{2,i}$ respectively the left and right extremity of the class i, t_i the counting time for the class i, $t_{0,i}$ being the time at which the count begins in the class i, f describes particle electrical mobility selected according to scanning time and k_i the kernel function (product of the charge distribution, the detection efficiency of the CPC, the DMA transfer function), then:

$$r_i = \frac{1}{t_{0,i}} \cdot \iint_{[d_{1,i},d_{2,i}]\times[t_i,t_i+t_{0,i}]} k_i\left(f(t), p, d_p\right) \cdot n(d_p) \cdot dd_p \times dt \ .$$

Starting from the deterministic model, next step is to focus on the variability of the measurements. Indeed, a model of noise based on experimental results that takes into account the CPC counting modes (single particle counting, live-time counting and photometric mode) is created.

Knowing the concentrations for each class, data inversion consists in retrieving the size distribution. It is a minimization problem with the constraint of positivity of the solution. Regularization technique of Tikhonov and Arsenin (1977) that penalizes non-smooth solutions is performed. In our case, the inversion has been proved to be fast and stable to perturbations in the input space and can then be used for the sensitivity analysis.

Primary Results

Since the number of parameters involved in the model is high, sensitivity analysis would require too much computing time, that's why analysis based on the decomposition of the variance is carried out by using indices defined by Sobol (1993). Then, according to experts in aerosol physics, the range of variation for each influent parameter of the system is chosen and a 95 % confidence interval is computed using Monte-Carlo simulations as shown in figure 1 for a typical atmospheric aerosol size distribution (Whitby, 1978).

Introduction:
Atmospheric aerosols are known to be an important yet highly uncertain component of the earth's climate and air quality (Solomon et al 2007). Owing to the complexity and diversity of atmospheric aerosol components, quantification of the properties that determine their highly uncertain climatic and human health impacts requires the development of novel technological applications. Inorganic material is restricted to a few well-understood compounds. However, organic material can comprise many thousands, as yet largely unidentified, compounds with a vast range of properties.

We must be able to predict however many thousands of components can exist in particulate matter. Predicting the evolution of aerosol requires calculating the distribution of all components between the gas and aerosol phase. This requires knowledge of all component vapour pressures and other thermodynamic properties. The many thousands of individual aerosol components ensure that explicit manual calculation of these properties is laborious and time- consuming. The emergence of explicit automatic mechanism generation techniques (Aumont, 2005; Jenkin, 2003) including up to many millions of individual gas phase products as aerosol precursors renders the process impossible and automation is necessary.

It can require significant resource to develop methods for automating these processes, but also to develop efficient numerical frameworks that drive the complex calculations. In this presentation we showcase development and application of a new online facility that combines benchmark aerosol models with open source informatics software to provide a new community service.

The model system:
The facility is written in python, a high-level language is widely used as a scripting language for web applications. It supports both fixed-point and floating-point numeric calculations, string manipulation and facilities for structures and multi-dimensional arrays. It is distributed under a permissive free software license and is available for all major operating systems, which will enable our software to be highly portable. Also, a PYTHON interface has been developed for the chemical informatics software of our choice (Open Babel) as described by O'Boyle et al (2008).
The SMILES chemical informatics syntax is used to automate extraction of molecular substructure information from individual compound identifiers (figure 1). Commonly employed in commercial and public software, it can be imported by most molecular editors and has a wide base of software support and extensive theoretical backing (www.daylight.com).

We will demonstrate the need for developing libraries that capture all functionality of compounds expected in the atmosphere, a problem that occurs in other available online services used by the community.

Example applications:
Important uncertainties are in those parameters which dictate the aerosol water content and gas / aerosol partitioning. To this end we will demonstrate the use of this facility to calculate fundamental properties, such as pure component vapour pressures, for an unlimited set of compounds. Absorptive partitioning simulations carried out on the facility will demonstrate the ability to predict secondary organic aerosol loading and composition using output from complex gas phase degradation mechanisms. Specifically we will use output from the Master Chemical Mechanism (MCM Jenkin (2003)) to simulate the detailed composition of aerosol in multiple scenarios.

Future outlook:
The facility is also designed to act as a springboard for collaborative purposes, the inclusion of specific visualization techniques enabling the modeling and measurement community to directly compare outputs from models and instruments. In addition we will present progress on using GPGPUs (General purpose graphical processing units) to obtain large increases in computational performance on the complex models hosted on the website. This is an exciting area of research and is already being explored for chemical models that are often heavily reduced to reduce numerical complexity.

The scale and seriousness of impacts of air pollution on health that have been detected by scientific investigations over the past decade is the subject of media reports and policy debate throughout Europe.

Particle size is one of the indicators can be used to describe airborne particulate matter (APM), since it is associated with the origin of the particles, their transport in the atmosphere and their ability to be inhaled into respiratory system. PM10 (particles with a diameter <10 µm) and PM2.5 (those with a diameter <2.5 µm) are nowadays commonly used to describe emissions and ambient concentrations of APM. An APM impact on mortality (life expectancy) seems to be attributable to PM2.5 while PM10 may have more visible impacts on respiratory morbidity.

Comprehensive evaluation of this evidence is needed in order to formulate effective APM pollution reduction strategies and national and international policies for reducing health risks due to pollution. For this reason, the European Directive 2008/50/EC, on ambient air quality and cleaner air for Europe, reinforces the need and obligation of Member-States to monitor the average exposure level of their populations to the particulate matter and to adopt measures to reduce these levels. Nevertheless, concerning the local authorities, managing local APM concentrations can be a rather frustrating affair, due to the existence of a quite number of different sources.

Therefore, in order to plan appropriate actions, it is necessary to have a deeper knowledge of the mains sources and their relative contributions to the formation of the ambient aerosol. This assessment, by providing concrete indications of the most important emission sources, helps decision and policy-makers to define appropriate mitigation actions and thus assuring a more effectiveness management of air quality.

The present study was accomplished in a port industrial area, which holds huge panoply of different fugitive and stationary sources such as industrial stacks, emissions from sea-going and berthed ships, harbour stock piles and road traffic (Figure 1).

This work focused it attention on road traffic emissions and aims to quantify the relative contribution of it to the solid fraction of the atmospheric aerosol in this industrial area.

Road traffic is one of the APM major anthropogenic emission sources, especially for finer particles. In fact, compliance with air quality standards requires control of this source emission. Fine exhaust particles are already subject to regulation but vehicle fleets increase whilst the non-exhaust emissions are totally uncontrolled and not well known. This kind of emissions comprise not only the only tailpipe vehicle exhaust emissions but also non-exhaust emissions derived mostly from the vehicle-induced ressuspension of dust deposited on the road.

Therefore, in this assessment special attention was given to the contribution of vehicles exhausted versus dust ressuspension.

For this propose the air dispersion model, using the computational tool TAPM - The Air Pollution Model, was performed according to Figure 2.

Results showed that the highest contribution of traffic resulted from dust ressuspension and not from vehicles exhausted. The heavy vehicles were the classes that that most contributed to the APM concentration.

People spend almost 70% of their time within a residence (Klepeis et al., 2001). During this time, typical resuspension activities within the home have been estimated to contribute 30 % of exposures to PM_{10} (Yakovleva et al., 1999). Chamber studies have also shown that for moderate walking intensities, for a wide cross section of participants, flooring type can impact the rate at which particles are re-entrained into the air column (Qian & Ferro, 2008). For this study, human activity patterns were randomly selected from the USEPA's National Human Activity Pattern Survey (NHAPS) to evaluate the impact flooring types may have on overall exposures to fine and coarse particles. The NHAPS 24-hr diaries were used to develop particle exposure schedules using NIST's multizone ventilation and mass transport model CONTAM. CONTAM was then used to assess the influence of flooring types on the daily (24-hr) average contribution of resuspended settled house dust to both $PM_{2.5}$ and $PM_{2.5-10}$ exposure concentrations (Figure 1).

The exposure assessment comparison was made for a range of floor loading and resuspension rate estimates found in the literature. For the purposes of this study, total floor loading represents the total mass of settled dust on floorings collected by studies cited in the literature. Owing to the wide variety of collection methods used the particle size collected in these studies, ranged from 5 µm to less than 500 µm (Adgate et al., 1995, Fortune et al., 2000).

From this study, reducing floor loading with a regular cleaning schedule would aid in reducing the impact of flooring type on exposures to fine ($PM_{2.5}$) and coarse ($PM_{2.5-10}$) particles. For a total floor loading of 0.1 g/m2 and resuspension rate of 10-3/hr for carpets and 10-4/hr for hard floors, the flooring type did not significantly affect the exposure to PM2.5. However, flooring type significantly affected exposure to course particles. Further when the resuspension rate was increased by one order of magnitude, that is of the order of 10^{-2}/hr for carpets and 10^{-3}/hr for hard floors, flooring type became significant for both flooring particle size ranges.

Dynamics of Spray Flames in Oscillating Flow with Droplet Grouping

D. Katoshevski[1] and J. B. Greenberg[2]

[1]Environmental Engineering Unit, Ben-Gurion University of the Negev, Beer-Sheva, 84105, Israel
[2]Faculty of Aerospace Engineering, Technion – Israel Institute of Technology, Haifa 32000, Israel

Keywords: Spray, Droplets, Combustion
Presenting author email: davidk@bgu.ac.il

The co-flow laminar spray diffusion flame in an oscillating flow field is investigated. A velocity lag is permitted between the droplets and their host surroundings and droplet grouping resulting from the host flow oscillations is accounted for (Katoshevski, 2006; Greenberg and Katoshveski, 2011; Katoshevski et al., 2008&2010). The spray is modeled using the sectional approach (Greenberg, 1989) and a perturbation analysis using a small sectional Stokes number is utilized for solving the liquid phase governing equations. The effect of droplet grouping is described through a specially constructed model for the vaporization Damkohler number. The large chemical Damkohler number assumption is adopted and a formal analytical solution is developed for Schwab-Zeldovitch parameters through which the dynamics of the spray flame front shapes and thermal fields are deduced. Computed results based on the solutions demonstrate how the phenomenon of droplet grouping can lead to the existence of multiple flame sheets as a result of the dynamic change in the *type* of the main homogeneous flame from under- to over-ventilated as the flow field oscillates. Concomitant fluctuating thermal fields are also shown to be present **indicating a potential impact on undesirable pollutants production.**

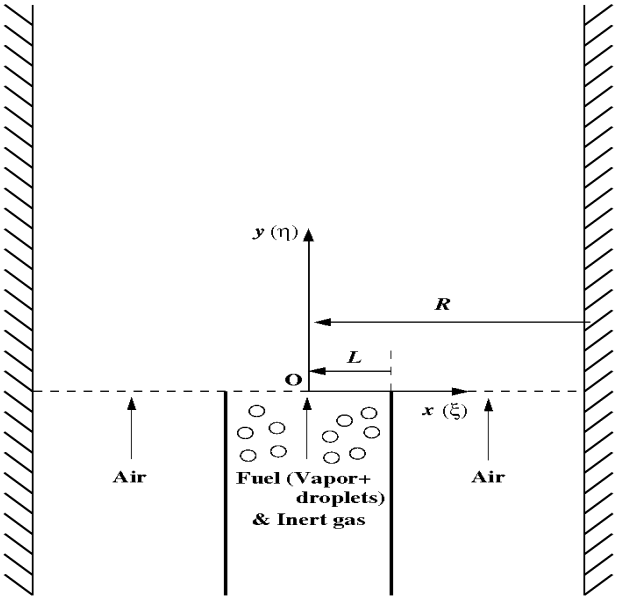

Figure 1. Schematic configuration.

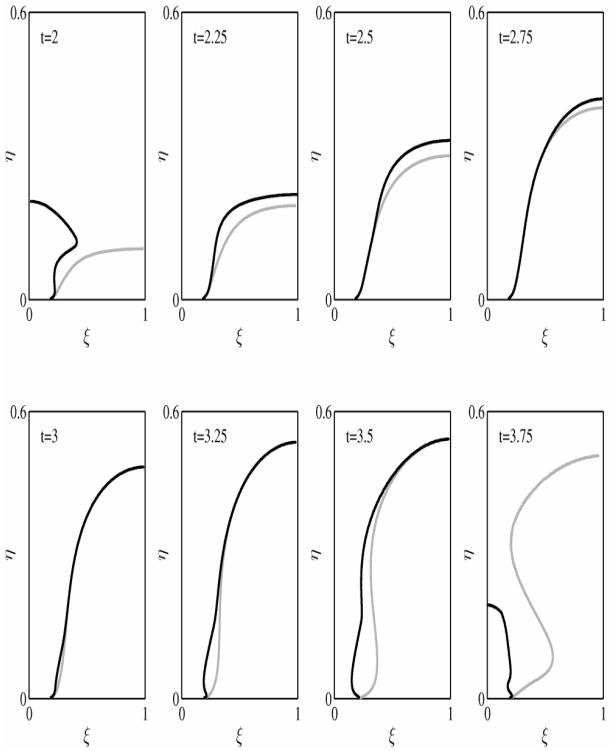

Figure 2. Stages in the evolution of a spray flame. The zone is at $x>0$ of Fig.1. Notation: black lines are flame fronts when ***droplet grouping*** is modeled, gray lines are flame fronts when droplet grouping is not accounted for.

The remarkable influence that grouping can have on the flame dynamics is illustrated in Fig. 2 where a typical cycle of a homogeneous spray flame is drawn, with and without droplet grouping.

Nonlinear oscillations and deposition of aerosol in tubes

D.A. Gubaidullin, R.G. Zaripov, A.L. Tukmakov and L.A. Tkachenko

Institute of Mechanics and Engineering, Kazan Science Center, Russian Academy of Sciences, Kazan, 2/31, Lobachevsky str., 420111, Russia

Keywords: aerosol, coagulation, deposition, particles, oscillations.

Presenting author email: damirgubaidullin@gmail.com

In the present work, longitudinal oscillations of an aerosol of different initial number concentration and dynamics of particles is considered in tubes of different length with various geometry on the end near to resonant frequencies.

Experimental investigations oscillations of an aerosol were carried out for different length of tubes in a shock-wave and no shock-wave modes near to subharmonic and natural resonances. Di-ethyl-hexyl-sebacate $C_{26}H_{50}O_4$ was used as the working fluid to generate aerosol. The majority of droplets have the geometric diameter 0.863 μm. Number concentration of drops for all experiments monotonously decreases with time and with growth of the excitation frequency. In the case of a closed tube, this process is defined by the coagulation of aerosol and deposition of droplets on the tube walls. In an open tube, the discharge of aerosol to the environment is observed in addition to the coagulation of aerosol and deposition of droplets on the tube walls. The dependence of the time of coagulation of aerosol on the excitation frequency likewise exhibits a nonmonotonic pattern with a maximum and a minimum when passing the resonance. It is established, that presence of a flange slows down process of a coagulation of an aerosol. Reduction of internal diameter of a flange results in increase in the time of coagulation. In so doing, the time of coagulation of aerosol in the case of an open tube is reduced by a factor of two and more compared to the time of coagulation in a closed tube. Nonlinear dependence of the time of coagulation of droplets is established at nonlinear oscillations of an aerosol in a tube from initial number concentration of an aerosol. It has been found that a decrease in the tube length and increase oscillation intensity results in a decrease in the time of coagulation of aerosol. It is shown, that with increase of intensity of the oscillations, the caused increase of amplitude, time of coagulation and deposition of an aerosol decreases. Time of a coagulation and deposition of drops of an aerosol in no shock-wave mode in 2-4 times is lower, than at a natural deposition. Ordered space-time structures of different densities have been revealed in the visible region in the vicinity of the middle of a closed tube.

The numerical modeling of a drift of the solid spherical particles were in a suspension in a nonlinear wave field of the closed tube and open flat channel at excitation of oscillations of a gas column on three first fundamental frequencies is executed. These researches have been carried out about use of model of a single particle and with application of model of interpenetrating continuums. It is obtained, that easy particles drift under an operation of acoustical current, and heavy are displaced under an action of wave pressure. In result easy and heavy particles concentrate in different areas of the resonator: easy are displaced to antinodes of a standing wave of velocity, heavy – to nodes. Depending on a steepness of a wave front of compression, the same particles can behave as easy at small nonlinearity, or as heavy at steep enough fast-head wave front. Drift of heavy particles in the open channel proceeds in two stages. The first quickly proceeding stage is connected to the mechanism of drift due to asymmetry of a wave, and the second with drift under action of developed acoustic stream. Influence of radius of particles on distribution of temperature and average density of a disperse phase along an axis of the channel is revealed.

Dynamics of a single particle with various physical and geometrical parameters is experimentally investigated at the longitudinal oscillations gas in tubes. Along an axis of a tube the particle moves from the closed (open) end to the piston, near to a wall – to the return side, making longitudinal oscillations with increase in the oscillations swing that is caused by acoustic streaming. In a radial direction, the oscillating particle moves from an axis to a wall of the tube up to a boundary point. Outside of a tube, the particle moves from the open end to an exterior wave field practically without oscillations with nonlinear increase of coordinate from time. It is revealed, that the increase in lengths of a tube and excitation frequency of gas in up to - resonant modes gives in growth of an oscillations swing of a particle and increase of its average velocity. Nonmonotonic character for dependence of oscillations swing and average velocity of a spherical particle from excitation frequency of gas is detected. At approach to a resonance oscillations swing and average velocity are incremented, attain the maximum value on a resonance frequency and decrease behind a resonance. Effect of a weight and diameter of a particle on its oscillations swing and average velocity is investigated. Shift of a curve maximum for dependence of a particle average velocity from oscillation frequency aside magnifications of frequency is shown at increase of a weight or diameter of a particle.

This work was supported by the Russian Fund of Foundation Investigation under grant 10-01-00098 and within the framework of the Federal target program "Scientific and scientific and pedagogical shots of innovative Russia for 2009-2013" (state contract №14.740.11.0351).

Dispersion and dissipation of weak waves in aerosols

Gubaidullin Damir, Nikiforov Anatoly, Teregulova Eugenia and Fedorov Yury

Institute of Mechanics and Engineering, Kazan Science Center, Russian Academy of Sciences,
Kazan, 2/31, Lobachevsky str., 420111, Russia
Keywords: aerosol, waves, damping, heat and mass transfer.
Presenting author email: damirgubaidullin@gmail.com

Propagation of acoustic waves in two-fractional mixtures of gas with vapor, with polydispersed particles and drops and in *n*-fractional mixtures of gas with particles is investigated. The mathematical model is presented, the dispersion relation is received, asymptotic at high and low frequencies is deduced, and dispersion curves are calculated. Influence of polydispersity of drops and particles or *n*-fractionality on dispersion and dissipation of small perturbations is analysed.

In Figures 1 the effect of polydispersity of water drops and ash particles on the form of dependences of decrement of attenuation on length of wave from dimensionless frequency of oscillations $\Omega_{5,3}$ is illustrated. ($\Omega_{5,3} = \omega\tau_{va5,3}$, where ω – frequency of oscillations, $\tau_{va5,3}$ – characteristic relaxation time of velocity of disperse phase, $a_{5,3}$ – average radius). Variables with an index *a* correspond water drops of radius *a*, with an index *b* – to particles of ash of radius *b*.

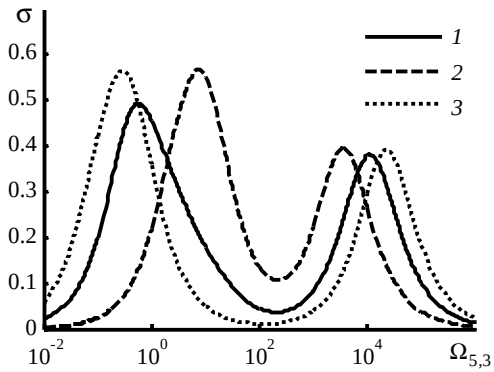

Figure 1. Dependences of decrement of attenuation on dimensionless frequency of oscillations: *1* – $a \in [10^{-5}, 10^{-4}]$, $b \in [10^{-7}, 10^{-6}]$, *2* – $a_0 = 2 \cdot 10^{-5}$, $b_0 = 10^{-6}$, *3* – $a_0 = 10^{-4}$, $b_0 = 4 \cdot 10^{-7}$

At calculations it was assumed: relative mass content of water drops $m_a = 0.3$, ash particles $m_b = 0.3$, pressure of bearing phase $p_1 = 10^5$ Pa ($T_0 = 271$ K). Distribution functions of drops and particles on sizes are accordingly equal $N(a) = a^{-3}$ and $N(b) = 1/\sqrt{2\pi}s \exp(-b_1^2/(2s))$, $s = (b_{\max} - b_{\min})/10$, $b_1 = b - (b_{\max} + b_{\min})/2$. Units of measure are given in SI system.

In Figure 2, The calculations are performed for a mixture of air with particles of ice, aluminum and carbon black particles with different mass concentration *m* of the ice, aluminum and soot. The radius of particles of aluminum was made $r_a = 10^{-5}$[m], by a ice – $r_l = 10^{-6}$[m] and by a soot –$r_s = 8 \cdot 10^{-5}$[m].

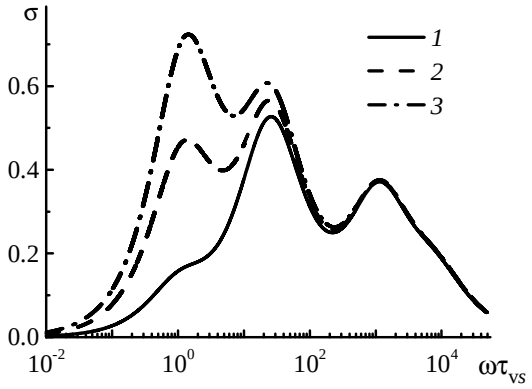

Figure 2. Dependences of decrement of attenuation on dimensionless frequency of oscillations: *1* – $m = 0.3$, *2* – $m = 0.5$,*3* – $m = 0.7$

Accounting for the three-fractional composition and difference in thermophysical properties of fractions gives rise to three peaks for the dependence of the decrement of attenuation at a wavelength at the characteristic values of the dimensionless frequency $\omega\tau_{vl}$, $\omega\tau_{va}$, $\omega\tau_{vs} = 1$. The increase in the mass concentration of one or several fractions (line *2* and *3* in Fig.2) of the dispersed phase significantly affects the dispersion and dissipation of weak waves in aerosols.

This work was supported by the Russian Fund of Foundation Investigation under grant 10-01-00098 and within the framework of the Federal target program "Scientific and scientific and pedagogical shots of innovative Russia for 2009-2013" (state contract №14.740.11.0351).

Gravito-potophoresis of aerosols: the insufficiency of “accommodation” forces action

M.S. Vasiljeva* and S.A. Beresnev

Aerosol Physics Laboratory, Ural Federal University, Ekaterinburg, 620083, Russia
Keywords: fundamental aerosol physics, stratospheric aerosols, photophoresis, accommodation coefficient
Presenting author email*: mary_ru@mail.ru

The description of gravito-photophoresis is based on the semi-empirical theory developed during some years by the Austrian scientist Rohatschek (1984). A simplified model of the physical mechanism of initiation of the gravito-photophoretic forces amounts to the following. A spherical particle with large heat conductivity is placed in the field of directed radiation, its mean volumetric temperature at the cost of absorption differs from the temperature of ambient gas but is homogeneous (in this case the force of radiometric photophoresis is negligible). The frontal to radiation and rear hemispheres of the particle are characterized by asymmetry of surface properties expressed, in particular, in the difference of energy accommodation coefficients on the particle surface.

To calculate the arising force the results of solution of the problem about the force acting in rarefied gas on a heated thin plate with different accommodation properties of surfaces (the plate radiometer) are used. This problem was analyzed earlier by Knudsen (1930), and formal transfer of this result to the problem of a spherical radiometer leads to a simple expression for the gravito-photophoretic force (Rohatschek, 1984). The obtained result predicts a very high efficiency of gravito-photophoretic forces in the vertical transport of stratospheric and mesospheric aerosol particles against gravity, with which none of the known force mechanisms can compete (including radiometric photophoresis). This theory, in particular, was proposed later for explaining the observed phenomenon of accumulation of soot particles from air transport engines at altitudes of the middle stratosphere (Pueschel *et al*, 2000). Recently this kind of vertical motion of particles at the high altitudes was discussed again as means of aerosol albedo modification for mitigation of global warming (Keith, 2010).

The goals of this report are, first, the independent development of the consecutive and rigorous gas-kinetic theory of the phenomenon for the free-molecular regime with detailed consideration of gas-surface interaction features and, second, an attempt of the measurement of predicted forces using an experimental technique with model macroparticles for quantitative comparison with the theoretical predictions.

Gas-kinetic theory of “accommodation” force. Consider a spherical particle of radius R_p suspended in infinite gas volume in the field of unidirectional electromagnetic radiation of intensity I and wavelength λ. The particle heat conductivity is λ_p, the complex refractive index is $m = n + ik$. The particle has a model asymmetry of surface properties: frontal and rear to the radiation direction hemispheres are characterized by constant but various values of the phenomenological accommodation coefficients of energy and momentum of gas molecules. The volume thermo-physical and optical characteristics for both hemispheres are the same. Thus, the physical model of this Janus particle fully corresponds to the model proposed by Rohatschek (1984). The obtained expression for gravito-phoretic force has the form (Beresnev *et al*, 2012):

$$F_{acc} = \frac{\pi}{8} R_P^2 \frac{1}{\bar{v}_g} I Q_{abs} \Delta A_n \text{, where}$$

$$\Delta A_n = \alpha_n(2) / [1 - \frac{9\pi}{32}(1 - \alpha_n(2))] - \alpha_n(1) / [1 - \frac{9\pi}{32}(1 - \alpha_n(1))] \cdot$$

This result can be reduced to the form obtained by Rohatschek (1984) at the same assumptions (free-molecular regime and the neglected radiation cooling of a particle). However, instead of the difference between energy accommodation coefficients $\Delta\alpha_E$, the complex ΔA_n occurs which is responsible for accommodation of the normal momentum of gas molecules on different particle hemispheres. The estimations with the use of known values of show that in the stratosphere the “accommodation” forces can be comparable with the radiometric photophoretic forces, but do not exceed the gravity force. These conclusions both qualitatively and quantitatively differ from the conclusions of the semi-empirical theory of gravito-photophoresis of Rohatschek (1984).

The experimental verification of “accommodation” forces. The measurements conducted in the model experiment with macroparticles have confirmed the existence of “accommodation” forces affecting a particle with artificial asymmetry of surface characteristics together with the forces of radiometric photophoresis. The experimental values for the system “steel particle–helium” are in good agreement with theoretical predictions, and the ratio of the “accommodation” force to the photophoretic force does not exceed 3%.

Thus, the action of "accommodation" forces, in our opinion, is not capable to provide effective vertical transport of aerosol particles against gravity at stratospheric altitudes.

The Polydispersity of Primary Particles in Aggregates undergoing Sintering

M.L. Eggersdorfer and S.E. Pratsinis

Department of Mechanical and Process Engineering, ETH Zurich, CH-8092 Zürich, Switzerland

Keywords: Aggregates, Particle size distribution, Particle surface area, Sintering.
Presenting author email: meggers@ptl.mavt.ethz.ch

Nanoparticles often exhibit unique properties which are confined to a certain size range, like quantum dots or plasmonic nanoparticles. A narrow distribution of primary particles is desired for these applications. Aerosol processes allow a rapid and scalable production of nanoparticles over a wide range of sizes. In such processes, particles grow, however, typically by coagulation that places a lower limit to the width of the size distribution, the so called self-preserving size distribution with a geometric standard deviation of σ_g = 1.45. If primary particles with different high temperature residence time histories (e.g. different streamlines) are mixed, agglomerates with quite polydisperse primary particle size distributions are obtained. This polydispersity can be overcome by sintering of primary particles in their agglomerates. Furthermore accounting for primary particle polydispersity is important as the characteristic sintering time depends strongly on primary particle size (Sander et al., 2009).

Heine and Pratsinis (2007) investigated the polydispersity of primary particles in agglomerates during coagulation and sintering by a two-dimensional sectional model. The detailed agglomerate and primary particle size distribution of TiO_2 formation was simulated. The narrowest primary particle size distribution was obtained when aggregates (particles with sinter necks) were produced. This effect could be observed for ZnO nanocrystallites which showed a blueshift of the absorption spectrum with decreasing crystallite size (1.5 – 12 nm, Mädler et al., 2002). Their average primary particle size by nitrogen adsorption measurements was larger than their X-ray diffraction crystal size, indicating multicrystalline aggregates. A narrow crystal size distribution is required to exhibit this so-called quantum-size effect.

Here, aggregate sintering by viscous flow (polymers, SiO_2, Eggersdorfer et al., 2011), lattice and grain boundary diffusion of crystalline materials (Ni, Ag, ZnO_2, TiO_2, Eggersdorfer et al., 2012) is simulated to track the primary particle growth. The change in particle distance, dx/dt, and particle radius, dr_p/dt, are calculated by energy and mass balances (Eggersdorfer et al., 2011). The restructuring during sintering from fractal-like agglomerates to aggregates and eventually compact particles (e.g. spheres) is simulated. The effect of initial primary particle size distribution and sintering mechanisms on the primary particle polydispersity and surface area mean diameter are investigated. The initial primary particle size distributions are log-normal with σ_g = 1, 1.45 and 2. Each sintering mechanism exhibits a different primary particle size distribution evolution but almost identical growth in surface area mean diameter. Grain boundary diffusion has the strongest impact among all densifying sintering mechanisms and results rapidly in the narrowest primary particle size distributions (Fig. 1). Nevertheless, the relations between surface area mean primary particle and mobility diameter as well as the power law scaling between projected area and number of primary particles are independent of sintering mechanism. So these relations can be readily used for the characterization of agglomerates and aggregates regardless of material and sinter mechanism.

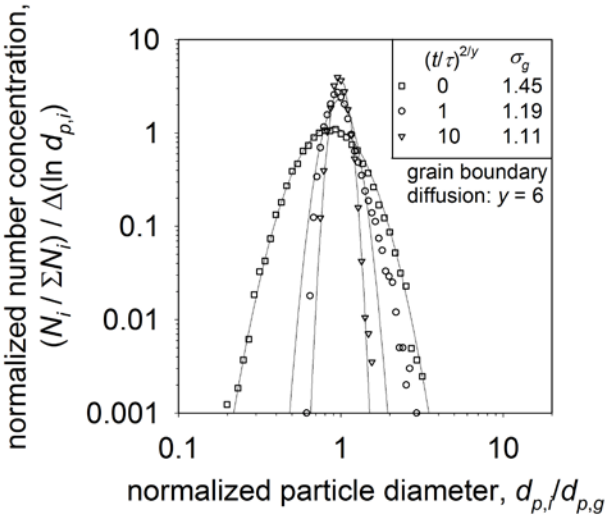

Figure 1. Evolution of the primary particle size distribution of agglomerates during sintering by grain boundary diffusion as a function of scaled time.

Temperature and particle vertical profiles: suitability of the ML concept under weak cyclonic conditions

J. Giménez[1], J.F. Nicolás[1], C.Pastor[1], R.Castañer[1], E. Yubero[1], M.J. Cuesta-Bolao[1], J. Crespo[1] and S. Caballero[1]

[1]Department of Applied Physics, Miguel Hernández University, Elche, 03202, Spain
Keywords: Particle number concentration; Mixing Height; Weak cyclonic conditions
Presenting author email: j.gimenez@umh.es

Several studies have shown good correspondence between the Mixed Layer Depth (MLD) or Mixing Height (MH) calculated from aerosol profiles and the MH estimated from meteorological parameters (Giménez *et al* (2010); Ferrero *et al* (2011)). The MH is only determined under anticyclonic scenarios because in low pressure regions the upward motions carry boundary layer air away from the ground to large altitudes throughout the troposphere. In this work, we show that under weak cyclonic conditions aerosol profiles and MH estimated from meteorological parameters fit like we were under anticyclonic situation.

The vertical profiles of particle number concentrations and meteorological parameters were obtained using a motorized paraglider. The instrument used to obtain the particle number concentration was a GRIMM 1.109 aerosol spectrometer. This instrument determines particle number concentrations in 31 particle size channels from 0.25 to 32 µm. A Delta Ohm ultrasonic anemometer, model HD 2003, was used to record the temperature, relative humidity and pressure. No wind data was available. Altitude data was supplied from GPS and from meteorological parameters with good agreement between them.

Two flights were performed under weak cyclonic conditions on 22 September 2009 in flat terrain in southeast Spain (38°11´19.7´´N; 0°49´47.3´´W; 60 m a.s.l.), approximately 20 km from the Mediterranean coast. All heights refer to meters above ground level (a.g.l.). In the first flight, the paraglider took off at 07:45 UTC. In the second flight, the paraglider took off at 10:45 UTC. We use the following nomenclature: F1A (flight 1-ascent), F1D (flight 1-descent), F2A (flight 2-ascent) and 2D (flight 2-descent) to refer to the four vertical profiles, two per each flight. The horizontal displacement from the launch site in both cases was almost negligible. We calculated the hypothetical heights of the Stable Boundary Layer (SBL) and the Convective Boundary Layer (CBL) as if the flights had taken place under anticyclonic conditions. To determine the hypothetical SBL heights in flight 1, we focused on the heights where the temperature gradient vanishes ($\partial T/\partial z=0$; inversion top), (Stull, 1988). To determine the hypothetical CBL heights in flight 2, the parcel method (Seibert *et al.* (2000)) was used.

Fig. 1 shows the particle concentration, temperature and relative humidity (RH) vertical profiles in the two flights during the ascents and descents.

In F1A, the hypothetical SBL height was about 300 m. This height decreases until ~100 m when the inversion is disappearing (F1D), and we can appreciate

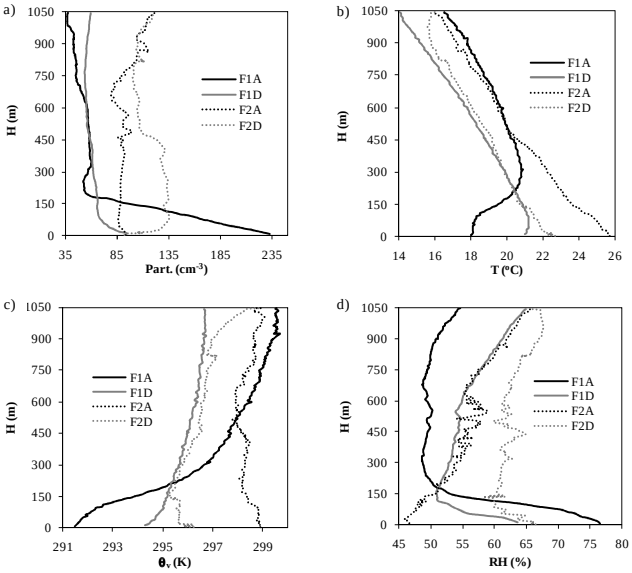

Figure 1. Profiles of: a) total particle concentration, b) temperature, c) virtual potential temperature, d) RH

that these inversion heights roughly coincide with the changes in particles vertical profiles slopes (Fig. 1a and 1b).

Between F1D and F2A around two hours passed and in that time weak convective movements developed. The CBL heights were ~950 m (F2A) and ~400 m (F2D) (Fig. 1c). This could be because of stratiform clouds formed and the entry of a cold air mass with higher RH (Fig. 1b and 1d). In F2D, particle profile decrease at ~400 m (CBL height). In F2A, the coincidence is not clear. However, it seems as if the atmospheric thermal effect prevails over the convergence dynamic effect.

Two-phase polydisperse spray in a wake of shattering drop

A. G. Girin

Odessa National Maritime University, 65029, Odessa, Ukraine
Keywords: dispersion, aerosol generation, aerosol modelling, evaporation.
Presenting author email: club21@ukr.net

A mathematical model of evaporation aerodynamics of a mist in the wake of a shattering drop in uniform gas stream is elaborated. It is grounded on the distribution function $f_{\text{n.p.}}(r,t)$ for stripped daughter droplets by sizes, which was obtained earlier on the base of concept of quasi-continuous stripping of daughter droplets from unstable part of parent drop surface due to action of high-frequency periodic gradient instability. Stripped droplets are considered as a polydisperse multi-velocity continuum and a system of three partial differential equations of two-phase spray dynamics is composed, which consists of equations of torn droplets motion, of evaporation and of transient density of their number distribution. The dependencies of droplets drag coefficient on velocities and sizes as well as intensification of evaporation due to their streamlining are taken into account. The system allows to describe quantitatively the evaporation and acceleration of each stripped droplet and thereby – the process of formation of liquid-phase jet and vapor cloud in a wake.

Spatial structure of two-phase wake spray has transient complicated character since every droplet has its own values of velocity, radius, evaporation rate and distances between droplets vary due to non-uniform field of accelerations. To take into account all the peculiarities of evaporation ballistics we have introduced into consideration the transient distribution function of daughter droplets by sizes $f_{\text{n.d.}}(r,x,t)$ as it exactly reflects the entire evolution of stripped droplets in time t, in space x, as well as in sizes r. The parent drop is considered as located in spray origin $x=0$ source of daughter droplets with a given source distribution function $f_{\text{n.p.}}(r,t)$. The daughter droplets are moving in a direction of spray axis OX with velocity $w_{\text{d}}(r,x,t)$. As well, each daughter droplet is regarded as a moving point source of vapor, and they altogether form the distribution of a vapor mass $m_{\text{v}}(x,t)$ in a wake.

At one-dimensional spatial approximation of a wake flowfield the mathematical problem is formulated and solved in a closed form in dynamic 3D space. A detailed calculation of the ballistics of evaporating spray, generated in the wake of a kerosene drop fragmented by air stream, is performed and the formation of liquid-phase jet and vapor cloud in a wake is described. Calculations showed, that times of living of finest and largest droplets are the characteristics of liquid jet formation in spray. Soon after moment of entire evaporation of droplets of minimum in spray radius, that were stripped at the beginning, the evaporation mass rate and current value of liquid-phase mass in spray exceed their maximum values because of droplets vanishing begins. After moment of vanishing of droplets of maximum radius the vanishing of droplets of new radii doesn't occur, and this is the necessary condition for stabilization of length of liquid-phase jet.

The proposed model allows to calculate spray mean diameters, so, the evolution of the dispersive characteristics of the liquid-phase jet of spray is studied. Parameters of two kinds were considered: the first are defined at any cross section of jet and characterize its spatial structure at fixed moment, while the second are calculated at any moment for the whole set of droplets and describe temporal changing of jet dispersity in total. At the beginning the bunch of first set of curves is narrow, that testifies to weak polydispersity of jet, but after droplets vanishing starts, the polydispersity increases. The stabilization proceeds gradually along jet from astern part to the tip. The dependencies of the second set of curves confirm the conclusions. In final state the jet polydispersity is much greater than that, produced by source. In the case considered the stabilization of jet is discovered and the range of a jet is found. The internal structure of the spray is investigated as related to the dynamic process of spray formation.

The process of vapor cloud formation in spray was studied. At the beginning the intensification of evaporation due to rapid growth of liquid surface is so large, that vapor wave appears which has sharp front similar to blast wave. After losing contact with liquid phase this wave has convectional drift, keeping its form invariable. Gradual weakening of droplets source capacity generates rarefied wave in vapor mass distribution, so, far from the source the distribution tends to "triangle" form. Analysis of the processes of jet and vapor cloud formations is done and their structures are described thus.

By rough estimations, in the case of a fuel drop, combustible mixture in wake of a shattering drop is substantially overreached in average, as vapor density several times exceeds the stoichiometric value. Vapor oversaturation leads to cooling of the mixture. Equation of heat balance for process of vapor – air mixing yields the temperature dropping in about 300°K which means that delay of ignition may jump several orders high.

The proposed model can serve as a core of the entire model of formation, ignition and combustion of homogeneous inflammable mixture in a wake, and thereby – of heterogeneous detonation wave, but also of some kinds of engine furnaces.

Ab initio molecular dynamics study of sulfuric acid clusters with ammonia/dimethylamine

Keywords: atmospheric clusters, *ab initio* molecular dynamics
Presenting author email: ville.loukonen@helsinki.fi

Previously

Arguably, during the recent years various *ab initio* calculations have increased our understanding on the first steps of atmospheric new-particle formation.

Most of these studies concentrate on finding the minimum energy structures for small molecular clusters and often the characterizing quantity is the formation free energy. Lately, the formation energies have also been converted into evaporation rates (Ortega et al., 2012) and these in turn have been used in kinetic models to obtain insight on how the cluster concentrations evolve (McGrath et al., 2012).

On the other, in the atmosphere all the molecules are under constant thermal motion. However, in the static minimum energy calculations the effect of non-zero temperature is most often taken into account as a correction term to the electronic energies. Furthermore, this correction term is typically obtained by approximating the clusters as rigid rotors and harmonic oscillators. The static calculations are inherently unable to capture the real dynamics of the system.

This study

In the current study, we have used *ab initio* molecular dynamics simulations to probe the actual dynamics of sulfuric acid - ammonia and sulfuric acid - dimethylamine clusters.

In *ab initio* molecular dynamics the forces acting on atomic nuclei - and thus driving the dynamics of the system - are calculated from the electronic structure of the cluster in question. The advantage of the method is its ability to keep track of both the kinetic and potential energy, thus providing a full picture of the energetics and dynamics at the chosen level of computational sophistication. The downside is large computational cost.

We used a timestep of 0.5 fs and simulated the clusters in NVT ensemble ($T = 300$ K) for 45 ps. The chosen clusters

$$(\text{sulfuric acid})_n \bullet (\text{ammonia})_{n-1}$$

$$(\text{sulfuric acid})_n \bullet (\text{dimethylamine})_n,$$

where $n = 2,3,4$ were found the be very stable in a recent minimum energy structure study (Ortega et al., 2012), and as such are good initial structures for the current study probing the dynamics and stability.

The simulations show that the stability of the clusters in non-zero temperature is largely dependent on the hydrogen bonding patterns, similarly to the static minimum energy calculations. In most of the studied clusters the equilibrium was reached between 0-10 ps. However, even after the equilibrium was reached there was notable bond rearrangement in both the ammonia and dimethylamine containing clusters: the number of hydrogen bonds stayed the same but the individual atoms forming the bonds changed (cf. Figure 1).

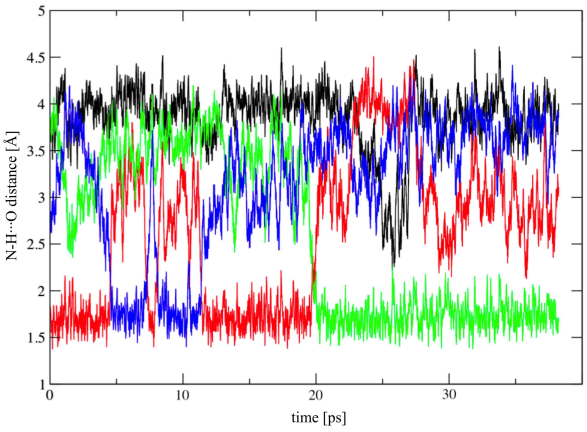

Figure 1: One particular H-bond as a function of time in $(\text{sulfuric acid})_2 \bullet (\text{dimethylamine})_2$ cluster. Different colors correspond to different O atoms in H_2SO_4 participating in the bond.

Regardless of the bond rearrangement the clusters remained bound together during the simulation period. It is likely that similar bond forming and breaking will take place also during the initial formation of atmospheric molecular clusters.

This paper focuses on dust mobilisation problems. It describes a finite volume approach to approximate solutions of a *k-ε* turbulent model which is applied to the analysis of transient two-phase flows with gas and particles. This development has been carried out in the context of the fusion reactor ITER and its application is restricted to high dilute mixtures of gas and particles which are the type of mixtures expected to have inside the tokamak. This development has been implemented inside the DUST code (García-Cascales, 2010). The model includes the effect of particle-wall interaction, interfacial friction, interfacial heat transfer, and lift forces. The closure laws used in the model are realistic enough for the problems studied. Gas phase is modelled as a perfect gas and the solid phase is considered incompressible. Despite its specific application, the model can be extrapolated to study other dust mobilisation and/or explosion problems in industry.

In fusion devices such as the ITER, the interaction of plasma with the surfaces that comprise the vacuum vessel of a fusion reactor may produce certain amount of dust which may adhere or deposit on to such surfaces. This is expected to be formed by a polydisperse mixture of particles of carbon, beryllium, stainless steel, and tungsten. The geometric median diameter of the particles will be of about 2 μm and a standard deviation ranging 2-5. Estimates for ITER point out that the expected amount of dust may range from several kg to hundreds kg depending on the case (Winter, 2000). Associated to its existence, a great amount of problematic scenarios have been reported:

Dust causes tritium uptake and its deposition may make difficult the facility maintenance. Its mobilisation, due to a loss of vacuum accident, may lead to the exit of radioactive, reactive or toxic chemicals which can contaminate the surroundings and be a potential risk for the public. In a loss of coolant event, dust can contribute to hydrogen generation (e.g. Be or C in the presence of water or steam), which in presence of air may deflagrate or detonate.

Dust might also ignite if the necessary conditions were met. Its permanent deposition may reduce heat transfer and therefore the cooling capacity of the refrigeration system. In general, it may be the cause of plasma disruptions, impede start-up or breakdown, and globally contribute to the malfunction of the system.

The understanding of dust sources, the characterization of its effects, and the performance of experiments which simulate fusion plasma conditions will help to improve the development of reliable tools for the analysis of such problems (Sharpe et al., 2002). At the same time, this will avoid problems in operation and prevent accidents. Their validation with suitable benchmark tests will contribute to reduce the uncertainties in safety analysis and safety limits.

During the last years, several works have appeared in the existing literature. Great effort has been done in order to develop and validate numerical codes for the analysis of the kind of scenarios that may be encountered inside the vacuum vessel of a fusion reactor. Examples of them are Takase (2001) or Porfiri (2006) who experimental and numerically studied the mobilisation of particles in closed reservoirs.

Considering our previous work (García-Cascales et al., 2008) and the physical laws added to the code (García-Cascales et al. 2010), in this paper, the k-ε model and the system of equations adopted in DUST are presented. Some details about the finite volume model implemented are given and numerical results are provided. Finally, some conclusions are drawn.

Microgravity experiments on particle motion in the region of negative thermophoresis

A.A. Vedernikov[1], S.A. Beresnev[2] and A.V. Markovich[1]

[1]Université Libre de Bruxelles, Brussels, B-1050, Belgium
[2]Ural Federal University, Ekaterinburg, 620083, Russia
Keywords: aerosol dynamics, thermophoresis, microgravity, accommodation coefficient
Presenting author email: sergey.beresnev@usu.ru

Thermophoresis (motion of particles due to temperature gradient in a gas) is a subject of many-year experimental and theoretical investigations of great significance for fundamental and applied aerosol physics.

Substantial improvement of accuracy and sensitivity due to diminishing convective effects is possible to get in microgravity conditions performing experiments in drop towers, in parabolic airplane flights, or onboard the orbital space station. Microgravity conditions are the most advantageous, if not the only suitable for decisive experiments in tackling the problem of "negative thermophoresis", i.e. predicted for high-conductivity aerosol particles at small Knudsen numbers motion in the direction of temperature gradient and not against as for the traditional thermophoresis.

According to theoretical analysis the thermophoretic force and velocity are very sensitive to the variation of energy accommodation coefficient α_E. The value of α_E governs the magnitude of the heat flux normal to the surface, which, in its turn, controls the competition of oppositely directed thermal creep and thermal stress gas flow near the particle surface so that the thermophoretic velocity can be positive even for high-conductivity particles at very small Kn numbers. Experimental analysis of negative thermophoresis thus splits into two tasks: 1) testing which theories are adequate – those taking into account the thermal stress slip or without it and 2) which model most accurately takes into account peculiarities of these phenomena.

Experiments were performed at Bremen Drop Tower (Germany) with 4.7 s duration of high quality microgravity (better than 10^{-5}g). We used two types of particles *a*) high heat conductivity ($\Lambda = \lambda_p/\lambda_g$ =20500) polydisperse copper spherical particles with mean diameter of 74 μm and *b*) low conductivity ($\Lambda = 1.8$) hollow glass spheres with about the same particle size distribution. Particles were injected separately into the cubic cell filled with nitrogen at normal pressure with four windows for stereoscopic observation in back illumination. The gradient was created by a heated wire in the cell center. Velocities were analyzed for the particles, for which three-dimensional trajectories were identified. Radial components of particle velocities were related to the thermophoretic motion. Previous results (Vedernikov *et al* (2008) and Beresnev *et al* (2008)) are here completed with the analysis of motion of low conductivity particles and detailed three-dimensional simulation of residual convective motion.

Typical velocities of low conductivity particles were around 0.3-0.5 mm/s depending on their distance from the wire and showed excellent agreement with the theory of Brock (1962). Velocities of copper particles appeared to be 30-50 times lower under the same conditions. Reduced thermophoretic velocities of copper particles are presented on Fig. 1 after refinement on residual convective motion.

These results meet predictions of gas-kinetic theories that take into account the thermal stress slip flow. As for the second task mentioned at the beginning, the experiments were still not sensitive enough to define the sign of the motion and relate it to a particular set of accommodation coefficients. Using the same experimental approach in future in a wider range of Kn number, different ratio of heat conductivities and different accommodation coefficients should allow solving most current problems of the theory of negative thermophoresis.

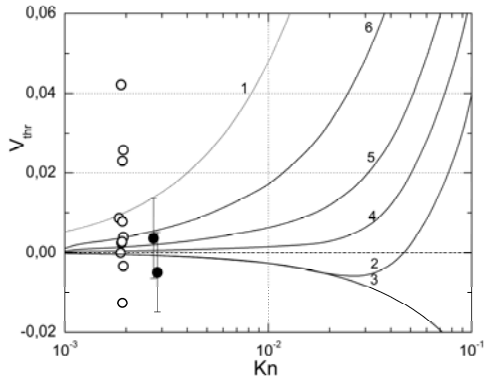

Figure 1. The dimensionless thermophoretic velocity V_{thr} for copper particles. Microgravity experiments: black circles stand for particles close to the wire where negative thermophrsis is dominant; open circles stand for particles far from the wire where dominates residual convection. Theory: 1 – Brock (1962) with $C_{ts} = 1.17$, $C_t = 2.18$, $C_m = 1.14$; 2-6 – Beresnev et al (1995): 2 – calculations and 3 – asymptotic solution at $\alpha_\tau = \alpha_E = 1.0$; 4 – calculations at $\alpha_\tau = 1.0$; $\alpha_E = 0.95$; 5 – at $\alpha_\tau = 1.0$; $\alpha_E = 0.90$; 6 – at $\alpha_\tau = 1.0$; $\alpha_E = 0.80$.

High order operator splitting adaptive time marching Monte Carlo for aerosol dynamics

Kun Zhou and Fabrizio Bisetti
Clean Combustion Research Center, King Abdullah University of Science and Technology (KAUST),
Thuwal, 23955, Saudi Arabia
Keywords: Monte Carlo simulations, aerosol dynamics, particle size distribution.
Presenting author email: kun.zhou@kaust.edu.sa

Aerosol dynamics are usually described by the population balance equation (or general dynamics equation). Direct discretization and moment methods are two popular ways to solve the population balance equation. In principle, Monte Carlo (MC) methods are more flexible than both direct discretization and moment methods in that they can readily accommodate complex physical models for aerosol dynamics, e.g., a bi-variate volume-surface description of aerosol particle morphology. In this work we develop and validate a new Monte Carlo method that distinguishes itself from available methods for accuracy, adaptivity, and ease of use. The algorithm combines a stochastic modeling of coagulation and a deterministic description of nucleation and particle growth processes adopting a high-order operator splitting technique.

Figure 1 shows the flowchart. The dynamic equations for nucleation and surface growth are integrated via an adaptive Runge-Kutta method within every time step δt. Within δt, coagulation is modeled by the stochastic scheme of Gillespie (1975). Gillespie's scheme is parallized with MPI and the parall version of the algorithm exhibits nearly linear (optimal) speedup with increasing CPUs at fixed number of Monte Carlo particles N. First order and second order (Strang) operator splitting techniques are compared. It is found that the second order symmetric Strang splitting produces signficantly more accurate results at the same cost of the first order splitting. The operator splitting error is controlled by the adaptive time step δt, which is set according to two criteria based on number density and volume fraction rate of change.

Stochastic noise in the ensemble quantities is one of the key issues in Monte Carlo methods. The stochasticity comes from three steps in the current MC method (filled blocks in the flowchart in Fig. 1). Re-sampling is necessary to increase or decrease the total number of simulation particles N, according to a underlying probability distribution function. The number of particles N cannot be too large due to the algorithmic complexity. Here we present a mathematical proof that re-sampling will not introduce any statistic bias. The other stochastic steps are the draw of the event time increment from its probability density function and the random selection of the two coagulating particles.

As expected, it is found that the variance tied to coagulation modeling is inversely proportional to N. Conversely, the computational cost is proportional to N^2. Hence, increasing N to reduce the variance is not a good strategy. Detailed numerical simulations on various test cases show that repeated Monte Carlo simulations are independent of each other and can be used to reduce the sample variance. The total cost of repeating the simulation m times is CmN^2, where C is a constant. The expression for the cost suggests to chose N as small as possible while increasing m to reduce the variance.

The numerical efficiency and error of the MC method are studied in four cases: (i) constant kernel coagulation, (ii) free molecular regime coagulation, (iii) constant nucleation and constant kernel coagulation, and (iv) constant nucleation and free molecular regime coagulation. For cases (i) and (iii) analytical solutions are available. It is found that for N equal to several hundred to thousand particles, and m equal to several hundred iterations, the MC method provides very good results for lower order moments of the particle size distribution function. This sort of simulation needs only a few hours on a typical multi-core engineering workstation. Conversely, if one is interested in predicting high order moments (i.e., the tail of the particle particle size distribution function), a rather large N is needed.

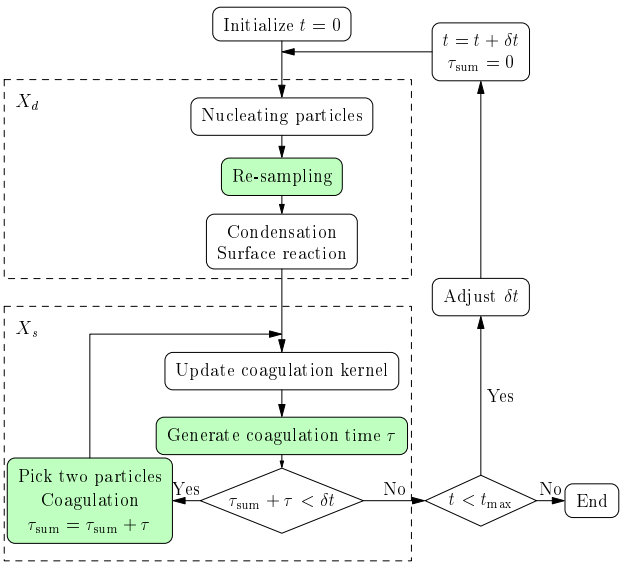

Figure 1: Flowchart of the MC method. Filled blocks denote stochastic steps. X_d and X_s denote different operators in the operator splitting method, which can be grouped in various ways to achieve numerical efficiency and accuracy.

Modeling of the behavior of droplets deposited on the smooth and rough fiber surfaces

J.M. Gac[1] and L. Gradoń[1]

The separation of the liquid droplets from the stable mist system is a crucial process in industrial technologies, natural gas cleaning, crank case ventilation systems and many other applications. The most efficient devices for such separations are fibrous filters (coalescers). A properly designed coalescer structure, defined through the space distribution of the local porosity and fiber diameter involves the phenomena of a droplet coalescing in the bulk, deposition of drops on the fiber, coalescing of the deposited droplet on the fibers and the drainage of the filter fibers.

In our presentation, a two-color lattice-Boltzmann method (LBM) is used for simulation of the behavior of droplets deposited on a fiber. This kind of well-known LBM scheme is an effective tool for simulating of two-phase flow, including surface tension effects. The interaction of the droplet with the gas flowing around a fiber having smooth and rough surfaces was analyzed.

As a results of our simulations, we derive the equilibrium of conformation of droplets. For a smooth fiber we obtain results consistent with analytical results presented in (Carrol, 1986). By contrast, the droplet on rough fiber takes often completely different conformations, what is explained by means of merging the theory of rough surfaces of Wenzel (1936) with the results of (Carrol, 1986).

Further, we investigate the axial and transversal motion of a droplet on a fiber. We have found that in case of smooth fibers the velocity of the asymmetric droplet is higher than the velocity of axisymmetric droplet, what is consistent with recent results of Gilet *et al* (2010). By contrast, the roughness of the fiber facilitates the motion of the droplet for the situation when the mean distance between the insets is big in comparison to the diameter of the droplet. The reason is that the droplet, moving through the inset, transits from the axisymmetric to the asymmetric conformation, for which the equilibrium velocity is higher. However, if the typical distance between the insets is smaller than the diameter of the droplet, its motion is rubbed. Both these situations are presented in Fig. 1.

The transverse motion of the droplet on rough fiber is slower than the motion of smooth one – so the roughness of the fiber impedes the detachment of the droplets. The difference of the times of detachment from rough and smooth fiber decreases with the value of contact angle, as it has been shown in Fig. 2.

The results of calculation show the distinguished patterns of the interaction depending on the structure of the fiber roughness and the fiber and droplet dimensions. The modeling data indicate a new approach for the designing of a novel generation of the efficient coalescers.

INTRODUCTION

The separation of particles from a flow by the use of fibrous filters is common practise. Such filters generally consist of numerous fibres, of varying sizes, which are positioned more or less normal to the flow. The flow passes through the regions between the fibres and particles are removed by attaching to the fibre surface. The mechanisms by which the particles are removed depend on various particle and flow properties, such as flow velocity, particle size, etc. As the deposit accumulates inside the filter the flow through it, and hence the efficiency with which further particles is collected, is altered. Hence an understanding of the areas in which deposit collects on the fibres and its effect upon the flow field is crucial in predicting the performances of filters. This is dependent on numerous parameters making this is a complex problem. In this work the numerical model that we have developed in previous papers, Dunnett and Clement (2009), is used to investigate this dependence.

NUMERICAL MODEL AND PARAMETERS

The numerical model we have developed previously investigates the performance of fibrous filters in the early stages of particle loading for particles for which diffusion and interception with the fibre are the main mechanisms of deposit. In the model the Boundary Element Method is used to determine the flow field around a single fibre containing deposit. The neighbouring fibres are taken into account in the model by the application of the boundary conditions. The deposit collected on the fibre is assumed to form a smooth porous layer and the flow through the porous layer is assumed to be modelled by Darcy's law. In this work we consider the effects upon filter performance of the various parameters in the problem.

In the literature there are various expressions available for the filter efficiency if deposition is dominated by one mechanism, Brown (1993). Results obtained by our model have found that the parameter **s** defines whether diffusion or interception are the dominant mechanism. This parameter is a function of particle and fibre size, fluid velocity, filter packing fraction and diffusivity, D. It is given by $s = \frac{d_p k_h}{d_f Pe^{1/3}}$. Where d_p and d_f are the particle and fibre diameter respectively and k_h is a hydrodynamic factor given by $k_h^3 = -2\ln\alpha - 3 + 4\alpha - \alpha^2$, α is the filter packing fraction. Pe is the Peclet number $Pe = d_f U_0 / D$ where U_0 is the freestream velocity. It has been found that diffusion dominates for $s<1$ and interception for $s=O(1)$. The numerical model has also shown that the value of s is important in determining whether or not porosity in the deposit subsequently increases the deposition rate.

Another important parameter identified by the model is the dimensionless permeability of the porous deposit, k'. This parameter is dependent upon the deposit porosity and the particle size. There are various expressions available in the literature for k' and these have been investigated and the effects they have upon the predicted flow field will be reported on. An example of the different expressions is shown in Figure 1 where k' is shown as a function of porosity, φ using 3 different expressions from the literature.

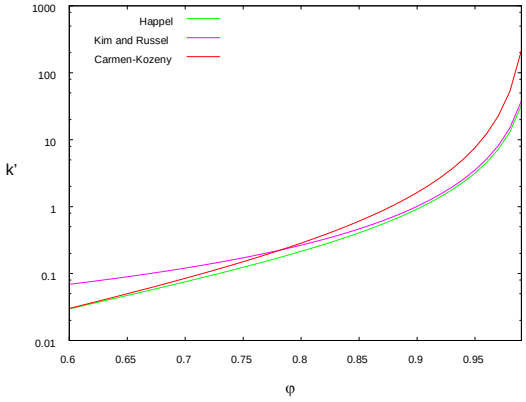

Figure 1. k' as a function of φ

As with all numerical models assumptions have been made, and the range of validity of the model as a result of these will be discussed.

Application of filter utility factor in the filtration of dust and liquid aerosol

T. Jankowski
Department of Chemical, Aerosol and Biological Hazards, Central Institute for Labour Protection – National Research Institute, 00-701 Warsaw, Poland
Keywords: oil mist, aerosol, dust, filtration efficiency, fibrous filters

The melt-blown nonwovens are important part of fibrous filters used in local exhaust ventilation. The filtration efficiency and pressure drop are fundamental parameters which determine operation of fibrous filter.

According to a classic filtration theory (Brown, 1993), the quality factor (QF) was introduced for evaluation of relationships between filtration efficiency (E_{total}) and pressure drop (Δp) through filtration systems in the steady state process.

$$QF = \frac{-\ln(1 - E_{total})}{\Delta p} \quad (1)$$

In the transient state of air filtration process Podgórski (2003) proposed to use the filter utility factor (FUF) takes into account the actual investment and operating costs the use of filtration system.

$$FUF = \left(\frac{C_0 \cdot \eta_p}{\Delta p_0 \cdot u_{pe}} \right) \left[\frac{\int_0^{t_f} E_{total}(t)dt}{t_c + \int_0^{t_f} \frac{\Delta p(t)}{\Delta p_0} dt} \right] \quad (2)$$

This article presents results of tests of influence of changes of the pressure drop and filtration efficiency on the QF and FUF of systems used to filtration of oil mists and dust. Tests were conducted using the melt-blown nonwovens made from polypropylene fibers.

Table 1. Structural characteristic of filter systems.

Filter No.	Filter thickness	Fiber diameter	Porosity	Main pore size
	[mm]	[μm]	[%]	[μm]
PP2	2.55	2.86	97.08	11.26
PP6	1.93	6.71	95.32	42.13
PP12	1.75	12.38	94.59	75.56

Calculations of QF and FUF values were carried out for experimental conditions and the conditions of use filtration system during metal machining. Summary of variables parameters used in the calculation of QF and FUF of systems PP2, PP6, PP12 shown in Table 2.

Table 2. Calculation parameters of FUF.

Ratio $C_{0,exp}/C_{0,real}$	Unit price of electricity	Mechanical effic. of fan	Price of unit mass of filter	Testing time
[-]	[PLN/kWh]	[%]	[PLN/m^2]	[min]
10^3	0.2555	100	29; 35; 50	120

Investigations are performed synthetic dust (ASHRAE 52.1) and liquid aerosol (DEHS) test using a setup composed of aerosol generator AGF 2.0 iP, powder disperser RGB-1000, TSI DMA 3080L, CPC 3022A and CPC 3775.

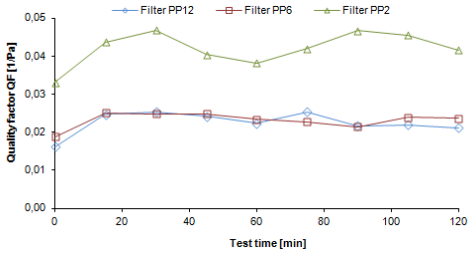

Figure 1. QF of tested filter in testing time.

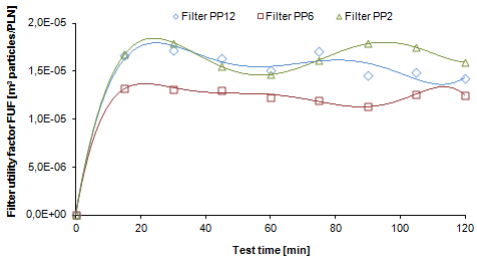

Figure 2. FUF of tested filter in testing time.

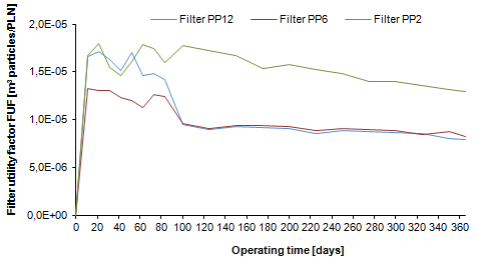

Figure 3. FUF of tested filter in operating time.

It was found that for the initial stage filtration the highest QF value for system PP2 (0.028 1/Pa) was observed. In systems PP6 and PP12 was observed similar values of QF in the range of 0.017 ÷ 0.019 1/Pa (Fig. 1). The highest FUF value for tested systems were similar and ranged from $1.3 \cdot 10^{-5}$ do $1.8 \cdot 10^{-6}$ m^3 particles/PLN (Fig. 2). The optimal time of use PP6 and PP12 was 85 days (Fig. 3), while in the case of PP2 almost twice and it was 150 days (Fig. 3).

This paper has been prepared on the basis of the results of research task I.B.11 carried out within the National Programme partly supported in 2011-2013 within the scope of research and development by the Ministry of Science and Higher Education. CIOP-PIB has been the Programme main coordinator.

Simultaneous removal characteristics of particulate and nitrogen oxides by the SCR catalyst packed high temperature pleated filter bags

Y.O. Park[1], N.Hasolli[1]

[1]Clean Fuel Research Center , Korea Institute of Energy Research, Deajeon, Deaduk Science Town, 305-343, Korea

Keywords: high temperature pleated filter bag, SCR catalyst, particulate, nitrogen oxide, NOx and particulate removal system

Presenting author email: yopark@kier.re.kr

Removal of hamful nitrogen oxides(NO, NO_2 and N_2O) from the exhaust presents a great challenge to the ctalysis community. A variety of investigations have been undertaken to reduce nitrogen oxide emissions, with selective catalytic reduction(SCR) being the mos widly used worldwide. A number of tudies on catalysts for SCR processes have been carried out. The catalysts used most frequently to reduce nirogen oxides emissions from stationary sources(incinerastors, coal-fired power plants and sinter plants) are V_2O_5/TiO_2(anatase) catalysts mixed with WO_3 or MoO_3. The V_2O_5 catalysts exert high effiecncy between 250 and 350oC. To meet this temperature ranges, SCR equipment can be installed before pariculate removal facility and desulurization equipment. In this case, however, SO_2 and particulate may cause catalyst deactivation and poisioning . Furthermore, after the particulate removal facility and desulfurization equipment whose temperature range is about 250^{o}C, the effluent gas must be reheated. The reheating creates an extra opreational cost. To reduce operational costs, SCR equipment can be installed between the particulate removal facility and desulfurization equipment. However, in such a layout, effluent gas also contains SO_2 and As which may cause catalyst deactivation. Accordingly, extensive effort have been made to develop low-temperature SCR catalysts capable of activation under 250^{o}C.

The catalyst packed high temperature filter bags are special multifunctional reactors capable of carrying out two operations at the same time: particulate removal and catalytic abatement of noxious gases such as VOCs, dioxin and furan, nitrogen oxides. This might entail a potential reduction in space requirements as well as energy and investment cost, as pointed out in a recent review.

A pulse jet baghouse , placed downstream of the desulfurization equipment, is a widely used industrial separator for particulate removal to prevent the contamination of catalyst in the SCR equipment. A filter bag installed in the pulse jet baghouse must be operates at high temperature up to 250 ^{o}C. A high temperature pleat filter bags have been developed for high temperature flue gas filtration from coal-fired boilers, waste incinerators and sinter plants. These filter elements are constructed from a patent-pending high density unsupported needle felt media that is stiffened by a state of the art thermal bonding process. These elements are a direct replacement for standard filter bags and cages. Their shorter length keeps the filter element out of the inlet gas stream, reducing abrasion problems and providing for a large drop-out area.

In this study, the SCR catalyst packed high temperature pleated filter bag containing V_2O_5/TiO_2 installed in the Nox and pariculate removal system (DDN-System) was exaimed in the pilot-scale unt and also in a demonstration plant to determne its feasibility in a real system.

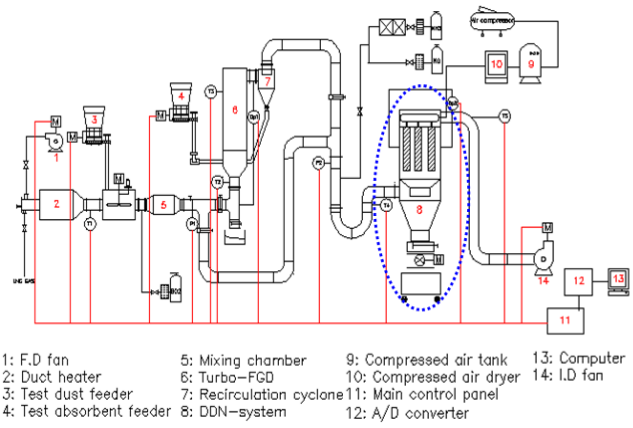

Figure 1. A schematic flow diagram of the particulate and NOx removal system.

The hot flue gas generated from the duct heater was introduced into the new developed desulfurization equipment (Turbo-FGD), particulate, reacted sorbent and nitrogen oxides flow in the particulate and NOx removal system (DDN-System) as shown in Figure 1. The DDN-System had 12 the SCR catalyst packed high temperature pleated filter bags arranged in 4 rows. The system was equipped to conduct cleaning based on pressure set points. The pulse jet cleaning parameters were as follows-cleaning pressure of 3.5 kg/cm^2, pulse time of 0.15 seconds, and time between pulses of 6 seconds.

Presenting author email: yopark@kier.re.kr

Introduction

Recently pleated filter bags are used for cleaning of dust laden gas in various industrial applications. Pleated filter bags made of cleanable filter media have been used in combination with the pulse jet cleaning unit. Surface filter media are designed to hold the particles on their outer surface so that efficient removal of dust cake and dislodging of particles form the filter media means the regeneration of the filter after pulsing by pressurized air. Since the operation mode does not change during the pulsing the air flows back through the pleated filter soon as the pulsing impact is reduced and the filtration process can start again. At this stage if the dust is not dislodged properly the dust will reintrain and mix with the incoming air flow. In complex flue gas treatment facilities, filter bags are loaded with particles generated through the combustion process and other solid matter reactants for removal of gaseous pollutants. Therefore it is very important to optimize the bag cleaning unit by finding proper setting for pulsing unit as well as the venturi. In order to investigate the effect of the venturi design on the pleated filter bag cleaning efficiency we have prepared two types of venturi.

Experimental method and material

Experimental conditions are set constant for all three tests as displayed in the Table 1. Terminal pressure drop was chosen 100 mmH_2O and the pulsing pressure was set for the initial stage as $3kg_f/m^2$. Solenoid valve was opened during pulsing for 150 ms. These tests were run on the clean-on-demand mode where the pulse was triggered after the total pressure drop reaches the value of terminal pressure drop.

Table 1. Experimental conditions.

Conditions	Value
Reaction temp.	180°C
Filtration area	35.2 m^2
Filtration velocity	0.5, 0.6, 0.7 m/min
Gas flow rate	17.6, 21.1, 25 m^3/min
Dust inlet conc.	5 g/m^3

Tests were performed in our integral test unit which contains 8 pleated bags of 2 meter in length together with the air pulsing unit and clean air plenum.

Results and Discussion

Filtration velocity was varied from 0.5, 0.6 and 0.7 m/min. At the higher filtration velocity the pulsing interval is very short and the residual pressure drop increases very fast due to the re-entrainment of the dust. The standard venturi used in traditional baghouse has shown almost no advantage noticed compared to the arrangement without venturi. On the other hand the arrangement with double venturi shows better results in bag cleaning performance as shown in Figure 1.

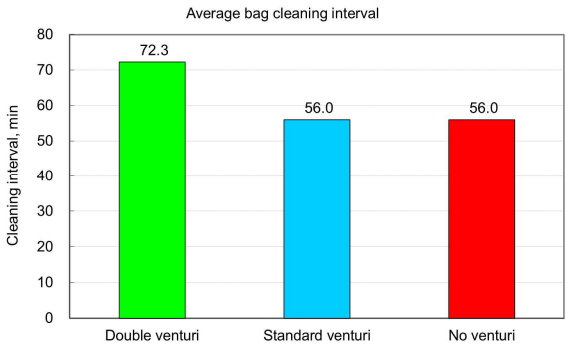

Figure 1. Comparison of bag cleaning efficiency.

The unique design of the double venturi is responsible for the secondary air flow after induction of primary high pressurized air flowing directly through the center of the pleated filter bag opening. This enables the higher pressure impact inside the filter bag down to the bag bottom thus resulting in better cleaning efficiency. As result the pulsing interval was longer and the residual pressure drop lower than the remaining two arrangements with standard and without venturi.

Filtration of airborne carbon nanotubes with nanofiber filters

Y.K. Bahk[1, 2] and J. Wang[1, 2]

[1]Institute of Environmental Engineering, ETH Zurich, Zurich, ZH, CH-8093, Switzerland
[2]EMPA, Analytical Chemistry, Dubendorf, ZH, CH-8600, Switzerland
Keywords: airborne CNT, filtration, nanofiber filter.
Presenting author email: ykbahk@ifu.baug.ethz.ch

Carbon nanotubes (CNTs) have been used as a structural material for a decade in many applications such as sports equipment, semiconductor devices, etc. The amount of CNT production is increasing every year, at the same time, toxicity of CNTs has raised increasing concerns. For this reason, filtration of airborne CNTs is an important issue for inhalation protection of workers (Kim *et al*, 2010, Wang *et al*, 2011). Nanofiber filter media may possess a larger specific surface area and higher permeability for air flow than conventional filter media (George, 2007, Wang *et al*, 2008). In this study, several nanofiber filters, with different solidities, were tested against airborne CNTs.

Fig. 1 shows a schematic of CNT filtration experiments with nanofiber filters. Airborne CNTs were generated by an atomizer or electrospray. In order to classify the generated airborne CNTs, a differential mobility analyser (DMA) was used. The mobility size distribution was obtained by using the scanning mobility particle sizer (SMPS). Classified airborne CNTs by the DMA were carried by the air flow with controlled flow rate to challenge the filters. A neutralizer (Kr-85) was used to avoid electro static precipitation. Concentration of CNTs was measured by condensation particle counters (CPC) at upstream and downstream of the filters. The tested filters were composed of a nanofiber layer and micrometer fiber substrate. Different numbers of layers were tested and the CNT penetrations compared. Polystyrene latex particles (PSL) were used to provide the penetration of spherical particles as a comparison with CNT penetration.

Experimental results of different types of CNTs, including multi-walled CNTs (MWCNTs) with diameters of 8-10 nm, 15-20 nm and 20-30 nm, are reported in the study. These CNTs were aerosolized from suspensions with either an atomizer or electrospray. For example, MWCNTs Baytubes, BMS, Germany with diameters about 15-20 nm, which were functionalized by the nitric acid refluxing method, were dispersed in DI water.

Fig. 2 shows CNTs captured by nanofiber filters. The results show significantly higher collection efficiency for CNTs than spherical particles when nanofiber filters with higher solidities were used. Due to the geometrical characteristics of CNTs, which possess extremely high aspect ratios, CNTs were easily captured by interception in the tested mobility size range. The experimental results are also compared with model calculation, which includes mechanical mechanisms for particle capture by diffusion, interception and inertial impaction.

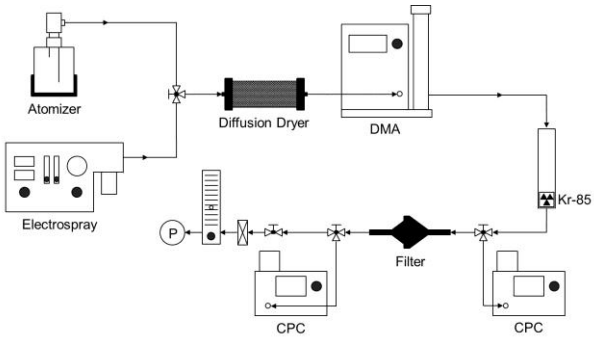

Figure 1. Experimental system for CNT filtration tests.

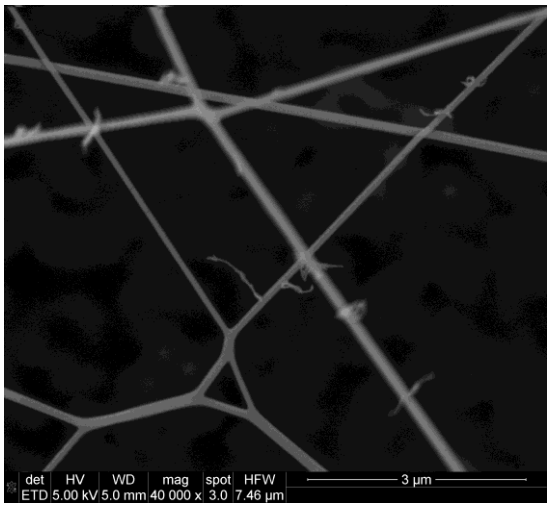

Figure 2. SEM image of captured CNTs by a nanofiber filter.

Presenting author email: f.belosi@isac.cnr.it

Worldwide, filters for air purification are predominantly produced of synthetic and non-biodegradable materials. This includes filters in air conditioning systems for homes, offices, vehicle cabins and clean rooms in addition to air intakes for engines and in respirators worn by humans.

Environmental concerns have increased the general interest in renewable materials, such as cellulose; and microfibrillated cellulose (MFC) has remarkable properties both derived from composition (high strength and the ability to adhere to each other and make strong inter-fibril bonds) and from the fibers small size (high surface area). Indeed, this class of nanomaterials have spanned out the volume of application every year by creating new products in new domains.

The development of microfibrillated cellulose filters are very promising to enhance aerosol filtration at the nanosize aerosol particles (below 100 nm) and could help in the prevention of nanoparticles connected pathologies (nanopathologies).

In this work, a range of various air filters have been prepared from microfibrillated cellulosic material using freeze-drying technique, with the aim to create alternative air filters which are completely biodegradable.

In freeze drying, the material is frozen below its triple point with subsequent sublimation. The solvent is thus transferred directly from solid to gaseous state by reducing the surrounding pressure to avoid the liquid-gas transition.

During the freezing process, the nanocellulose fibrils are separated from the growing ice crystals and are confined to the interstitial regions between them.

.

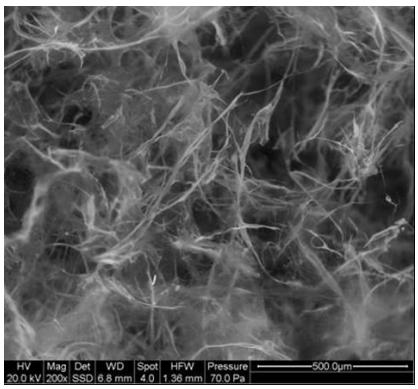

Figure1. Filter structure, 20gm^{-2}, 0.1% dry content of the initial MFC suspension

When the ice crystals in a frozen cellulose-water suspension are removed by sublimation, gas-filled pores are left behind. The pore structure of the freeze-dried filter is therefore a direct reflection of the original distribution of ice crystals. The ice crystal size in the frozen MFC suspension is highly dependent on how the water in the suspension is frozen.

All synthesized filters had tensile strengths above the required for air filters used in commercial and residential filtration systems. Filtration tests have been carried out on freeze-dried filter samples made of 0.1 - 0.2 % dry content of the initial MFC suspension having 5 – 30 gm^{-2} gramages (Figure 1).

The challenge particles for the filter transmission efficiency were NaCl obtained through a Collison nebulization (0.6 bar pressure) of a water solution. The filter face velocity was set at 5.5 cms^{-1}. Particle number concentration upstream and downstream the filter was measured by means of an SMPS+C system (CPC model 5.4 with DMA model 5.5, Grimm GmbH). Pressure drop across the filter was measured using an electronic manometer (Testo mod. 511 AG, Germany). The filter Figure of Merit (FOM), given by the ratio between the logarithim of the particle penetration and the pressure drop, was measured.

Results show a better capture efficiency of these filters, respect to the previously studied impregnated ones, although the filtration efficiency is modest for 100-500 nm particle size domain.

The most penetrating particle size (MPPS) varies for the same type of nanofibrils type used for films fabrication and lies between 100-300 nm.

This work was supported by PFI project 196119/V30 – Nanofilter: Nanofibril filter for environmental nanoparticles, financed through the Research Council of Norway.

Aerosol retention in the secondary side of a tube bundle: Insights into a key scenario for nuclear safety

R.D. Tardáguila*, C. Lopez, L.E. Herranz, M. García

Unit of Nuclear Safety Research, CIEMAT, Madrid, 28040, Spain
Keywords: aerosol surface interaction, deposition efficiency, measurements, nuclear aerosols, particle nature
rosario.delgado@ciemat.es

The Pressurized nuclear water reactors rely on shell-and-tube heat exchangers to generate the steam that expands in the turbine stage of a Rankine cycle. Under the highly unlikely conditions of a reactor core melt accident, a tube rupture in the heat exchanger could result in a release of radioactive particles to the environment. This scenario, generally called severe accident Steam Generator Tube Rupture (SGTR), is of an outstanding importance in nuclear safety. Previous investigations (Auvinen et al, 2005), showed that the most challenging condition from the safety point of view would be the absence of water in the secondary side of the steam generator. However, even under these unfavorable conditions, the secondary side of the steam generator is capable of retaining a fraction of particles carried by the gas (Herranz et al., 2006).

In order to explore the SGTR scenario and build up a sound database on aerosol retention during this accidental sequence, ambitious research programs (EU-SGTR, Auvinen et al, 2005; ARTIST, Guntay et al, 2004; and the current ARTIST2) have been developed. As a contribution to the ARTIST2 project, an experimental campaign (CAAT2, CIEMAT Aerosol ARTIST Tests # 2) aimed at measuring the aerosol retention in the break stage of a dry steam generator has been performed. In particular, the influence of particle nature (agglomerates formed from primary TiO_2 nano-particles; and spherical, single- or few-particle aggregates of SiO_2, Figure 1), the breach size (fish-mouth break: 1D, 0.5D and 0.25D sizes) and the gas mass flow rate has been investigated. Comparison of present results with previous experimental CAAT series performed under guillotine configuration (Sánchez-Velasco et al, 2010) have allowed to explore the effect of the breach shape on the aerosol retention too.

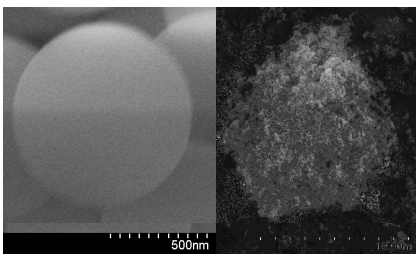

Figure 1. SEM images of SiO2 (left) and TiO2 (right).

The CAAT2 campaign has been conducted at the PECA-SGTR facility of the Laboratory of Analysis of Safety Systems (LASS). A mock-up of 11x11 tubes with the broken tube placed in the 3th row from the bundle edge mid-plane position was set-up in the PECA. The experimental rig consisted of a gas supply system, the Fluid Bed Generator where aerosols are produced, and a measuring system (i.e. sampling and instrumentation). The instrumentation used (i.e. APS®, ELPI®, cascade impactors, membrane filters) characterized the aerosol size distribution and concentration upstream the broken tube and at the bundle exit. The aerosol deposits on tubes surfaces were also collected and weighted to characterize the deposition pattern on the tube bundle.

Particles entering through the breach deposit to some extent, no matter the particle type. However the amount of material collected on tubes surface is highly dependent on its physical nature. The SiO_2 average collection efficiency (η) resulted to be more than one order of magnitude higher than the TiO_2 ones. In case of SiO_2 the net η values have been shown to be consistent with the η distribution as a function of size (Figure 2). Other system variables investigated like breach size and/or shape are of less relevance for net η. Nevertheless, in-bundle deposition patterns have been found to be largely dependant on the breach shape: guillotine breaches result in deposition patterns that only depend on jet penetration, whereas fish-mouth breach profiles do also on orientation.

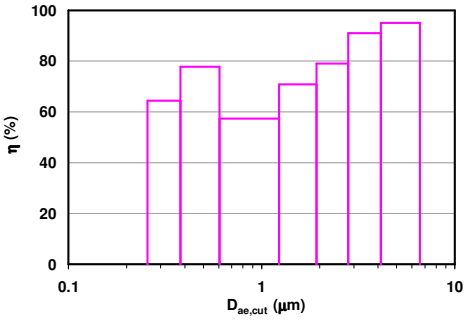

Figure 2. SiO_2 collection efficiency distribution.

Deposition efficiency of charged aerosol particles in cylinder array

T.S. Zaripov, A.G. Egorov

Kazan Federal University, 420008, Kazan, Russia

KEYWORDS: aerosol filtration, collection efficiency, charged particles, CFD
Presenting author email: zaript@gmail.com

The transport and deposition of aerosol particles in the porous medium have many experimental and industrial applications. The diffusion, impaction and gravity actions are not enough to provide the deposition of aerosol particles in the intermediate range of sizes ~0.1-1 μm. In this case the particle charging is used to increase the deposition by the electrostatic force action (Alonso&Alguacil, 2007, Yu&Chandra, 1977).

The aerosol flow with charged particles in a periodic bar of height *H* of an array of circular cylinders of radius R_f .at initial velocity U_0 is studied. The motion of two-phase flow with charged particles is described by the system of non-dimensional equations

$$\nabla \cdot \bar{u} = 0 \quad (1)$$

$$\mathrm{Re}(\bar{u} \cdot \nabla)\bar{u} = -\nabla p + \Delta \bar{u} \quad (2)$$

$$\bar{u} \cdot \nabla c - \mathrm{Pe}^{-1} \Delta c + \beta \nabla \cdot \left(c \nabla \varphi\right) = 0 \quad (3)$$

$$\Delta \varphi = -c \quad (4)$$

$\bar{u} = \frac{\bar{U}}{U_0}$, $p = \frac{PL_0}{\mu U_0}$, $\varphi = \frac{F\varepsilon_0}{qC_0 L_0^{\,2}}$, $c = \frac{C}{C_0}$, $\mathrm{Re} = \frac{\rho U_0 L_0}{\mu}$, $\mathrm{Pe} = \frac{L_0 U_0}{D}$, $\beta = \frac{q^2 b C_0 L_0}{U_0 \varepsilon_0}$, where $\bar{U}$ is the gas velocity, P is the pressure, C is the particle concentration, F is the potential of electric field, L_0, U_0, C_0 are scales of length, velocity and concentration, D is the diffusion coefficient, q is the particle charge quantity, ε_0 is the permittivity of the air. To express the inertia of gas flow the Reynolds number Re is used. Nondimensional parameters Peclet number Pe and β characterize the influence of diffusion and electrostatic force on the particle deposition. The boundary conditions for the hydrodynamics problem (1), (2) include unity values of gas velocity at the bar inlet, the symmetry conditions on top and bottom lines of the bar, zero value of pressure on the right boundary. As a boundary conditions for problem (3), (4) zero values of concentration and potential on the cylinders surfaces are taken. The relative input concentration of particles is equal unity. Zero periodic conditions are takes for electric potential along the flow.

The Navier-Stokes equations (1), (2) are solved independently, then joint solution of equations (3), (4) gives the distributions of concentration and electric potential on the found velocity field. The distributions of particle concentration and electric potential and particle deposition efficiency are studied numerically at the various values of particle size, initial particle concentration, quantity of particle charges, array porosity and flow Reynolds number.

Dependencies of capture efficiency of single cylinder on Peclet number are shown in fig. 1. The formula for capture efficiency due to diffusion η_D within the boundary layer flow model was obtained by Stechkina (1966)

$$\eta_D = 2.9 Ku^{-1/3} Pe^{-2/3} + 0.624 Pe^{-1}$$

where $Ku = -0.5\ln\alpha - 0.75 + \alpha - 0.25\alpha^2$, α is the solidity. The dependence $\eta_D(\mathrm{Pe})$ is shown in fig.1 (dotted line). Calculations for neutral particles give very close curves $\eta(\mathrm{Pe})$. In the case of charged particles the deposition efficiency tends to constant values that are determined by the parameter β. It is possible to provide high deposition of submicron particles by increase the charge quantity q of particles.

Inertial deposition of aerosol particles on a porous cylinder

O.V. Grigorieva[1], S.K. Zaripov[2]
[1]Kazan State Power University, 420066, Kazan, Russia

Presenting author email: rara_avis86@mail.ru

In the process of air filtration suspended particles deposited on filter elements form a porous layer that acts on the flow around a single fiber and the process of particle settling. In addition, porous fibers can be used as single filter elements. It was shown (Kirsh, 2007) that the use of porous cylinders as an element of aerosol filters significantly increases the efficiency of diffusion capture of small particles. The presence of an additional gas flow through a porous body also affects the inertial capture. In this paper the problem of aerosol flow through a porous cylinder is solved.

A two-dimensional flow of an incompressible gas flow with suspended particles around the porous cylinder radius r_c is considered. In the assumption that particle concentration is small the influence of the dispersed phase is neglected. The air motion around the cylinder and in porous area is described by the equations (Bhattacharyya et.al., 2006):

$$\nabla \bar{u} = 0 \qquad (1)$$

$$\varepsilon^{-2} \rho \bar{u} \nabla \bar{u} = -\nabla p + \frac{\mu}{\varepsilon} \Delta \bar{u} - b \frac{\mu}{k} \bar{u} \qquad (2)$$

where $\bar{u}$ is the gas velocity, μ and ρ are the coefficient of dynamic viscosity and the air density, p is the pressure, ε is the porosity, k is the permeability of the porous medium. The parameter b equals to zero outside the cylinder and to one inside the cylinder. The gas velocity $\bar{u}$ averaged over the volume of pore space is associated with flow rate $\bar{u}_f$ by the relation $\bar{u} = \varepsilon \bar{u}_f$.

In the region outside the cylinder ($\varepsilon = 1, b = 0$) equations (1), (2) become the Navier – Stokes equations for an incompressible gas. Inside the porous body they are extended Darcy– Brinkman equation. The equations of the carrier medium (1), (2) are solved by finite volume method using CFD FLUENT software. The equations of motion of suspended particles are numerically integrated in the obtained velocity field. The particulate flow is characterized by the dimensionless parameters: the Reynolds number $\mathrm{Re} = \rho U_\infty 2r_c / \mu$ (U_∞ – velocity of the undisturbed flow), the Darcy number $\mathrm{Da} = k / r_c^2$, the Stokes number $\mathrm{Stk} = U_\infty / r_c \tau$ (τ – the relaxation time of a particle).

To calculate the deposition efficiency E the particle trajectories are traced outside the porous cylinder. The coefficient E can be expressed as a product of the efficiency E_e of the particles that reach the surface of cylinder and the efficiency E_i of their deposition within the porous body: $E = E_e E_i$. To find E_e it is suggested that all the particles reached the surface of the porous cylinder should be settled. In the absence of gas flow through the cylinder the inertial deposition efficiency drops to zero at a finite number of Stokes. For a porous cylinder at sufficiently small values Stk the quantity E_e remains finite. Under the assumption that the cylinder is consisted by packed fibers of equal radius r_f the coefficient E_i of particle deposition inside the porous body is expressed through the integral ($\tilde{y} = y / r_f$ – dimensionless ordinate):

$$E_i = \int_0^1 \left[1 - \exp\left(-\frac{\sqrt{1-\tilde{y}^2}(1-\varepsilon)\mathrm{Stk}}{0.0058} \right) \right] d\tilde{y} \qquad (3)$$

The approximate formula for the depth of penetration of dispersed particles in the porous structure obtained in [1] is taken into account in (3). Fig. 1 shows the dependence of the efficiency E on the Stokes number. With the increase ε the efficiency of deposition of particles inside the cylinder drops. It is seen that the additional advantage in the total deposition efficiency decreases for large values of porosity due to the lower efficiency of deposition of particles inside the cylinder.

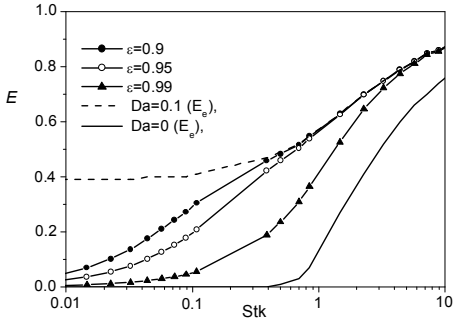

Fig. 1. The deposition efficiency as a function of Stk number.

Soot Nanoparticle Aggregate Filtration in Layer-Coated Diesel Particulate Filters

N. D. Vlachos[1], A.G. Konstandopoulos[1,2]

[1]Aerosol & Particle Technology Laboratory, CPERI/CERTH, P.O. Box 60361, 57001, Thessaloniki, Greece
[2] Dept. of Chemical Engineering, Aristotle University, P.O. Box 1517, 54006, Thessaloniki, Greece
Keywords: filter wall microstructure, digital reconstruction, gradient porosity.
Presenting author email: ndv@cperi.certh.gr

An ideal filter wall microstructure should provide high filtration efficiency at the expense of low pressure drop, targets that cannot be independently pursued due to the porosity – filtration efficiency trade-off. To overcome this, filtration media with so-called gradient (or asymmetric) structures have been introduced into industrial (liquid) filtration since 1962 (Loeb *et al*, 1962) and a first attempts to introduce to the Diesel filtration field were made by Yoshida *et al* (1989) and more recently in a publicly-funded project ("CERFIL", 1998). Multifunctional layers, having also catalytic action, have also been developed for modern DPFs, e.g. Ogyu *et al* (2008) and Lorentzou *et al* (2008). Similar layers, only with filtration action, have been suggested for commercial application by Mizuno *et al* (2008). In the present work we outline the first principles (ab initio) simulation of such gradient filter wall microstuctures, focusing on the prediction of nanoparticle filtration behaviour.

In support of the above task, we have developed a set of process-mimetic reconstruction techniques to numerically generate realistic 3-D representations of DPF porous wall microstructures (Vlachos *et al* 2006). Using such digital materials and microflow simulation the flow field in the pore spaces of the filter wall can be obtained (Konstandopoulos *et al* 2007). Such calculations have shown that, inside typical DPF materials, there can be more than an order of magnitude variation of the filtration (approach) velocity. This feature is not accounted for in traditional mean-field type filtration theory which therefore cannot be used in developing new material structures but only for describing existing ones, provided that a proper calibration of the phenomenological parameters of the model is performed.

The framework employed here relies also on the use of realistic representations of the soot aggregates, generated by a dedicated computational engine that matches morphology and mobility of the digital soot to distributions derived from Diesel exhaust by methods similar to e.g. Virtanen *et al* 2004. Size-specific filtration efficiency can thus be calculated for the clean filter wall as well as during transient soot deposition in the filter wall, the latter being carried out by iterating between soot aggregate deposition and flow field updates.

To illustrate the application of this framework we examine the influence of a thin coating layer on DPF filtration and pressure drop. We consider a realization of a grain-sintered porous wall with a wall-thickness of 180 μm, representing a SiC DPF wall with a porosity of 42% and an average pore size of 11 μm (as determined by mercury porosimetry). Such a wall structure is typical of a down-sized DPF which, due to the higher filtration velocities expected, features a thinner wall for reduced pressure drop. The needed filtration efficiency is recovered by coating the upstream side of the wall with a nanoparticle-based layer of 20 μm thickness and 62% porosity, results for which are shown in Figure 1 below.

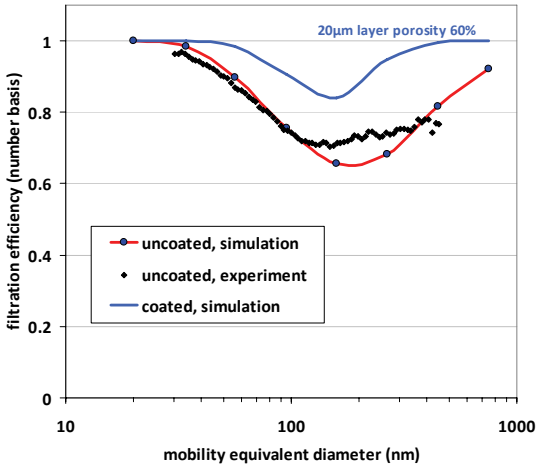

Figure 1. Filtration efficiency of a grain-sintered DPF wall with and without a nanoparticle-based layer.

Experimental study on small cyclones for combustion engine gas cleaning

B. Sagot and J. Giardi

[1]Thermo-Fluids Laboratory, ESTACA, 92300, Levallois-Perret, France
Keywords: cyclone separator, collection efficiency, pressure drop.
Presenting author email: benoit.sagot@estaca.fr

Cyclone separators are widely used in industry for separating dispersed particles from their carrying gas. Theses devices are frequently used in large-scale industrial processes, for both separation and drying applications. However, small cyclones have also found various applications, such as personal cyclone samplers which are used in environment control. Small cyclones are also widely used in combustion engines, for the separation of oil mist from blow-by gases. Theses so-called “blow-by gases” result from leakage between the combustion chamber and the crankcase, especially when piston rings wear occurs. An important function of crankcase venting systems is the separation of the oil mist resulting from the circulation of these blow-by gases through the crankcase, which contains lubricating oil.

The size of the sampling cyclone is of great importance for its collection efficiency: a reduction of this size produces an increase of the collected oil flow, but also results in an increase of the pressure drop.

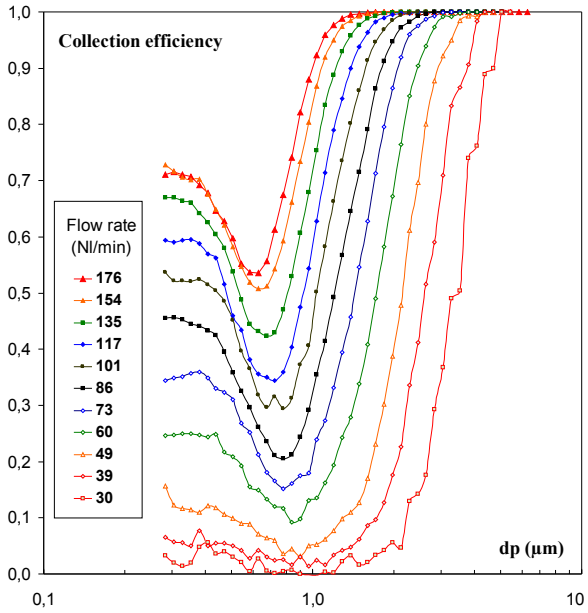

Figure 1. Collection efficiency measurements for a cyclone with 35 mm diameter.

Few data are currently available for small cyclones operating with high flow rates. We present in this study a new set of experimental data on the particle collection efficiency and pressure drop, for three different cyclones which are systematically studied, for combustion engine operating conditions (80°C), and with droplet size in the range 0.3 to 10 µm. For this purpose, we developed a temperature controlled flow bench, with an aerosol generator (PALAS), measurements of the aerosol particle concentrations upstream and downstream of the cyclone (WELAS). As illustrated in figure 1, the collection efficiency curves demonstrate that different mechanisms generate deposition (inertia for large particles, turbulent and Brownian diffusion for small particles).

Every cyclone geometry is normalized, all internal dimensions within the cyclone being proportional to its diameter, which has been varied from 25 to 45 mm.

The measurement results are compared with available models, as reported by Cortés and Gil. (2007), Avci and Karagoz (2003), and Zhu and Lee (1999), for the evaluation of both cumulative collection efficiency and pressure drop.

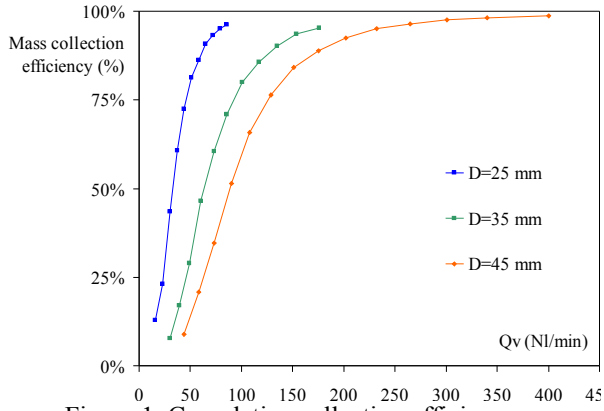

Figure 1. Cumulative collection efficiency.

The aim of this study is to provide a consistent comparison between a new set of measurements and available models, to identify the most relevant models for the design and optimization of cyclone separators applied to liquid droplet aerosol filtration.

The calculating method of resuspension based on the combination deterministic and statistical approaches

D.V.Tsaplin and V.N. Piskunov

Russian Federal Nuclear Center – VNIIEF; Sarov, Nizhniy Novgorod region, 607190, Russia
Keywords: aerosol dynamics, resuspension, aerosol-surface interaction, particle size, modelling
Email: tsaplindv@mail.ru, v-n-piskunov@yandex.ru

Resuspension, this is the process of detaching the particles from the underlying surface to the near-surface layer of the atmosphere under the wind flow. It plays the important role in transporting the contaminations.

It is possible to allocate the statistical and deterministic approaches to the description of resuspension. The statistical approach determines the resuspension rate of particles from the surface under the wind flow, taking into account the fluctuations of aerodynamic forces, the turbulent bursts and the spread of adhesive force (e. g., the rock'n roll model (Reeks and Hall, 2001; Zhang, Reeks and Kissane, 2010)). The deterministic approach allows estimating the threshold velocity of a stream to begin with the resuspension of the particles of the set size. In many models (Ziskind et al., 1997; Ibrahim et al., 2003) this threshold velocity is determined by the balance of the moments acting on a particle to start its rolling on a surface as the particle resuspension often begins after their rolling. Thus it is necessary to consider, that rolling and immovable particles are in different conditions for resuspension as the force of adhesion acting on the rolling particles, is much less.

In the given report there is the calculating method of the resuspension uniting the deterministic and statistical approaches to description of resuspension of immovable and rolling particles on a surface. This method uses rock'n roll model based on the statistical approach for representation of resuspension of immobile particles, which size is less than threshold diameter D_{th}.

Quantity of the threshold diameter D_{th} is evaluated from the balance of adhesive M_A and drag M_D moments, operating on the particles:

$$D_{th} = 0.489\left(\frac{\left(F_A(D)\right)^3 \gamma}{\rho_f^3 E u_*^6}\right)^{1/7}, \qquad (1)$$

where γ is the surface energy and E is the composite Young's modulus of the particle-surface contact, ρ_f is the fluid density, u_* is the friction velocity. Dependence of the adhesion force on the particle's diameter is set by the adhesion model taking into account of a surface roughness.

The resuspension rate of small particles ($D<D_{th}$) is calculated, using expression for the resuspension rate constant p under the action of the fluctuating aerodynamic force, obtained in model rock'n roll (Reeks and Hall, 2001). Resuspension of rolling large particles of diameter $D>D_{th}$, which doesn't undergo any significant adhesion, occurs immediately if aerodynamic lift force F_L acting on them exceeds their weight:

$$F_L > m_P g = \pi \rho_P D^3 g/6, \qquad (2)$$

where m_P is the particle mass, ρ_P is the density of the particle's material and g is the gravitational acceleration. Too large and as a consequence too heavy particles, for which the inequality (2) is not suitable, still rolling on a surface, not taking part in resuspension. The full fraction of the particles, which has been resuspended in time t from surface unit under the wind flow, is evaluated by sum of a fraction of the rolling particles, for which the inequality (2) is satisfied, and a fraction of immovable particles, which resuspension is defined by the rock'n roll model.

On basis of the described algorithm of the resuspension calculation the program for estimation short-term resuspension was written by using the application package MATLAB. Figure 1 illustrates that the calculations carried out by this program are better close to the experimental data, then the predictions of the usual rock'n roll model.

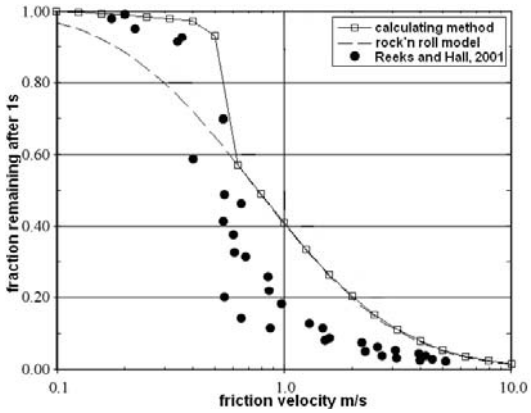

Figure 1. Comparison of the calculated and measured fractions of alumina particles of nominal size 20 μm, which have remained on a surface at various friction velocity.

The suggested method can be used for the account redistribution of contaminations on a surface after their deposition.

Analysis of asymptotic behavior of disperse systems with particle coagulation and breakage

V.N.Piskunov

Russian Federal Nuclear Center – VNIIEF; Sarov, Nizhni Novgorod region, 607190, Russia

Keywords: particle formation, coagulation, fragmentation, asymptotic behavior, self-similar spectra

Presenting author email: piskunov@vniief.ru

In general terms, the following three regimes can be implemented in coagulation and breakage systems at large times $t \to \infty$:

- Eventually, the loss of small particles due to their merging is compensated for large particle fragmentation into small ones; steady spectra are shaped in the system.

- The breakage process is too slow as compared to coagulation; particle spectrum evolves into the range of large sizes, similar to free coagulation.

- Breakage results in spectrum cumulation in the initial range of sizes; either quasi-stationary singular or non-steady (including self-similar) spectra are shaped.

Analysis show that the following self-preserving types can be formed.

1. Spectra governed by self-preserving hypothesis (Friedlander, 1960):

$$c(g,t) = \frac{N^2(t)}{\rho}\Psi(x),\ x = \frac{gN(t)}{\rho},$$

$$\int_0^\infty \Psi(x)dx = \int_0^\infty x\Psi(x)dx = 1\ , \qquad (1)$$

where $N(t)$ and ρ – are number and mass concentrations. In this case the asymptotic behavior of $L_\alpha(t)$ spectrum moments at $t \to \infty$ is as follows:

$$L_\alpha(t) = \int_0^\infty g^\alpha c(g,t)dg \approx B_\alpha \rho^\alpha N^{1-\alpha}(t)\ ;\ B_\alpha = \int_0^\infty x^\alpha \Psi dx \quad (2)$$

2. Self-similar singular spectra (Lushnikov and Piskunov, 1976), for which function $\Psi(x)$ is not integrable in zero: $\Psi(x)\,|_{x\to 0} \approx \varphi(x)/x^\gamma$; $\varphi(0) \neq 0$: $1<\gamma<2$.

3. Self-similar collapsing spectra.

The breakage can provide a different type of self-similarity corresponding to spectrum accumulation (collapse) in zero ($g \to 0$). Equation (1) does not vary for integrable $\Psi(x)$. Formally, the behavior of moments (2) $L_\alpha(t) \sim N(t)^{1-\alpha}$ remains the same, but in this case moments with $\alpha < 1$ increase, and with $\alpha > 1$ decrease, opposite to a general coagulation pattern.

4. Slowly decreasing self-similar collapsing spectra.

Divergence of moments $L_\alpha(t)$ is valid for self-similar collapsing distributions, but physically it should be generated by too slow decrease of $\Psi(x)$ at $x >> 1$: $\Psi(x)\,|_{x\to\infty} \approx A/x^\Gamma$, $\Gamma > 2$.

Moments asymptotic behavior $L_\alpha(t)$ can be defined by increase exponent $F(\alpha)$:

$$F(\alpha) = \lim_{t\to\infty} \frac{d\left[\ln L_\alpha(t)\right]}{d\left[\ln N(t)\right]};\ L_\alpha(t) \sim N(t)^{F(\alpha)} \qquad (3)$$

The possibility of self-similarity regime formation in particle coagulation and breakage system can be predicted according to the diagram of Figure 1 using moments asymptotic behavior $L_\alpha(t)$ for $t \to \infty$ derived either analytically, or with numerical computations.

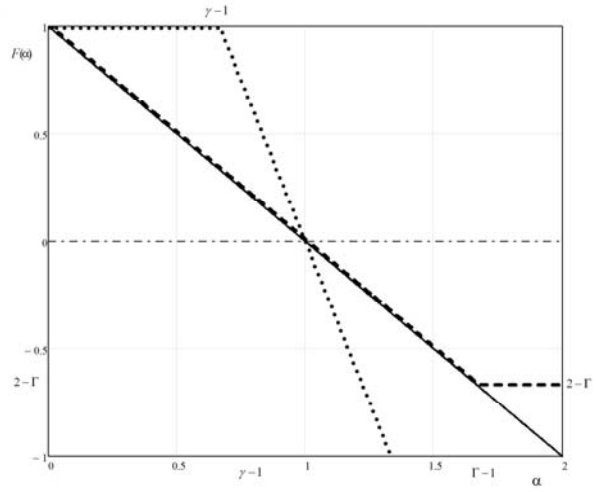

Figure 1 – Increase exponent behavior $F(\alpha)$ for different types of self-similarity: ——— dependence (2) for ordinary and collapsing self-preserving spectra (1), - - - for singular spectra; — — for slowly decreasing collapsing spectra; — · — steady-state regime

For homogeneous coagulation kernels $K(g,n)$ and breakage rates $f(g,n)$:

$$K(ag,an)=a^\lambda K(g,n)\ ,\qquad f(ag,an)=a^\mu f(g,n) \quad (4)$$

(λ and μ - are homogeneity corresponding parameters) the following condition has been obtained required for self-similar regimes existence in coagulation and breakage systems:

$$2 - \lambda + \mu = 0\ , \qquad (5)$$

Condition (5) means range boundary $2-\lambda+\mu > 0$, where steady-state regimes are implemented according to (Vigil and Ziff, 1989).

Analytical tests for simultaneous coagulation and condensation of composite particles

V.N.Piskunov

Russian Federal Nuclear Center – VNIIEF; Sarov, Nizhni Novgorod region, 607190, Russia

Keywords: aerosol formation, coagulation, condensation, composite particles, analytical solutions, numerical program verification

Presenting author email: piskunov@vniief.ru

A short description is considered to be efficient for kinetics numerical simulation of composite particles when one of the components (impurity) is taken integrally – by zero $n(g,t)$ and first $m(g,t)$ moments of entire spectrum (Simons, 1981; Piskunov, Golubev, Goncharov and Ismailova, 1997):

$$n(g,t)=\int_0^\infty C(g,\alpha,t)d\alpha\,;\quad m(g,t)=\int_0^\infty \alpha C(g,\alpha,t)d\alpha \quad (1)$$

where $C(g,\alpha,t)$ - is particle concentration with total mass g and impurity mass α at time t, and $\overline{\alpha}(g,t) = m(g,t)/n(g,t)$ – is impurity average mass in a particle. For simultaneous processes of coagulation and condensation, the complete kinetic equation is given by (Piskunov, 1999):

$$\partial_t C(g,\alpha,t)+\partial_g\left[V(g,\alpha,t)C(g,\alpha,t)\right]+$$

$$+\,\partial_\alpha\left[U(g,\alpha,t)C(g,\alpha,t)\right]\;=S(C;g,\alpha,t)\;, \quad (2)$$

where S – is Smoluchowski operator, $d_t g = V(g,\alpha,t)$ – is total condensation rate, and $d_t\alpha = U(g,\alpha,t)$ is impurity condensation rate. Taking

$$V(g,\alpha,t)\cong V(g,\overline{\alpha},t)\equiv v(g,t)\;;\;\; U(g,\alpha,t)\cong U(g,\overline{\alpha},t)\equiv u(g,t)$$

and integrating (2) between 0 and g over α (with weights 1 and α), we get the following system of equations:

$$\partial_t n(g,t)+\partial_g\left[v(g)n(g)\right]\;=$$

$$=\frac{1}{2}\int_0^g K(g-s,s)n(g-s)n(s)ds - n(g)\int_0^\infty K(g,s)n(s)ds \quad (3)$$

$$\partial_t m(g,t)+\partial_g\left[v(g)m(g)\right]-u(g)n(g)=$$

$$=\int_0^g K(g-s,s)n(g-s)m(s)ds - m(g)\int_0^\infty K(g,s)n(s)ds \quad (4)$$

In case when the impurity is condensed, and the ballast substance (core) is relocated due to coagulation, it must be assumed that $u(g,t) = v(g,t)$, simplifying solution (3) – (4). In this case, for impurity particles we have:

$$\partial_t c(g,t)+\partial_g\left[v(g)c(g)\right]=$$

$$=\frac{1}{2}\int_0^g K(g-s,s)c(g-s)c(s)ds \;- c(g)\int_0^\infty K(g,s)n(s)ds \quad (5)$$

Equations (3), (5) agree with kinetic equations for water-ice phase transitions obtained in (Piskunov, 2000; Piskunov, Petrov, 2002), but they have more general meaning. Equation (4) is additional and describes impurity relocation between the particles.

The following statement is true.

Theorem 1. Let $u(g,t) = v(g,t) = \beta g$ and $n(g,t)$ be solution of (3). Let the initial conditions be arbitrary, but $m(g,0) = gF_0/A_0\, n(g,0)$. Then (4) is given by:

$$m(g,t)=\varphi(t)gn(g,t)\;;\;\; \varphi(t)=e^{-\beta t}\left(D+\beta\int_0^t e^{\beta s}ds\right), \quad (6)$$

where D – is arbitrary constant.

The proof consists in forward substitution of function $m(g,t)=\varphi(t)gn(g,t)$ in (4) accounting for (3). g quadratic terms are canceled, and linear terms are reduced to equation $\frac{d\varphi}{dt}+\beta\varphi-\beta=0$ with solution

$$\varphi(t)=e^{-\beta t}\left(D+\beta\int_0^t e^{\beta s}ds\right)$$

Conclusion

Solution (5) for free impurity is a separate task, but, for example, for kernels $K_c(g,n)=2$, $K_+(g,n)=g+n$ and $K_*(g,n)=2gn$ it is solved in (Piskunov, 2000; Piskunov, Petrov, 2002). Thus, we can talk about the complete solution of chain of equations (3)-(5) for composite particles. Certainly, what is meant here is short (integral) moment description of impurity particles distribution functions and for a particular type of condensation rates. It is reasonable to use the analytical solutions obtained for numerical program verification.

Collapsing self-similarity in systems with coagulation and fragmentation of particles

V.N.Piskunov, I.V.Piskunova

Russian Federal Nuclear Center – VNIIEF; Sarov, Nizhni Novgorod region, 607190, Russia

Keywords: particle formation, coagulation, fragmentation, self-similarity, collapsing spectra

Presenting author email: piskunov@vniief.ru

The possible types of self-similarity in particle breakage and coagulation systems have been analyzed in report (Piskunov, 2012). For homogeneous coagulation kernels *K(g,n)* and breakage rates *f(g,n)*:

$$K(ag,an)=a^{\lambda} K(g,n) \quad , \qquad f(ag,an)=a^{\mu} f(g,n) \qquad (1)$$

the following condition required for self-similar regimes should be fulfilled:

$$2 - \lambda+\mu = 0 \quad , \qquad (2)$$

The possibility of collapsing regime formation when spectrum is accumulated (collapsed) in zero ($g \to 0$), is mentioned the report.

The analysis shows the additional constraints for self-similar collapsing spectra:

$$2 - \lambda + \mu = 0 \; ; \quad \lambda > 1 \; ; \quad \mu > -1 \qquad (3)$$

We take coagulation kernel *K(g,n)* = *gn* and breakage rate *f(g,n)=a.* In this case, the required conditions (3) are fulfilled. Equation for number concentration $N(t)$ is:

$$\frac{dN}{dt} = \frac{\rho}{2}(a-\rho) \; ; \quad N(t) = N_0 + \frac{\rho}{2}(a-\rho)\cdot t \; , \qquad (4)$$

i.e. $N(t)$ increases at $a > \rho$ and decreases at $\rho > a$. Let us analyze the first case $a > \rho$, when breakage is dominant. Since $N(t)$ increases in time, spectrum collapse in zero ($g \to 0$) is possible.

Let us represent the self-similar solution in the form of:

$$c(g,t) = \frac{N^2(t)}{\rho}\Psi(x) \qquad , \qquad x = \frac{gN(t)}{\rho},$$

$$\int_0^{\infty} \Psi(x)dx = \int_0^{\infty} x\Psi(x)dx = 1$$

Insertion in breakage coagulation kinetic equation gives:

$$(Q-1)\left(2\Psi + x\frac{d\Psi}{dx}\right) = \int_0^x \Psi(x-y)\Psi(y)(x-y)ydy - \qquad (5)$$

$$-(2+Q)x\Psi + 2Q\int_x^{\infty} \Psi(y)dy \; , \quad Q = a/\rho > 1$$

Function $\Psi(x)$ has finite value in zero $\Psi(0) = a/(a-\rho)$. If there is no coagulation, i.e. *K(g,n)* = 0, *h(g)=a,* then (5) is given by $\Psi(x) = \exp(-x)$, corresponding to collapsing self-similarity only for breakage (Fillipov, 1961).

In the general case, moments behavior at large times resulting from (5), is as follows:

$$L_{\alpha}(t) = \int_0^{\infty} g^{\alpha} c(g,t)dg \approx B_{\alpha}\rho\left(\frac{a-\rho}{2}\right)^{1-\alpha} t^{1-\alpha} \; ;$$

$$B_{\alpha} = \int_0^{\infty} x^{\alpha}\Psi(x)dx \qquad (6)$$

Integrals B_{α} are taken convergent. Hence, moments with α < 1 should increase, and moments with α > 1 should decrease (which is opposite to a general pattern for free coagulation).

GA-computations (Piskunov and Golubev, 2002) were used to verify that for α = {0, 1/3, 1/2, 2/3, 1, 2} asymptotic moments behavior also agrees with (6), proving the existence of self-similar regime (5), (6). Solution (5) can be found either with Laplace transformation or numerically.

At $\rho > a$ critical phenomena similar to free kernel coagulation, are valid (Lushnikov, 1978). Critical phenomena with mass disbalance occur at time $t_c = 1/L_2(0)$. Criterion of this occurrence is the second moment $L_2(t)$ becoming infinite. GA-computations formerly successfully applied in (Piskunov, Golubev, Barrett et al., 2002) to detect critical phenomena in free coagulation, have been used to determine the behavior of $L_2(t)$ at arbitrary a. Computations t_c were carried out at $\rho = 1$ and $L_2(0)$=1. The results are given Table 1. As it must be according to physical content, the moment of critical phenomena is pulled by breakage.

Table 1 – Computational results t_c for different $a < \rho$ at ρ=1, $L_2(0)$=2

a	0	0.2	0.5	0.6	0.8	0.9	0.95
t_c	1	1.340	2.106	2.416	3.266	3.904	4.338

Thermophoretically Modified Brownian Coagulation

M. Arias-Zugasti[1] and D. E. Rosner[2]
[1]Departmento de Física Matemática y de Fluidos, UNED, Madrid, 28040, Spain
[2]Department of Chemical and Environmental Engineering, Yale University, New Haven, CT, 06520, USA

Keywords: Coagulation, Fundamental aerosol physics, Aerosol modeling.
Presenting author email: *maz@dfmf.uned.es*

For particle populations in a highly non-isothermal carrier gas, size-dependent particle thermophoresis provides an often-neglected coagulation mechanism (Rosner and Arias-Zugasti 2011a), which can either induce the coagulation of non-Brownian particles, or systematically alter the coagulation frequency for Brownian particles. In the present work we focus on this second scenario, in which an aerosol of Brownian particles evolves under the simultaneous influence of both coagulation mechanisms: the well-known Brownian coagulation first studied by Smoluchowski, and thermophoresis-induced coagulation (Arias-Zugasti and Rosner 2011b, Rosner and Arias-Zugasti 2011c). In the present case all particles in the population are assumed to have the same thermal conductivity and, except for their rapid coalescence upon contact, behave like solid spheres.

We first derive a combined coagulation frequency based on a thermophoresis-modified continuum-limit coagulation frequency of Smoluchowski. The Brownian + thermophoresis combined coagulation frequency is modeled in a way similar to the Brownian + sedimentation coagulation frequency (Simons et al. 1986), but with the gravitational sedimentation velocity replaced by the size-dependent near-continuum thermophoretic velocity.

We show that the relative intensity of each coagulation process is characterized by a dimensionless Peclet number, defined by the ratio of the characteristic coagulation frequencies. Introducing the combined coagulation frequency as a kernel into a Smoluchowski-type population-balance integro-PDE, we perform a systematic parametric study of the time evolution of a coagulation-aged, initially log-normal population, as a function of the Peclet number (Pe) and the particle/gas Fourier thermal conductivity ratio, kp/kg. We also investigate the errors associated with the frequently made “additive kernel” approximation.

Our results show that in the long-time limit a quasi-self-preserving population (QSPP) is reached. Regarding the dependence of this QSPP on Pe and kp/kg, we find that when the reference Peclet number is much smaller than, say 0.1, we recover the previously well-studied Brownian self-preserving populations. However, for intermediate Pe-values characteristic distortions set in, corresponding to increased spread and skewness, and slightly smaller departures from log-normality. Ultimately (for Pe-values larger than about 10) our QSPP become indistinguishable from our previously reported TP-dominated results (Rosner and Arias-Zugasti 2011a). It has been observed that the dependence on kp/kg reduces to a slight modification of the characteristic time- and size- scales (for kp/kg > 10), and, hence, our results for the self-similar normalized PDF reached in the long-time limit are almost independent of kp/kg over the entire range of Peclet numbers.

This recent work was supported, in part, by Comunidad de Madrid (S2009/ENE-1597), Ministerio de Ciencia e Innovación (CSD2010-00011, ENE2011-26868), and NSF(USA)-CBET (Grant 1037733). Extensions currently in progress deal with composition-dependent thermal conductivity, thermocapillary effects for mists, and dense carrier vapour effects.

Presenting author email: Anastasios.Melas@jrc.ec.europa.eu

We calculated the mobility radius of fractal aggregates in the continuum regime as suggested by Isella and Drossinos (2011) who related it to the molecule-aggregate collision rate. We created the fractal aggregates with the cluster-cluster aggregation method proposed by Thouy and Jullien (1996).

The fractals used in our simulations have different fractal dimension (d_f), fractal prefactor (k_f) and they consist of 8 up to 64 monomers. In each case the scaling law is exactly satisfied. In Fig. 1 the mobility radius (R_m) is plotted as a function of the radius of gyration (R_g). Both of them are scaled with R_1 (as all length scales are).

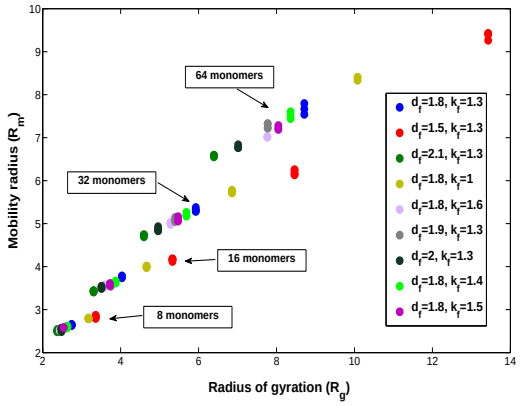

Figure 1: The mobility radius as a function of the radius of gyration for fractals with different N, d_f, k_f.

For a number of monomers N a linear relationship between R_m and R_g is observed. By fitting we obtain:

$$R_m = 0.512\left[1-\frac{1}{\ln(2N)}\right]R_g + 0.72N^{0.413}. \qquad (1)$$

We used a Levenberg-Marquardt algorithm to perform the fit, and we found it to be stable. As expected Eq. 1 reproduces the $R_m - R_g$ relationship shown in Fig. 1. We used the same equation to calculate $\beta = \frac{R_m}{R_g}$ for a large number of monomers ($N = 1000$). The fractal aggregates we chose have the same fractal dimension and prefactor as DLCA ($d_f = 1.85, k_f = 1.17$) and RLCA ($d_f = 2.05, k_f = 0.94$) clusters. We find $\beta = 0.769$ for DLCA and $\beta = 0.86$ for RLCA clusters, in good agreement with the literature values 0.765 and 0.831, correspondingly (Lattuada et al., 2003).

Two very important conclusions can be exctracted from Eq. 1: (1) R_m can be estimated for a single fractal; (2) both d_f, k_f are very important as far as they influence the radius of gyration according to the scaling law,

$$R_g/R_1 = N^{1/d_f}k_f^{-1/d_f}. \qquad (2)$$

The dependence on N may be eliminated by scaling R_m and R_g with a characteristic length which we call outer radius (R_o). This radius is the largest distance in a fractal between its center of mass and the center of mass of a monomer. In Fig. 2 we replot the data of Fig. 1 scaled with R_o.

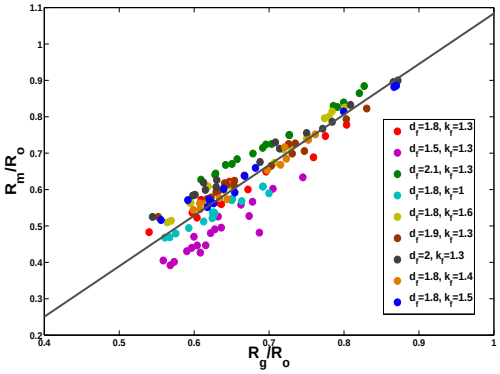

Figure 2: Fractal mobility radii as a function of radii of gyration scaled by their outer radius.

By fitting all the data we get

$$\frac{R_m}{R_o} = 1.389\frac{R_g}{R_o} - 0.305. \qquad (3)$$

Equation 3 relates three different radii of a fractal, two based on geometrical properties and one on dynamical; it reproduces our calculations to a good accuracy.

Virtual generation of realistic soot particles: Impact to their morphological and optical properties.

A.Bescond[1], J.Yon[1], C. Rozé[1], F. X. Ouf[2]

Since the emergence of the fractal concept (Jullien and Botet, 1987), the taking into account of soot particles non sphericity gave rise to multiple studies. The experimental interpretation of light scattering by fractal aggregates by Static Light Scattering (SLS), light extinction or their visualization by Transmission Electron Microscopy (TEM) implied the development of adapted theory for light-particle interaction (Dobbins and Megaridis, 1991) or establishment of $3D \rightarrow 2D$ projections laws (Brasil, et al., 1999; Köylü, et al., 1995). These studies enabled theoretical calculations of angular scattering cross sections related to the particle fractal dimension d_f, amount of absorbed light, albedo or methods for analyzing TEM images for the determination of particle size (gyration radius R_g) and morphology. Up to now, all the studies meaning with aggregate particles usually employ these results.

For these studies, virtual aggregates are usually generated by using DLCA (Diffusion Limited Cluster Aggregation) or RCA (Reacted Limited Cluster Aggregation) (Meakin, 1999). The resulting aggregates are most of the time made of primary spheres monodisperse in size and characterized by one point contact between two spheres. Moreover, for the optical calculations, uniform optical index have been considered. Though, visualization of real soot particles put in evidence a more complex morphology (figure 1-a).

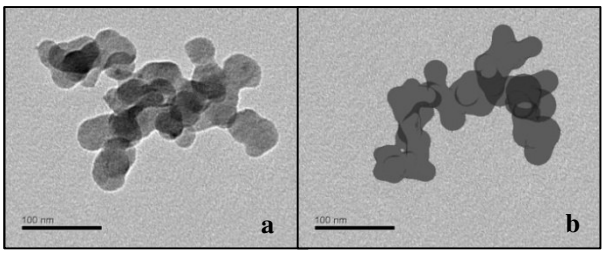

Figure 1, Aggregate of Ethylene flame ($\overline{D_p} = 34.19nm$); a) Real TEM pictures; b) Virtual TEM pictures for $Cov = 0{,}2$; $\zeta = 2$ obtained with PovRay

Indeed, primary spheres present an amount of overlapping and a coating that may increase the surface of contact between two spheres. The impact of spheres overlapping on fractal prefactor has been evaluated by Brasil, et al., (2001) who introduced the overlapping parameter $\boldsymbol{Cov}$. Eggersdorfer, et al. (2011) simulated the thermal sintering effect which creates aggregates with softered outlines but they did not evaluated the impact of this smoothed shape on interpretation of SLS, extinction or TEM measurements.

The aim of this work is firstly to present a method for generating more realistic aggregates by using a 3D level set function (figure 1-b). Additionally to the overlapping coefficient $\boldsymbol{Cov}$, we introduced a coating parameter $\boldsymbol{\zeta}$. The second objective of the present work is to evaluate the impact of this realistic morphology on the optical and morphological properties of soot aggregates.
It will be seen if the parameters of the fractal law, which links the aggregates size R_g and the number of primary spheres $N_p = k_f \left(\frac{R_g}{R_p}\right)^{d_f}$, are affected by the adjunction of overlapping and coating. So, the analysis of TEM images based on the maximum projected length L and the projected area A_a have to be checked. We will observe the impact of $\boldsymbol{Cov}$ and $\boldsymbol{\zeta}$ parameters on the classical relationships between 2D and 3D parameters, i.e. κ, k_a and α, $\left(L = \kappa R_g\,, N_p = k_a \left(\frac{A_a}{A_p}\right)^{\alpha}\right)$ where A_p is the projected area of a primary particles. The evaluation of angular or total light scattering and extinction cross sections for realistic aggregates is based on the Discrete Dipole Approximation Code DDSCAT7.1 (Draine and Flatau, 2010) It will be seen if fractal dimension measurement by SLS is affected by $\boldsymbol{Cov}$ and ζ parameters. Additionally, the impact on light scattered depolarization and albedo will be also presented.

Finally, one of the advantages of the level set method for generating realistic aggregates resides in its ability to control a space dependent optical property. Indeed, we will evaluate the albedo of soot aggregates covered by a thin layer of ice (Hong, et al., 2008) for the practical study of aeronautics emissions.

Atmospheric aerosol particles meet a growing interest in today's environmental concerns because of their potential impacts on the global radiative budget and human health. In this context, combustion aerosols are extensively studied as they originate from industrial and transport activities for a large part. They usually are in the form of more or less compact aggregates made of primary particles. The evaluation of their effects on the environment requires the knowledge of their microphysical properties.

One way to determine these properties is based on a Transmission Electron Microscopy (TEM) analysis. 2D characteristics of the aggregates' projection (Fig. 1 left) are measured on the micrographs and extrapolated to 3D using 2D-3D transposition relationships (Baron and Willeke, 2001). These mathematical relationships were established from studies of numerically generated aggregates of pre-defined fractal dimension and composed of monodisperse primary particles. They are nowadays widely used (Neer and Köylü, 2006). However, very few works have focused on the validity of these relationships when applied to real soot aggregates. Indeed, it is difficult to establish 2D and 3D characteristics of soot aggregates using a single experimental approach.

We investigate aircraft soot aggregates sampled at the exit of a turbofan engine by combining TEM and Electron Tomography (ET) analyses. Micrographs are processed using the "ImageJ" software (http://imagej.nih.gov/ij/). Statistical values for the population of aggregates are issued: primary particles mean diameter, aggregates mean gyration diameter.

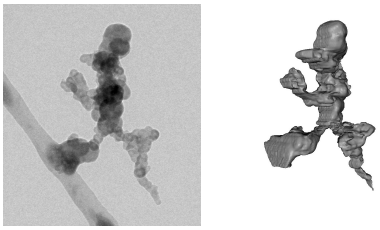

Figure 1. TEM micrograph of an aircraft soot aggregate (left) and the 3D visualization of its tomogram (right).

The 3D tomogram of this aggregate is built by ET using the plug-in "TomoJ" (Messaoudi *et al.*, 2007). We developed a plug-in *SootExpert* able to determine the 3D characteristics of an aggregate on its tomogram (volume, gyration diameter and fractal dimension). In a first step, we validate our plug-in on a numerically generated aggregate (Fig. 2), its volume and gyration diameter are known. The values determined by *SootExpert* are very close to the characteristics of this aggregate (Table 1), assessing the reliability of our plug-in.

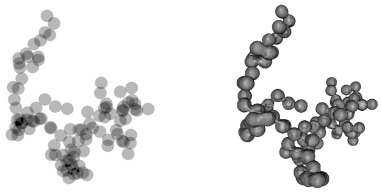

Figure 2. Projection of a numerical aggregate (left) and the 3D visualization of its tomogram (right).

	Known 3D characteristics	*SootExpert* 3D characteristics
Gyration diameter (nm)	310	298
Volume (nm^3)	$1\,456\times10^3$	$1\,616\times10^3$

Table 1. Comparison between the known and the determined 3D characteristics of a numerical aggregate.

In a second step, the ET analysis is applied to aircraft soot aggregates (Fig. 1 right). Van Poppel *et al.* (2005) and Adachi *et al.* (2007) have used ET to characterize atmospheric aerosols, with no special interest to the links between 2D and 3D characterizations. We study, for a single aggregate, the correlation between the 3D characteristics determined on its tomogram and the statistics resulting from the TEM analysis of the series of its projections. We can thus indicate the validity of the transposition relationships for aircraft soot aggregates. Then we compare this aggregate's 3D characteristics determined by *SootExpert* with the statistical values determined on the population, to investigate if a single aggregate is representative of its population.

During certain severe nuclear reactor accidents, e.g., a Steam Generator Tube Rupture, radioactive agglomerates may impact onto surfaces in near sonic conditions (Guntay et al. 2004). Due to this impaction, the physical properties of these agglomerates may change which may affect their transport in the power plant and possible release into the surrounding environment. The determining factors to solve the outcome in these situations are the interactions within the agglomerate, and the interactions between the surface and the agglomerate. Whether the agglomerates adhere onto the surface, bounce and/or break-up under certain conditions remains a question to be answered. For this purpose agglomerate impaction behavior was studied.

A combination of a single stage Micro Uniform Deposit Impactor (MOUDI) and a low pressure sampling chamber was used to carry out the impaction studies. TiO_2 agglomerates were impacted onto an impaction plate located in the MOUDI and the sampling chamber was used to collect the aerosol at low pressure after the impactor. The particles which deposited to the impaction plate were studied using a Transmission Electron Microscopy (TEM). The TEM-grid for this purpose was located on the impaction plate. The bounced particles were collected from the sampling chamber at ambient pressure for analysis with the TEM and a Scanning Mobility Particle Sizer (SMPS). The measurement system is described in details in Ihalainen et al. (2010).

The following parameters of the TiO_2 agglomerates were varied to find out how they affect the impaction behavior: the primary particle size, agglomerate size and degree of sintering. The TiO_2 agglomerates were generated through chemical vapor synthesis (CVS) in a hot wall reactor while controlling the primary particle size with the temperature of the reactor. A Differential Mobility Analyzer (DMA) was used for the size classification of the generated particles. The degree of sintering of TiO_2 agglomerates was altered by placing another hot wall reactor downstream the DMA.

Both the primary particle size and the degree of sintering affected the break-up and bounce of the TiO_2 agglomerates (Figure 1.). For instance, the geometric mean diameter (GMD) of the bounced particles increased as the primary particle size was decreased from about 27 nm to 16 nm, meaning that on average fewer bonds per agglomerate broke up during the impaction. The GMD of the bounced particles also increased as the degree of sintering of the agglomerates was increased, indicating that fewer bonds per agglomerate broke up. Decreasing the primary particle size and increasing the degree of sintering lowered the number concentration of the bounced particles. Further data analysis will be carried out to estimate the mass based bounced particle fraction of the impacted particles.

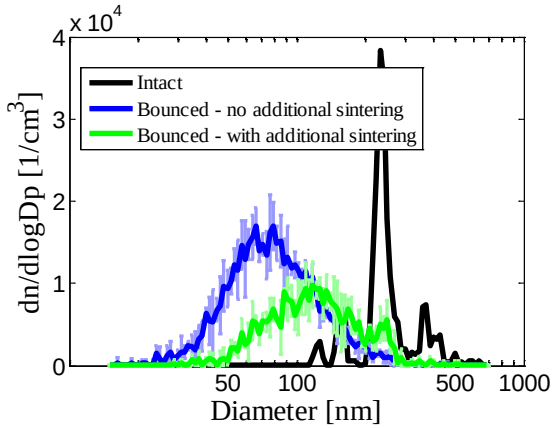

Figure 1. The number size distributions of the intact and bounced particles measured with the SMPS. The impaction results of agglomerates with and without additional sintering are shown.

This work was carried out in support of the international ARTIST II program. The authors express their gratitude to those members of the Laboratory for Thermal-Hydraulics at PSI and of the Fine Particle and Aerosol Technology Laboratory at the University of Eastern Finland that participated in the experimental work and construction of the facility.

Clothing surface safety has been a consideration in many studies. When motions are performed, the air exchange increases and results in a functional loss of clothing insulation. This phenomenon is called the pumping effect (Havenith and Nilsson, 2004), or clothing ventilation. In addition, this phenomenon occurs at the collar, cuff, waistline, and hemline body- clothing boundaries. Several studies have simulated or estimated the pumping effect on thermal insulation loss of work wear and cold-weather clothing in wind conditions (Aoyagi et al., 1994; Havenith et al., 1990). However, there has been little research into the pumping effect on leakage of airborne pollutants. The purpose of this study is to determine if particulate leakage into protective clothing worn by volunteer simulated workers would happen after a series of designed exercises. Finally, a leakage ratio was introduced to assess the pumping effect on protective clothing in various conditions, such as exposure time and body parts.

For simulating the intensity and range of activities in hospitals and factories, simplified and disciplined exercises were taught to volunteers wearing protective clothing before exposure-and-leakage tests. The designed exercises included squatting, standing, raising elbows, turning left and right, holding arms across the chest, and stooping. All action sets were performed and finished successively in one minute, and repeated for the next minute if necessary. Therefore, the ten-repetitions of designed exercises lasted ten minutes. Volunteers wearing protective clothing performed designed exercises in a stabilized chamber, described below, for two- and ten-repetitions. Protective clothing was a one-piece coverall of high-density polyethylene fibers, registered as Tyvek® of DuPont.

For controlling the physical conditions, a closed chamber 360 cm (length) × 213 cm (width) × 180 cm (height), was fanned with a wind velocity of 1.3 m/s to simulate an indoor environment. The temperature was set at 21(±3) ℃ by an air conditioner, and relative humidity was controlled at 50 ± 3 % by a dehumidifier. The aerosol solution was prepared by a mixture of SiO_2 powders, an ethanol solution of 20% (v/v), and the Hoechst 33258 fluorescent dye ($C_{25}H_{24}N_6O$•3HCl, Aldrich Inc.). A nebulizer consists of air-extractor and flow-presser was used to disperse the aerosol solution to produce challenged aerosols with fluorescence. The fluorescent aerosols with a count median diameter of 0.15 μm were dispersed into the chamber through a nozzle (model 8012/1010L, Natural Fog® , Taiwan) with a caliber of 0.80 mm. The concentration detected by a portable aerosol spectrometer (model 1.109, Grimm Aerosol Technik GmbH & Co., Germany) was 10^5－10^6 particles/cm^3.

After a series of designed exercises, volunteers left the chamber, removed protective clothing, and stood in a darkroom. If boundary leakage of protective clothing happened, the selected boundary parts deposited by challenged aerosols presented fluorescent in a UV scanner of 365 nm. Fluorescent pictures were taken with a digital camera (Nikon D3000) equipped with a manual and automatic focusing lense (Nikon AF NIKKOR 50mm 1.8D, Japan). Its charge-couple device's (CCD) picture quality is 3872 × 2592 pixels. A digital comparison of the photograph of the chart and the chart confirmed the constancy of CCD quality. Finally, fluorescent areas were segmented and analyzed for their fluorescent gray levels (or brightness) by an image processor developed using an entropy-based algorithm

The results imply the exposure time was a major factor for evaluating leakage of protective clothing. An increase of leak ratio occurred on the neck, chest, and wrists with increased exposure time. The neck, comparatively, presents the most multiplicative increase of leak ratio at the end of exposure. The highest contamination possibility of aerosols transmitted from the neck to nose and mouth happens during the removal of personal protective clothing.

Presenting author email: heine@fhi-berlin.mpg.de

Ions influence various chemical and physical processes in the atmosphere, such as the electrical conductivity and the formation of polar stratospheric clouds (PSC).They also play a critical role in aerosol formation through ion nucleation. Among the most abundant anions in the troposphere and stratosphere are nitrate (NO_3^-) and bisulfate (HSO_4^-), in particular, clusters of these ions with nitric acid, sulfuric acid and water (Heitmann and Arnold, 1983). While below ~30 km, nitrate- core cluster are dominant, bisulfate-core clusters are more abundant above this height (Viggiano, A.A., Arnold, 1981). The negative ion $NO_3^-(HNO_3)_2$, for example, accounts for over 90% of all negative ions at heights around 27-30 km. In order to understand the chemical and physical properties of these anionic clusters, as well as to test the structural predictions from previous computational studies (Galvéz *et al*, 2006), experimental information on the cluster structure is required.

Here, we present first results on the vibrational action spectroscopy of the atmospherically relevant clusters $A^-(H_2SO_4)_m(HNO_3)_n(H_2O)_o$ with $A^- = HSO_4^-$, NO_3^-. In particular, we focused on the series $NO_3^-(HNO_3)_{1-3}(H_2O)_{1-2}$, as well as small mixed acid clusters. Infrared multiple photon dissociation (IR-MPD) spectra, measured using the tunable and intense radiation from the infrared free electron laser FELIX (Oepts *et al*, 1995), are reported in the fingerprint region (550 – 1800 cm^{-1}), directly probing the NO/SO-stretching and -bending modes. The assignment of the spectra is aided by comparison with calculated B3LYP/TZVPP structures and harmonic frequencies, as well as with higher-level calculations.

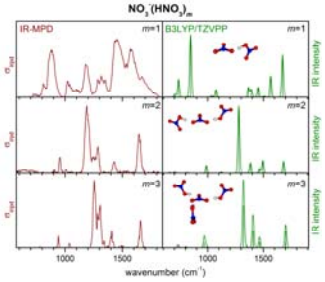

Figure 1. Experimental (left) and simulated (right) vibrational spectra of $NO_3^-(HNO_3)_m$ with m = 1 - 3.

The IRMPD spectra of $NO_3^-(HNO_3)_{1-3}$ are shown in Figure 1. Reasonable agreement is observed for the predicted lowest energy structures. DFT predicts that the nitrate–nitric acid clusters prefer non-planar structures at 0 K, but these become effectively planar at higher temperatures due to vibrational averaging. The biggest discrepancy between the experimental IRMPD and simulated harmonic spectra is observed for m=1. This is due to the presence of strong low-barrier hydrogen bond in hydrogen dinitrate ($^-O_2NO\cdots H\cdots ONO_2^-$), which is not well described within the harmonic approximation. With increasing cluster size, the hydrogen bond strength decreases, evidenced by an increase in the O-O distance of the O-H···O moiety from 2.43 Å (m=1) to 2.62 Å (m=3).

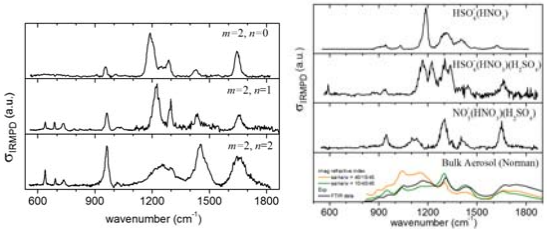

Figure 2. IRMPD spectra of $NO_3^-(HNO_3)_m(H_2O)_n$ (left) and of mixed NO_3^-/HSO_4^--acid clusters (right).

The IRMPD spectra of microhydrated $NO_3^-(HNO_3)_m(H_2O)_n$ clusters are shown for m=2 and n=0-2 in the left part of Figure 2. The vibrational features observed for n=0 remain discernible throughout all three spectra, indicating that binding of water to nitrate is weaker compared to nitric acid and consequently the addition of water does not perturb the $NO_3^-(HNO_3)_2$ core structure substantially.

IRMPD spectra of mixed sulfuric acid/nitric acid anion clusters are shown and compared with FTIR-spectra of bulky aerosols containing H_2SO_4, HNO_3 and H_2O taken by Norman *et al* (2002) on the right of figure 2. Two interesting observations can be made. First, a core switching behaviour is observed. Depending on the number and nature of the neutral ligands, evidence for either a nitrate or a bisulfate anion is found. Second, the best agreement between bulk and cluster can be found within the small systems, containing HSO_4^-.

Conjugate base anions are ubiquitous species in aqueous phase chemistry. However, how these anions are hydrated at the molecular level is far from completely understood. A molecular-level understanding of ion hydration is also important in understanding the surface speciation and reactivity of aerosols, which play a key role in atmospheric and oceanic chemical cycles.

We use infrared multiple photon dissociation (IRMPD) spectroscopy over the spectral range of 550-4000 cm^{-1} as a structural probe of size-selected clusters in which the polyatomic anions HCO_3^-, NO_3^-, HSO_4^-, SO_4^{2-}, $H_2PO_4^-$ and $(CH_2)_n(COO^-)_2$ are hydrated by a known number of water molecules *n*. (Asmis and Neumark, 2012) The experiments follow how the H-bonded solvent network around these anions evolves, one water molecule at a time. Structural assignments are made by comparing the experimental IR spectra to those obtained from electronic structure calculations. Our results show how changes in anion structure, symmetry, charge state and acidity have a profound effect on the structure of the solvent network and, vice versa, how hydration can markedly affect the structure of the anion core in a microhydrated cluster.

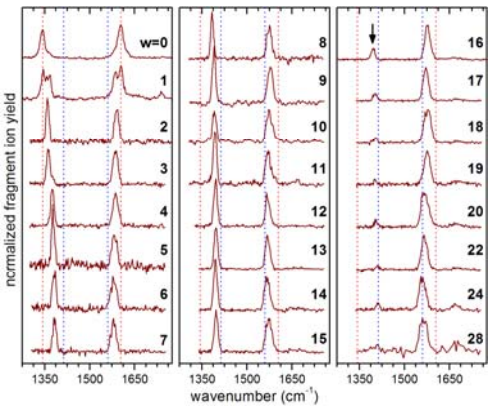

Figure 1: IRMPD spectra of $(CH_2)_6(COO^-)_2(H_2O)_n$.

Some key results include the following. The first few water molecules bind to the anion terminal oxo groups in a bridging fashion. Each oxo group can form up to three hydrogen bonds. When there are more than three hydrating water molecules, the formation of a particularly stable four-membered water ring is observed for NO_3^- and HCO_3^-. In the case of HCO_3^-, additional water molecules then add to this water ring rather than directly to the anion, indicating a preference for surface hydration. In contrast, doubly charged sulfate dianions are internally hydrated and characterized by the closing of the first hydration shell at $n = 12$. The situation is different for dicarboxylate dianions, which adapt to the hydration network by changing from a linear to a folded structure (see Fig. 1) at $n > 15$. (Wende *et al.* 2011)

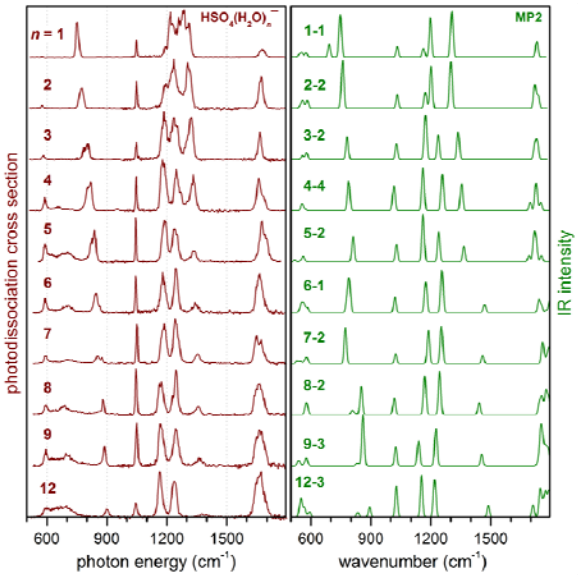

Figure 2. IRMPD (left) and simulated IR absorption spectra (right) for $HSO_4^-(H_2O)_{1\text{-}9,12}$.

For $HSO_4^-(H_2O)_n$ the comparison with electronic structure calculations (see Fig. 2) suggests that the acidic proton of HSO_4^- is involved in the formation of a hydrogen bond from $n \geq 1$. (Yacovitch *et al.* 2011) The blue shifting of the SOH bending mode accompanied by a dramatic decrease in its IR intensity suggests increased incorporation of the bisulfate hydrogen atom into the H-bonding network, the first step toward acid dissociation.

Heat effects at self-similar regime of droplet diffusion growth and the vapor-gas outflow

A.E. Kuchma and A.K. Shchekin

Department of Statistical Physics, St Petersburg State University, St Petersburg, 198504, Russian Federation
Keywords: droplet growth, nonstationary diffusion and heat conduction, nonisothermal condensation.
Presenting author email: akshch@list.ru

It is a well known fact that release of the latent heat at condensation on aerosol particles plays a key role in dynamics of the Earth atmosphere (Colbeck (2008)). The aim of this report is to consider how the condensation heat affects the character of vapor-passive gas flow produced around a droplet at diffusion regime of the droplet growth. A novelty in our approach is finding new self-similar solutions for the vapor density and temperature profiles at the nonstationary nonisothermal droplet growth and showing their importance for existence of a vapor-gas inflow at small distances from a droplet and an outflow at larger distances.

We will consider the problem of nonstationary diffusion growth of the droplet with allowance for the motion of droplet surface, nonstationary Stefan's flux of the vapor-passive gas medium, thermal diffusion and thermal conduction in the vapor-gas mixture as a result of releasing of the latent heat at vapor condensation onto droplet. In the coordinate system with an origin in the droplet center, the equation of vapor diffusion to the growing droplet at fixed total pressure of the vapor-gas medium can be written (Landau and Lifshitz (1987), Frank-Kamenetskii (1969)) as

$$\frac{\partial n_1}{\partial t}+\frac{\partial j_1}{\partial r}+\frac{2}{r}j_1=0 \qquad (1)$$

where vapor flux density j_1 is determined in the form

$$j_1=-D\left[\partial n_1/\partial r+n_1\left(1+\frac{\rho^2}{m_1m_2n_1n}k_T\right)\partial\ln T/\partial r\right]+n_1\mathrm{v}, \qquad (2)$$

n_i and m_i are the volume density and the mass of molecules of gaseous component i ($i=1$ and $i=2$ refer to vapour and passive gas, respectively), t is the time, r is the radial coordinate, $\rho=n_1m_1+n_2m_2$ and $n=n_1+n_2$ are the total mass and volume densities of the vapor-gas medium, $T=T(r,t)$ is the local temperature, $\mathrm{v}=\mathrm{v}(r,t)$ is the radial velocity of hydrodynamic flow of the vapor-gas medium caused by vapor condensation, $D=D(n_1,T)$ and $k_T=k_T(n_1,T)$ are the vapor diffusion and thermal diffusion coefficients in the vapor-gas medium.

Let us denote the radius of the growing droplet at time moment t as $R(t)$. In order to find the radial velocity $\mathrm{v}(r,t)$, we consider a mobile sphere of a certain radius $R_1(t)>R(t)$ surrounding the droplet. If the rate $\dot R_1(t)$ of variation of $R_1(t)$ with time coincides with the radial velocity $\mathrm{v}(r,t)$, one can write

$$4\pi n_l R^3(t)/3+4\pi\int_{R(t)}^{R_1(t)}r^2n(T(r,t))dr=const \qquad (3)$$

where n_l is the volume density in the liquid droplet. By differentiating Eq.(3) with respect to time, assuming $T(r\to\infty,t)=T_0$, $T(R,t)=T_d$, and $n(T)T=n(T_0)T_0$, we obtain the following relationship

$$\mathrm{v}(r,t)=\dot R\frac{R^2}{r^2}\frac{T(r,t)}{T_d}\left[1-\frac{T_dn_l}{T_0n(T_0)}+\frac{T_d}{R^2\dot R}\int_{R(t)}^{r}dr_1r_1^2\frac{1}{T^2(r_1,t)}\frac{\partial T(r_1,t)}{\partial t}\right]. \qquad (4)$$

In the case of isothermal condensation at $T(r,t)=T_d=T_0$, Eq.(4) gives $\mathrm{v}(r,t)=-\dot R(t)\left(R^2(t)/r^2\right)[n_l/n(T_0)-1]$ (Kuchma and Shchekin (2012)). This result corresponds to the inflow of the vapor-gas medium at any distance from the droplet. The presence of the positive third term in the brackets on the right-hand side of Eq.(4) gives the possibility of an outflow of the vapour-gas medium at some distances from the droplet. It may be of importance for explaining the cloud floating in the Earth atmosphere. Note that this term disappears at stationary regime of diffusion.

It can be shown that equation of heat conduction in the form

$$\frac{\partial T(r,t)}{\partial t}=\kappa\Delta T(r,t) \qquad (5)$$

(where κ is the coefficient of the thermal conductivity of the vapor-gas medum) provides a sufficient accuracy for finding the profiles of vapor density $n_1(r,t)$ and flow velocity $\mathrm{v}(r,t)$ around a droplet at nonisothermal condensation. For self-similar solutions of Eqs.(1) and (5) (similar to that in Grinin et al (2011) and Kuchma and Shchekin (2012)), approximate expression for $\mathrm{v}(r,t)$ has a form

$$\mathrm{v}(r,t)=\dot R\frac{R^2}{r^2}\left[1-\frac{n_l}{n(T_0)}+\frac{T_d-T_0}{T_0}\frac{\kappa}{R\dot R}\left(1-\exp\left(-\frac{R\dot R}{2\kappa}\left(\frac{r^2}{R^2}-1\right)\right)\right)\right]. \qquad (6)$$

High temperature oxidation of tungsten particles with account of Stefan flow

S.G. Orlovskaya, M.S. Shkoropado and F.F. Karimova

Department of Physics, Odessa National I.I. Mechnikov's University, Odessa, 65082, Ukraine
Keywords: metal, combustion particle, modelling, temperature.
Presenting author email: svetor@rambler.ru

Wide applications of tungsten and molybdenum alloys at high temperatures require detailed data on these metals heat and mass transfer in oxidized media. Effect of Stefan flow arising as a result of chemical reactions and phase transitions on the particle surface isn't clarified till now. At elevated temperatures the oxide scale forms on the metal surface which melts at the temperature further rise. Evaporating oxides forms the flow outwards the particle (so called Stefan flow) which affects its ignition and burning characteristics (Kalinchak, 2001; Orlovskaya, 2009).

It is known that oxide scale properties affect significantly the metal oxidation kinetics. The tungsten particle high temperature oxidation is modeled mathematically to obtain the oxide scale thickness history. The maximum on this dependence is found which is explained by concurrence of oxide formation and evaporation processes. When the scale thickness passes through this maximum its value decreases fast, as a result the oxidation rate increases and the particle temperature quickly rises up the metal melting point.

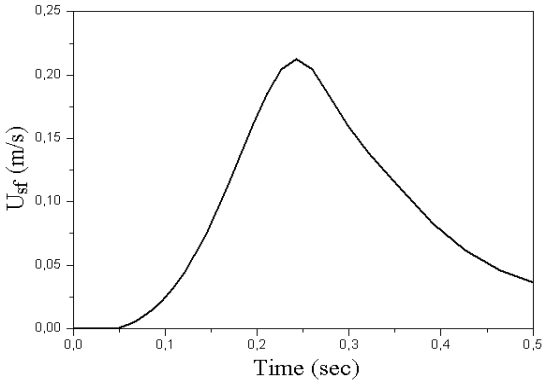

Figure 1. Stefan flow velocity versus time at the tungsten particle surface.

In case of small particles (d<200 μm) the Stefan flow direction changes during the oxidation process. At relatively low temperatures it is directed towards the particle due to solid oxide formation. At higher temperatures the Stefan flow is directed outwards the particle as a result of intense oxide evaporation. So the Stefan flow effect is ambiguous and depends on gaseous oxidizer temperature. For example, for the tungsten particle with diameter 200 μm at the gas temperature T_g = 1500 K and oxygen mass fraction ($n_{O_2\infty}$) 0.5, the oxide scale formation prevails the oxide evaporation so the Stefan flow is directed towards the particle (Fig.1).

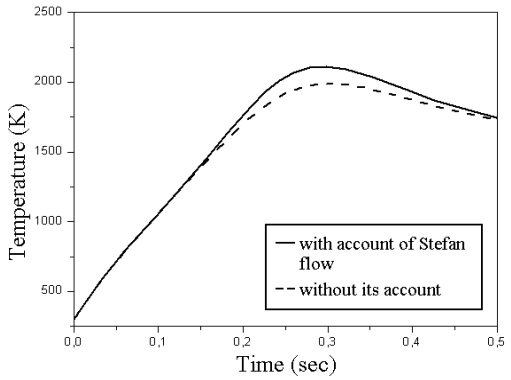

Figure 2. Tungsten particle temperature histories. d =200 μm, $n_{O_2\infty}$ =0.5, T_g =1500 K.

Stefan flow account leads to calculated temperature increase and oxide scale thickness growth. It is found that estimated value of the particle ignition delay increases and its burning time decreases.

It is established that Stefan flow effect on the particle burning characteristics is more pronounced at high gas temperatures and increased oxygen content (Table). Stefan flow account leads to significant burning time decrease in case of small particles.

Table. Ignition delay (t_d) and burning time (t_b) of the tungsten particle at T_g = 1800 K, $n_{O_2\infty}$ = 0.5.

(n/a – no Stefan flow account; w/a – with its account)

Heat and mass transfer and thermal decomposition of firm aerosols when laser radiation action

L.I. Ryabchuk and S.K.Protas

Department of Physics, Odessa National I.I. Mechnikov's University, Odessa, 65082, Ukraine
Keywords: heat and mass transfer, firm aerosols decomposition, ferosol-surface reactions, laser radiation action.
Presenting author email: svetor@rambler.ru

Process of firm aerosols burning and the chemical characteristic of burning has been studied on an example of a laser irradiation of the organic fuel rich with oxygen (peat).The theoretical model of laser irradiation of fuel with high humidity is submitted. Process of heat and mass transfer, thermal decomposition and burning of solid organic fuel at its laser irradiation is described by the presented model.

The model includes chemical reactions: oxidation of carbon to CO and CO_2, oxidation of CO_2 to CO, oxidation of carbon by hydrogen from steams of water and combustion of hydrogen. Heterogeneous reactions of oxidation of carbon take place on a surface of the sample and change its thermal balance. It was supposed that at heating of a fuel tablet, even before ignition, there was a thermal decomposition of fuel. Decomposition is accompanied by emission of coal-volatile matter and their emission is described by equation Arrenius. Ignition of flying substances of coal in an boundary layer warms up a gas phase Rise in temperature of a gas phase heats up a surface of the sample by convection and a radiating heat transfer and stimulates chemical reactions and decomposition. The model take into account: diffusive thermal conductivity, which determine endo- and exothermal chemical reaction; flow of coal-volatile matter from sample's surface; convection and molecular heat transfer between gas phase of the boundary layer and gas: radiation heat transfer.

The samples which thickness at considered parameters of process corresponds to a semi-infinite body, were studied. $H \succ\succ (at_i)^{1/2}$, τ - duration of an impulse a - thermal conductivity of peat.

The system of the equations for a considered problem contents:

The heat conductivity equation which defines distribution of temperature of a surface and in volume of the sample $mc\dfrac{dT}{dt} = P(t)A(x_1,...x_n) + \sum_i P_{ex}^i - P_{loss}(T)$,

where *m, c* – weight and a system thermal capacity; *P (t)* – capacity of radiation falling on the sample; A_λ – absorb ability of of a target at laser radiation wavelength; $x_i = x_i(t)$ – concentration of reacting substances; P^i_{ex} – capacity of power allocation of chemical sources – the reactions which are passing in the condensed phase; P_{loss} *(T)* – capacity of heat losses.

1) Partial absorption of laser radiation, thermal streams for the account thermolysis and the chemical reactions which are taking place on a surface, and also convective and radiating losses considers a boundary condition on an irradiated surface;
2) To define boundary layer temperature next factors were taken into account: inflows of heat from combustion coal-volatile matter and at the expense of diffusive heat conductivity coal-volatile matter and components of chemical reactions from an irradiated surface; convection-molecular heat transfer from surface of sample to gas of a boundary layer and also from boundary layer to environment, radiating heat transfer.

Intensity and the form of an impulse of a laser irradiation was various during researches. The irradiation of the sample with three various time dependences of impulses has been studied..

Two triangular form of an impulse $I(t) = \begin{cases} I_{\max}\cdot A_\lambda \cdot t/(\tau / t_{\max}) \\ I_{\max}\cdot A_\lambda \cdot t/(\tau /(\tau - t_{\max})) \end{cases}$, were I_{max} - the maximum value of laser radiation intensity, A_λ - absorb ability of a target at laser radiation wavelength, t_{max} - time when the impulse reaches the maximum value (t_{max} =1 - fast increase of intensity to I_{max} and its slow reduction to zero; t_{max} =3 - slow increase of intensity to I_{max} and its fast reduction to zero). The irradiation of the sample has been studied by the laser impulse which time form looks like curve Gaussa $I(t) = I_{\max}\left(\dfrac{\ln 2}{t}\right)^{1/2}\left\{-\left[\dfrac{r(\ln 2)^{1/2}(t - t_{\max})}{t_p}\right]\right\}$, were t_p - achievement time capacities I_{max} /2, t_{max} - time of achievement of the maximum capacity.

The thermal picture of warming up has been studied: main parameters of ignition and behavior of system after the termination of action of an impulse. Distributions of concentration and oxygen in a boundary film has been received. Influence of the processes occurring in a gas phase on propagation of burning, has been studied. The received data on minimal-necessary energy for ignition and propagation of burning of fuel as functions of intensity and forms of impulses represents as the diagrams.

Flow and Heat Transfer in a Particle Laden Differentially Heated Cavity

J. Kalilainen[1,2], P. Rantanen[1], T. Lind[2], A. Auvinen[1], A. Dehbi[2], S. Güntay[2] and J. Jokiniemi[1,3]

Presenting author email: jarmo.kalilainen@vtt.fi

In severe nuclear accidents the containment has the vital role of preventing the release of radioactive particles to the outside environment. A turbulent natural convective flow is induced in the containment by a temperature difference between the walls and hot gas. The turbulence can significantly influence the fraction of particles deposited to the walls and the floor of the containment.

DIfferentially heated cavity with **A**erosol in turbulent **NA**tural convection (**DIANA**) facility was constructed in order to experimentally investigate the effects of turbulent natural convection on aerosol deposition inside the cavity. The results from the experimental work will also be used in validation of the DNS (Puragliesi, 2010) and LES simulation results obtained at the Paul Scherrer Institut (PSI). DIANA facility contains two heated / cooled walls made of aluminium. The top, front and back walls have adiabatic boundary conditions and are made of glass in order to allow optical access to the cavity. Particle Image Velocimetry (PIV) is applied in measuring the flow fields and particle concentrations inside the cavity.

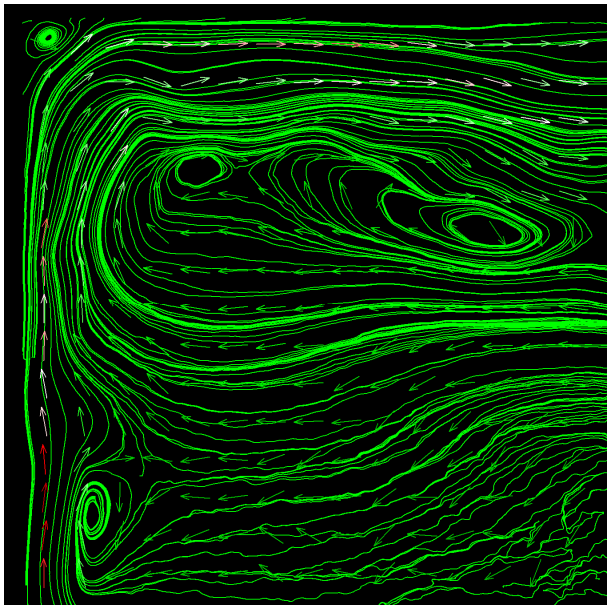

Fig. 1 *Instantaneous streamlines and part of the velocity vectors in the top corner of the differentially heated cavity on the hot side, measured with PIV. Vortexes moving slowly up and right.*

After the construction of the DIANA facility, three preliminary measurements were done to investigate the feasibility of the PIV measurements in this system. Particles were illuminated with a double pulse laser sheet. Laser beam was conducted from the laser to sheet optics with a guiding arm. Parallel laser sheet was formed with an adjustable telescope and a convex lens. The laser sheet was directed into the cavity from the top through a double layer window. Sheet thickness was about 1 mm. Duration of a laser pulse was about 5 ns and energy of one pulse was 10 to 250 mJ at wavelength of 532 nm.

Three measurement planes are situated at 330 mm, 210 mm and 70 mm from the front adiabatic wall. For each measurement, the imaged plane was divided into 16 200 x 200 mm sections. A double frame CCD camera with 2048 x 2048 pixel sensor was used for imaging. Interframe delay for PIV measurements was 10 ms to 100 ms. 500 images were taken from each imaging plane. Oil aerosol was used as tracer particles in PIV measurements. The cavity atmosphere consisted of air and the hot and cold wall temperatures were set to approximately 57 °C and 19 °C, respectively. This sets the Rayleigh number of the flow to an approximate value of 10^9, which was also used in the DNS simulation work (Puragliesi, 2010).

The preliminary flow measurements showed that there are slowly moving vortexes between the high velocity side flow and slowly moving centre. In the corners, there are obviously small stable vortexes. Fig. 1 shows the instantaneous streamlines and velocity vectors at the top corner near the heated wall. Also, other larger vortexes could be seen in the average flow fields, calculated from the PIV data.

After the flow field measurements have been completed, the particle depletion on the cavity walls is investigated. This is done using PIV to measure the change in particle concentration due to particle deposition and settling on the cavity walls and floor. Also, Condensation Particle Counter (CPC) and Tapered Element Oscillating Microbalance (TEOM) are used to help determine the change of particle concentration in time. Latex and/or hollow glass beads with 2 or 3 different particle diameters, varying from 1 to 20 µm are applied in the concentration measurements.

Modelling of spray drying of multicomponent aerosols

J.M. Gac[1] and L. Gradoń[1]

[1]Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warsaw, 00-645 Poland
Keywords: heat and mass transfer, medicinal aerosols, numerical simulation, particle formation.
Presenting author email: J.Gac@ichip.pw.edu.pl

The spray drying process is widely used in various aerosol techniques in aerosol technologies, as e.g. manufacturing of drug particles for inhalation. The main advantage of spray drying is possibility of obtaining of regular-shaped spherical particles with nearly uniform dimensions (contrary to e.g. crystallization followed by milling). Another advantage may be special segregation of components in particles formed. This segregation may improve the storage characteristics and facilitate the controlling of drug delivery.

Typically, the spray drying process consists on two stages. During the first one the droplet of solution gets a sensible heat from the surrounded gas and the evaporation occurs resulting in diameter shrinking. Following that, the mean concentration of all the components grows up. When the concentration of one of components exceeds its critical value (typically, it takes place near the droplet surface first), the solid porous crust forms and the second stage of drying starts. During this stage the evaporating water diffuses through the porous crust and the farther growing of the concentration of components takes place, resulting in increasing of crust thickness. The segregation of components may take place as a result of difference in their diffusivity (Wang and Langrish, 2009).

The aim of our work is to build numerical model of spray drying such multicomponent droplets. Because of moving boundaries (decreasing of droplet diameter in a first stage and increasing of crust thickness in the second one) the direct numerical solution of heat and mass transport in droplet seems to be quite difficult (Mezhericher *et al*, 2008). To solve this problem we adopt the shell model, first present by Parentia *et al* (2011). In this model the droplet is considered as a set of concentric shells between which the heat and mass is moving. The thickness of each shell decreases as a result of water evaporation. Contrary to the original work (Parentia *et al*, 2011), in our model we take into account the crystallization of components and solid crust formation.

As a result of our investigations, we describe the kinetics of spray drying of mulitcomponent droplet (see Fig. 1 for example). We have also examined the influence of drying agent temperature, initial droplet diameter and concentration of all the components, its diffusivity, solubility etc. on properties of particle formed: its diameter and composition. We have found that in most cases two regions of particle can be distinguished – the outer shell, where the composition strongly changes and the inner one where the concentration of each component is nearly constant, as it is seen in Fig. 2. The thickness of the inner shell depends mainly on the solubility ratio of all the components and has been also estimated in our investigations.

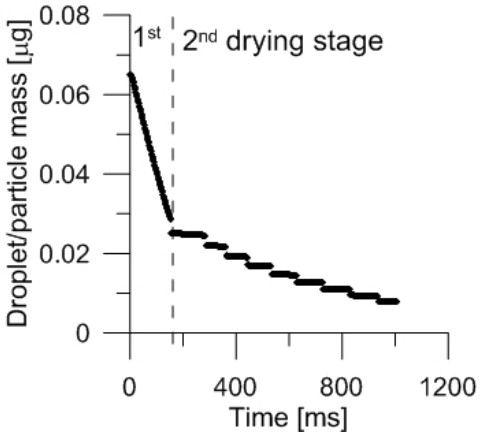

Figure 1. Droplet/wet particle mass as a function of time of drying.

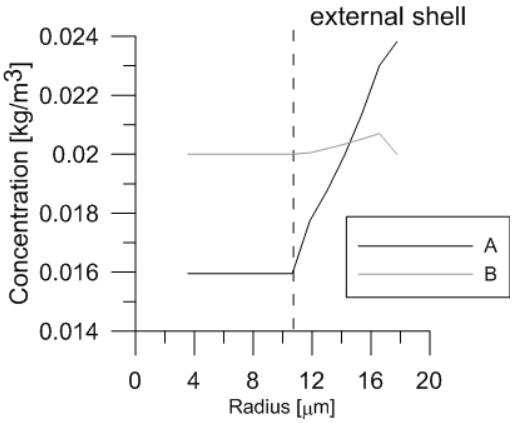

Figure 2. The composition of spray drying formed particle contained two components, *A* and *B*.

The effect of droplet size on the evaporation and mass accommodation processes of water: a molecular dynamics study

Jan Julin and Ilona Riipinen

Department of Applied Environmental Science (ITM), Stockholm University, SE-10691 Stockholm, Sweden
Keywords: mass accommodation, fundamental aerosol physics, molecular dynamics, water.
Presenting author email: jan.julin@itm.su.se

The majority of atmospheric particle number consists of particles in the ultrafine sub-100 nm size-range, thus understanding their growth processes has a central role in understanding the climate effects of aerosols. The condensational growth of ultrafine particles is quite sensitive to their ability to uptake various gaseous species, an ability which is quantified by the mass accommodation coefficient. Unfortunately, there still exists some controversy on the value of the mass accommodation coefficient even for the case of water-on-water, for which values ranging from 0.1 to 1 have been reported (see e.g. review by Kolb *et al.* and references therein).

On a molecular level the mass accommodation coefficient α is commonly defined as the fraction of incoming molecules that are absorbed to the surface. As such, the coefficient can be readily studied by using molecular dynamics (MD) simulations, where the trajectories of individual molecules can be followed as a function of time. Several such studies have reported a mass accommodation coefficient $\alpha \approx 1$ (e.g. Morita *et al.*, 2004, Neshyba *et al.*, 2009, Takahama and Russell, 2011), for various temperatures, water potential models, and even different bulk phases. However, to our knowledge all MD mass accommodation studies consider a planar interface. This practice can be considered quite reasonable if one is interested in relatively large particles, but nonetheless for smallest droplets size-dependent factors may affect the process.

We are performing MD simulations to study the effect of droplet size on the mass accommodation and the evaporation processes, and we have also simulated the familiar mass accommodation on a planar surface to facilitate a consistent comparison with the droplet simulations. This set of simulations allows us to examine how well the simulated evaporative flux agrees with the theoretical predictions, which are derived using bulk thermodynamic considerations. Furthermore, the size-dependence, or lack of one, of the various processes and properties help in the assessment of the validity of assumptions used in different kinetic mass-transport models. The simulations are performed with the GROMACS software (Hess *et al.*, 2008), using the TIP4P-Ew water model. After an initial equilibration of the target droplet, or the target liquid slab, incident molecules are generated at set time intervals with velocities pointing towards the target surface. The incoming water molecules are generated at a set distance but random locations around the droplet, with different initial orientations, and the velocities are drawn from the Maxwell-Boltzmann distribution corresponding to the desired temperature. A total of 1000 impact events are simulated per target surface, with a fresh simulation started after a set of ten incident molecules to ensure that the target droplet remains roughly at a constant size.

First results show that at T=273.15 K the accommodation coefficient on clusters consisting of as few as 1000 molecules (a radius of only about 2 nm) is ≈1, which is same as for a planar surface. In addition to the absorption and scattering of the incoming molecules, evaporation events are observed during the simulations. Conceivably some of them could be induced by the accommodation of an incident molecule, and the actual accommodation coefficient could therefore be lower. However, the trajectories suggest that from an already low number of evaporation events only few occur both spatially and temporally close to the location of an impact, thus reaffirming that α will be close to unity.

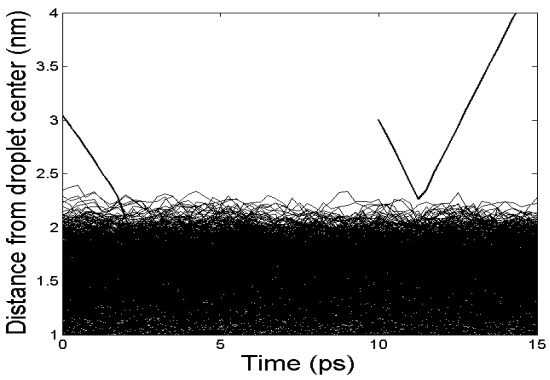

Figure 1. Example trajectories: absorption and recoil events.

Presenting author email: constantin.dragan@helmholtz-muenchen.de

The measurement and risk assessment of semi-volatile organic hydrocarbons in workplace air is complicated by their readiness to condense and form particles, evaporate from filters and adsorb onto surfaces.

Mineral oil fractions, frequently used as a coolant, lubricant or cutting fluid during the machining of metal components in many industrial processes are known to form oil mist. The used mineral oil fractions mainly contain a mixture of straight-chain, aliphatic hydrocarbons from $C_{12}H_{26}$ to $C_{23}H_{48}$ (Raynor, 1999). In the case of oil mist, the particulate phase is considered to be of greater toxicological concern than the vapour, even though the vapour is often present in much higher concentration (Simpson, 2008). Due to mist separation between vapour and particle phase, artefacts are likely to occur in workplace aerosol samplers (filter blow-on, blow-off, evaporation, condensation, particle penetration) and may lead to errors in risk assessment as a consequence.

Due to the different toxicological effects of particle and vapour there is an increasing need to accurately differentiate between particle bound mass and gas-phase concentration in workplace sampling and monitoring. Because traditional filter-denuder sampling may induce sampling artefacts we are now investigating a new online method that can accurately distinguish between the vapour and particle mass.

Our second aim is to study the dynamic processes related to oil mist formation, ageing and sampling. For this purpose our study focuses on a simulation facility for SVOC test aerosols and on the development of a theoretical evaporation model.

For the theoretical part we have developed a particle evaporation model that predicts the evaporation rate of a single component aerosol and for the experimental part we have designed an aerosol simulation facility inside two temperature controlled chambers.

The chambers are operated at constant temperatures ranging from 10 to 40 °C. The setup allows the simulation of the three phases in an aerosol life cycle: generation, transport/ ageing and deposition/ analysis. The experimental system consists of:

- a Sinclair-La Mer type aerosol generator (Topas SLG 270) to produce particles from the test substances by vapour deposition on condensation nuclei.
- a mixing head designed to obtain an homogenous aerosol - dilution gas mixing.
- a flow-tube reactor to study the dynamic processes during and directly after the aerosol production.
- a white light particle sizer (Palas WELAS 3000) and a FID hydrocarbon gas analyser (JUM 109A) coupled with a heated transfer line for quantification of particle- and gas phase concentration.
- a 300 l Tedlar ageing bag that allows 10 to 60 minutes of residence time to simulate aerosol ageing.

The particle diameter and lifetime are the most important factors in relationship to the inhalation risk. Our model shows that a 1µm aerosol particle can have a lifetime between a few fractions of a second and several hours depending on the droplet components, partial pressure and temperature. The particle lifetime can also influence the amount of inhaled aerosol as larger particle lifetimes lead to an enhanced transport distance and exposed area.

Our experimental data is in good agreement with the model prediction for 1-component systems. Multicomponent-mixture experiments are in preparation.

Measurement of neutral sulphuric acid dimer concentration during CLOUD

A. Kürten, L. Rondo, S. Ehrhart, J. Curtius and the CLOUD collaboration

Institute for Atmospheric and Environmental Sciences, University of Frankfurt, Frankfurt, 60438, Germany
Keywords: CIMS, CLOUD, nucleation, sulphuric acid, cluster
Presenting author email: kuerten@iau.uni-frankfurt.de

The nucleation of aerosol particles is an important process affecting atmospheric chemistry, visibility, weather and climate as well as human health.

Observations show that under atmospherically relevant conditions the particle nucleation rate is strongly dependent on the concentration of sulphuric acid. However, recent studies have shown that the binary system of sulphuric acid and water cannot explain atmospheric nucleation (Kirkby *et al* (2011)). Therefore, the influence of ternary substances is increasingly discussed. Likely candidates for enhancing the nucleation are basic molecules, and it has indeed been shown that the addition of ammonia at very low concentrations in the pptv-range can increase the nucleation rate by several orders of magnitude compared to the pure binary case (Kirkby *et al* (2011)). In addition to ammonia, modelling studies and experiments suggest that other ternary substances like amines and oxidized organic compounds can enhance the nucleation tremendously as well – potentially even stronger than ammonia (Kurten *et al* (2008), Metzger *et al* (2010), Zollner *et al* (2012)).

During the CLOUD (Cosmics Leaving OUtdoor Droplets) experiments conducted at CERN the effect of ammonia, dimethylamine and organic oxidation products on the particle nucleation rates has been studied systematically. During these experiments a certain concentration of sulphuric acid is established within a very clean stainless steel chamber. Adding different concentrations of ternary substances allows quantifying the enhancement of these substances on the nucleation rates. In addition to adding gas-phase substances, the effect of ions on the nucleation can be investigated as well by means of an ionizing particle beam provided by the CERN proton synchrotron.

The concentration of sulphuric acid during CLOUD is measured through chemical ionization mass spectrometry (CIMS). This method allows the accurate and precise measurement of sulphuric acid at concentrations above ~$5x10^5$ molecule/cm^3. In addition to measuring the monomer concentration, the CIMS instrument can be used to determine the sulphuric acid dimer concentration. This measurement is important because it allows identifying at which stage of the nucleation process the stabilizing effect of a base molecule becomes effective. In a recent study evidence has been found that the stabilizing effect is already affecting the dimer formation for the neutral nucleation pathway (Petäjä *et al* (2011)). This speculation was supported by the unexpectedly high dimer concentrations measured during nucleation studies conducted in a laminar flow tube as well as through modelling studies. However, the study by Petäjä *et al* (2011) was lacking the direct measurement of ammonia or amines and could therefore only link the enhanced sulphuric acid dimer concentrations to the presence of an unknown contaminant with unknown concentrations.

Here, we present results related to the measurement of neutral sulphuric acid dimers during the CLOUD experiment. The measured dimer concentrations will be discussed for the cases of binary sulphuric acid and water nucleation as well as ternary nucleation experiments involving ammonia and dimethylamine, respectively. The dimer formation rates will be presented with respect to the observed nucleation rates derived from various condensation particle counters. In contrast to most other studies, the concentration of ternary substances like ammonia and dimethylamine in the pptv-range has been measured with state-of-the-art instruments during CLOUD. Therefore, sulphuric acid dimer formation will also be discussed regarding different concentrations of these ternary substances.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. Nucleation and condensation on presence of aerosols in boundary-layer flows

L.L. Bonilla[1] and M.D. Camejo[1]

[1]Gregorio Millán Institute, University Carlos III, Leganés, Madrid, 28911, Spain
Keywords: Boundary layer, Condensation, Nucleation, Deposition.
Presenting author email: mdcamejo@ing.uc3m.es

Condensation of vapours is a very well phenomenon that occurs in a wide variety of scenarios ranging from nature to industry and, of course, at different spatial scales. Air flowing in the open atmosphere at the seafront carries water vapour molecules in a suspension of saline aerosols [1]. In combustion chambers, hot air carries a mixture of soot and vaporized substances produced by the combustion of fuels [2,3]. In both cases, flow contents are very aggressive.

The relatively colder walls of tall buildings or combustion chambers allow the formation of neighbouring condensation layers where active processes of nucleation and condensation take place and result in the subsequent deposition of condensate.

Wall temperature (considered to be constant) and density and size of suspended particles are the main controlling parameters for the problem while physical properties of substances and air are, in general, temperature-dependent. Depending on droplet size, condensation may occur according to a free molecular regime or by diffusion, so this aspect needs also to be considered.

We propose a thermophysical model to describe homogeneous and heterogeneous condensation in simple laminar boundary-layer flows near cold walls assuming that the supersaturated vapours are diluted [4]. Then the air velocity and temperature fields are independent of the condensation process. We determine the position of the condensation layers and obtain the profiles of vapour density, density and size of droplets, and the deposition rates on the walls. Droplet nucleation is modelled by the Zeldovich stationary flux of supercritical clusters. The droplet distribution resulting from nucleation is approximately monodisperse although we have also considered the polydisperse case.

We have solved numerically the thermophysical model and interpreted the results by using singular perturbation techniques. These approaches lead to a reduction of the problem and basically work by uncoupling the droplet density balance equation from the rest, estimating it, solve the remaining equations and iterate to improve the approximation.

The figure shows total deposition rates (vapour and condensate) as obtained by solving numerically the whole model (plot indicated as n) and by an asymptotic approach (plot indicated as a). The results are good for a very wide range of wall temperatures.

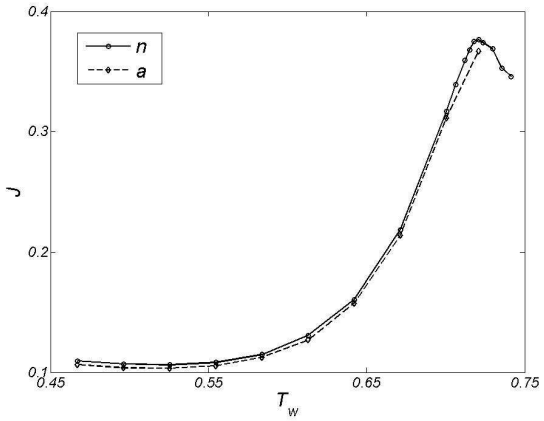

Figure 1. Total deposition rates on the wall (J) vs. wall temperature (Tw)

Particle nucleation in urban subtropical atmosphere

F. Salimi, L. Morawska, Z. Ristovski and M. Mazaheri

ILAQH, IHBI, QUT, Brisbane, QLD, 4001, Australia
Keywords: Nucleation, Particle growth, Condensation sink, Urban areas.
Presenting author email: f.salimi@qut.edu.au

New particle formation (NPF) and growth have been observed in different environments all around the world and NPF affects the environment by forming cloud condensation nuclei (CCN). Detailed characterisation of NPF events in a subtropical urban environment is the main aim of this study. Particle size distribution (PSD) of atmospheric aerosol particles in range 9-414 nm were measured using a Scanning Mobility Particle Sizer (SMPS), within the framework of the "Ultrafine Particles from Traffic Emissions and Children's Health" (UPTECH) study, which seeks to determine the relationship between exposure to traffic related ultrafine particles and children's health (http://www.ilaqh.qut.edu.au/Misc/UPTECH%20Home.htm). The UPTECH study includes measurements of air quality, meteorological and traffic parameters in 25 randomly selected state primary school within the Brisbane metropolitan area, in Queensland, Australia. Measurements at 17 schools have been completed so far.

SO_2, NO_x, CO, PM_{10} and $PM_{2.5}$ concentration, as well as solar radiation (SR), humidity, wind speed/direction and other air quality parameters were measured in each school. Data which were not measured or missed due to instrument faults were obtained from the nearest Department of Environment and Resource Management (DERM) or Bureau of Meteorology (BOM) site.

Several nucleation events were identified based on the method presented by dal Maso et al (2005) and the condensation sinks (CS) for all PSDs during these events were calculated. H_2SO_4 concentration was substituted with a proxy as follows (Salma et al. 2010):

$$[H_2SO_4] \propto \frac{[SO_2] \times Rad}{CS}$$

PSD, CS, SR, and SO_2 concentration during an NPF event at one of the schools (S09) is illustrated in Figure **1**. The temporal trend of PSD is illustrated by an image plot which shows a significant increase in particle concentration in the nucleation mode (<25nm) during the late morning, followed by an increase in particle size for several hours. The dashed line illustrates the geometric mean diameter (GMD) of particles in the nucleation mode, which shows an increase at the beginning of the event and then the particles exceed the nucleation size range. SR, SO_2 and O_3 concentration increased during event, however CS was at its minimum value throughout.

This study is part of an ongoing project and further measurements and analysis are currently in progress, including measurements for the last eight sites. The development of an automatic NPF identification procedure in the Igor Pro environment and a detailed analysis of the main parameters affecting new particle formation events are also still in progress.

Keywords: sulfuric acid, nano-particles, particle growth.
Presenting author email: skrabalova@icpf.cas.cz

This work presents measurements of sulfuric acid nano-particles produced by homogenous nucleation. Since sulfuric acid has a key role in atmospheric new particle formation (Sipilä et al, 2011), it has been intensively studied for a long time, however the exact mechanism of atmospheric nucleation and subsequent growth (Biskos et al., 2009) has not been fully understood yet.

The experiments presented here were conducted in a laminar flow tube which was kept at a constant temperature. A steady stream of particle free air saturated with high purity sulfuric acid (97% w.t.) was mixed with a mixing stream of particle free air saturated with water vapor and then the stream flowed through the tube. Temperature and humidity of the gaseous mixture were measured using probes (PT100 and Vaisala HMI38).

The measurements were performed at relative humidities ~1% and ~30% and at 4 residence times 30, 45, 60 and 90 seconds. The nucleation temperatures investigated were 10, 20 and 30°C. Temperature of the acid saturator was changed in seven small increments during the experiment resulting in gradually increasing concentration of sulfuric acid in the gaseous mixture. At the outlet of the flow tube there were measured number concentrations of produced particles using Ultrafine Condensation Particle Counter (UCPC TSI 3776) and particle size distributions using Differential Mobility Particle Sizer (DMPS with a short HAUKE type DMA and UCPC TSI 3025A). In Figure 1 is presented the observed variation in particle size distribution and particle number concentration with time obtained from inversion process of raw DMPS data from a single experiment. The increasing particle concentration and particle diameter correspond with increasing sulfuric acid concentration due to gradually growing temperature of acid saturator.

Figure 2 illustrates the dependency of particle median diameter on temperature of acid saturator at different residence times. As the concentration of sulfuric acid increases, the particle size generally increases at all residence times.

This work was supported by the Grant agency of the Academy of Sciences of the Czech republic (Grant no. IAA200760905).

Using A09 Particle Size Magnifier for resolving formation and growth rates below 2 nm

K. Lehtipalo[1,2], A. Franchin[1], T. Nieminen[1], S. Schobesberger[1], J. Kangasluoma[1], J. Mikkilä[2], J. Vanhanen[2], T. Petäjä[1], and M. Kulmala[1]

[1]Department of Physics, University of Helsinki, 00560 Helsinki, FINLAND
[2]Airmodus Oy, 00560 Helsinki, FINLAND

Keywords: nucleation, condensation particle counters, nano-particles, growth rates
Presenting author email: katrianne.lehtipalo@helsinki.fi

A reason why the molecular level processes leading to new particle formation are not yet completely understood has been the inability to detect neutral particles below 3 nm. Typically, the formation rate is calculated for larger particles, and then scaled back to the size of the nucleating clusters using assumptions of growth rate, particle losses *etc.* New kinds of condensation particle counters, like the A09 Particle Size Magnifier, allow deriving parameters describing the new particle formation process, *e.g.* the formation and growth rates, directly from measurements also in the size range well below 2 nm, *i.e.* exactly at the size of the critical clusters.

The Airmodus A09 Particle Size Magnifier (PSM) can be used to resolve the size distribution of particles below 2 nm. The PSM is a mixing-type condensation particle counter using diethylene glycol to activate particles. An external CPC is then used for growing and counting the activated particles. The nominal cut-off size of the Particle Size is about 1.5 nm (Vanhanen *et al.* 2011). However, the cut-off size of the instrument can be varied between about 1 – 2.5 nm by changing the mixing ratio of saturator and aerosol flow and thus changing the supersaturation created. Exact laboratory calibrations are needed for establishing the relation between the size and the mixing ratio.

The A09 PSM was tested and calibrated in University of Helsinki laboratory facilities using negatively charged ammonium sulphate clusters, which were produced in a tube furnace and size-selected with high-resolution Herrmann DMA. The exact composition of the produced clusters and the cleanliness of the sample were verified with an APi-TOF mass spectrometer (Junninen *et al.,* 2010). The detection efficiency was measured also for mobility standards, NaCl and silver ions. Since the activation probability of small particles and clusters in a CPC can depend on their charge and composition, the calibration strictly holds only for the measured compounds.

The formation rates and growth rates below 2 nm have been determined from the size distribution measured with the PSM, for example for nucleation experiments in the CLOUD-chamber (Duplissy *et al.,* 2010; Kirkby *et al.,* 2011) and for field measurements at the Hyytiälä SMEAR II measurement station (Kontkanen *et al.,* 2012). The growth rates (GR) were calculated from the difference between the appearance times of the newly formed particle population with different cut-off sizes of the PSM. The growth rates below 2 nm were also compared to the appearance times of differently sized charged clusters measured with the APi-TOF, and to the growth rates of 1.6-3 nm ions from ion spectrometers. However, the PSM gives additional information on the behaviour of the smallest neutral particles at the beginning of the new particle formation. This is crucial since nucleation in the boundary layer is most probably dominated by neutral mechanisms (*e.g.* Manninen *et al.*, 2010). The initial growth rates determine what fraction of the newly formed particles eventually reach sizes, where they can act as CCN and influence the climate.

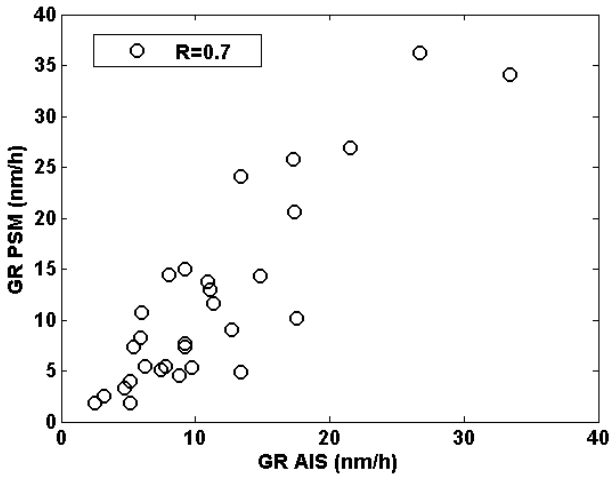

Figure 1. Comparison of the growth rate of the total particle population below 3 nm measured with the PSM and the growth rate of positive 1.6-3 nm ions measured with the AIS ions spectrometer.

Two amine campaigns; H_2SO_4 detection with different methods

K. Neitola[1], D Brus[1], U. Makkonen[1] and H. Lihavainen[1]

[1]Finnish Meteorological Institute, Erik Palménin aukio 1, P.O. Box 503, FI-00101, Helsinki, Finland
Keywords: nucleation, sulphuric acid, amine, flow tube.
Presenting author email: kimmo.neitola@fmi.fi

Atmospheric new particle formation is an important source of aerosol particles. Sulphuric acid is known to play key role in nucleation but third species is expected to participate in the first steps of nucleation. Laboratory studies have been recently focusing on the effect of amines and ammonia on the nucleation (e.g. Berndt et al., 2010).

Two similar campaigns have been conducted in the Finnish Meteorological Institute using flow tube technique to investigate the effect of four different base molecules (ammonia, monomethyl-, dimethyl- and trimethyl amine) on sulphuric acid-water gas to liquid-nucleation. Flow tube is a vertically positioned two meter long thermally controlled stainless steel cylinder. Sulphuric acid was produced from pure liquid sulphuric acid in a thermally controlled saturator.

In the first experiment, sulphuric acid concentration was detected with Chemical Ionization Mass Spectrometer (CIMS, Petäjä et al., 2009) or with Atmospheric pressure interface Time of Flight mass spectrometer (Api-TOF, Junninen et al., 2010) used with similar Chemical Ionization inlet as the CIMS. In the second experiment Sulphuric acid concentration was determined with the instrument for Measuring AeRosols and Gases (MARGA, ten Brink et al., 2007) from SO_4^{2-} concentration separately from gas and aerosol phase. Major difference in these methods is that with MARGA total sulphate concentration was determined and with CIMS/Api-TOF only the H_2SO_4-monomer concentration was measured. MARGA is able to detect five different acidic gases and eight major inorganic species from aerosol phase, so it can be used also to detect amines.

Particle concentration was measured with Ultra Fine Condensation Particle Counter (UFCPC, TSI model 3776) and custom made Differential Mobility Particle Sizes (DMPS) was used for measuring the number size distribution from 3 to ~260nm.

Measured nucleation rates covered several order of magnitudes, from 0.1 to ~500 #/cm^{3}s with sulphuric acid concentrations ranging from 10^5 to 10^7 mol./cm^3 (CIMS/Api-TOF) or 10^8 to 10^{10} mol./cm^3 (MARGA) depending which instruments were used for sulphuric acid detection. Mean particle size was always below 30nm, usually between 10-20nm.

Figure 1 presents particle number concentrations as a function of H_2SO_4 monomer measured by CIMS (lower x-axis) and as a function of total SO_4^{2-} measured by MARGA (upper x-axis) for sulphuric acid-water nucleation only. In both measurements the temperature of the saturator is only changed variable. It is clear that depending on the measuring instruments, similar nucleation rates are produced with sulphuric acid concentration that differs by orders of magnitude.

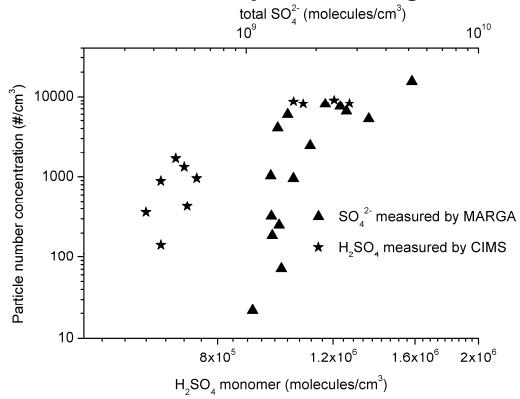

Figure 1. Particle number concentrations as a function of SO_4^{2-}/H_2so_4 monomer concentrations.

Amine enhancement of nucleation was detected when trimethyl amine was added in campaign one but the results of the base molecules in campaign two has not been analyzed yet. Figure 2 shows the enhanced particle count as a function of added trimethyl amine with constant sulphuric acid concentration with standard deviation as an error bar in campaign one. Next step is to compare the effect of the amines and ammonia to the nucleation rates and the size distribution of the particles.

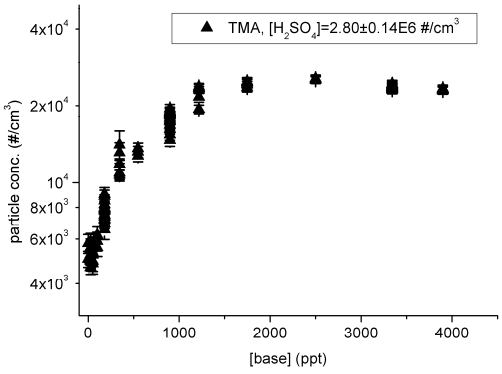

Figure 2. Particle concentration as a function of added trimethyl amine with constant sulphuric acid concentration in campaign one.

Sulphuric acid/water (SAW) aerosols are thought to play a major role in the climate. The low vapour pressure of sulphuric acid means it readily condenses, particularly in association with water and other species. These aerosols are thought to have a direct and indirect effect on the climate: the first is due to their light scattering properties and the second is where they act as cloud condensation nuclei. For these reasons sulphuric acid aerosols have been of particular interest in research concerning geoengineering schemes, but a better understanding of their formation is still needed.

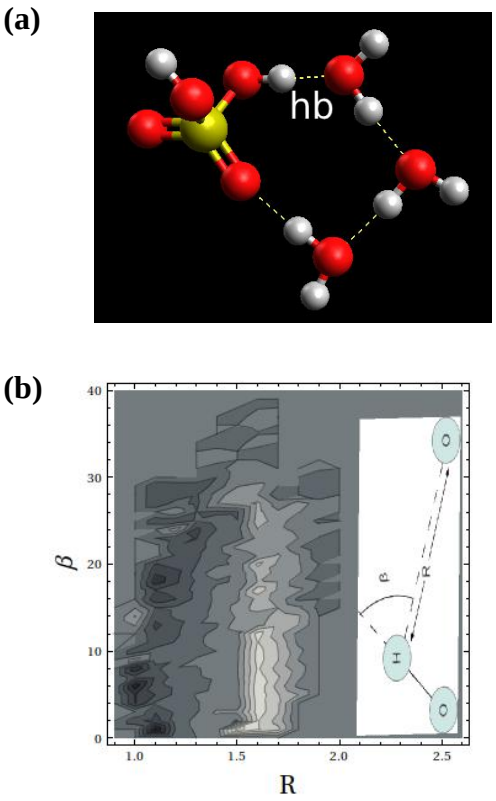

Figure 1: We study the hydrogen bond indicated in (a). The bond is identified in figure 2. The potential of mean force (PMF) indicates the work required to remove a particle from a given position to infinity. The difference between the PMF for standard DFT MD and PIMD (with 32 beads) is shown in (b). R and β are defined in the inset and contours are of width kT. The darker regions indicate where the PIMD PMF is deeper, and the lighter regions indicate where the standard DFT PMF is deeper. The background grey indicates zero change. The comparison shows that the PIMD simulation produces a shorter bond on average.

Classical nucleation theory does not reproduce nucleation rates well for SAW clusters and alternative theories have been suggested (Napari et al 2010) to improve upon it. Amongst these, Molecular Dynamics (MD) stands out as a method for the simulation of clusters and can be used to predict nucleation rates.

The work presented here concerns the creation of an MD-based method that improves upon schemes such as that of Ding et al. (2004) by explicitly treating proton transfer events. The charged species $[HSO_4]^-$ and $[SO_4]^{2-}$ have recently been shown to affect the nucleation rate significantly (Kirkby et al, 2011).

Configurations of sulphuric acid trihydrated (SATH) and tetrahydrate were studied using density functional theory (DFT) MD and path integral MD (PIMD), with the CASTEP code, to investigate the importance of quantum nuclear dynamics in small hydrated sulphuric acid clusters. This builds on work by several groups using both MD and geometry optimisations at the DFT level. The extra cost incurred using PIMD may be justifiable as suggested by Sugawara et al. (2011).

The results indicate that quantum effects change the dynamics of certain hydrogen bonds in the system. Figure 1(b) compares the potentials of mean force, with and without a quantum treatment of the nuclei, for hydrogen bond hb in Figure 1(a). The mean bond length shortens from 1.47Å to 1.36Å. However it does not seem to affect the gross stability of a configuration, such as the degree of hydration required for proton transfer. The importance of quantum nuclear dynamics to cluster nucleation at 300K therefore appears to be limited.

Additionally the DFT MD level of theory reveals effects not seen if the focus is on geometry optimisation alone. Another SATH configuration is expected to adopt a stable ionised state at $T = 0$ K according to such studies. However our DFT MD simulations at 300 K show this structure to exhibit a complex bimodal behaviour of proton hopping between ionised and neutral states. Current effort is being devoted to the parameterisation of an empirical valence bond potential to represent these effects.

Keywords: Optical properties, hygroscopic growth, refractive index, volume weighted mixing rule, twilight zone

Presenting author email: flores@weizmann.ac.il

One of the major uncertainties in the understanding of Earth's climate system is the interaction between solar radiation and aerosols in the atmosphere. This interaction is dependent on the physical and chemical properties of the aerosols and the wavelength of the incident light. Aerosols exposed to high humidity areas will change their chemical, physical, and optical properties. To model hydrated aerosols, atmospheric chemistry models use the volume weighted mixing rule to predict the complex refractive index (RI) of aerosols when they interact with high relative humidity areas, and, in general, assume homogeneous mixing. The validity of these assumptions is explored. Furthermore, the laboratory results were used as a basis to model the change in the total extinction, the single scattering albedo (ω), and the asymmetry parameter (g) in the twilight zone of clouds at 355 nm and 532 nm.

The extinction coefficient and growth factor of humidified aerosols, at 80% and 90% RH, and at 532 nm and 355 nm wavelengths was measured for size-selected aerosols with different degrees of absorption; from purely scattering to highly absorbing particles. The ratio of the humidified extinction coefficients to the dry (fRH$_{ext}$(%RH,Dry)) is explored and compared to theoretical calculations based on Mie theory. Using the measured hygroscopic growth factors and assuming homogeneous mixing the expected RIs using the volume weighted mixing rule are compared to the RIs derived from the extinction measurements. The differences between assuming a core-shell structure or a homogeneous mixing of the substances is also examined.

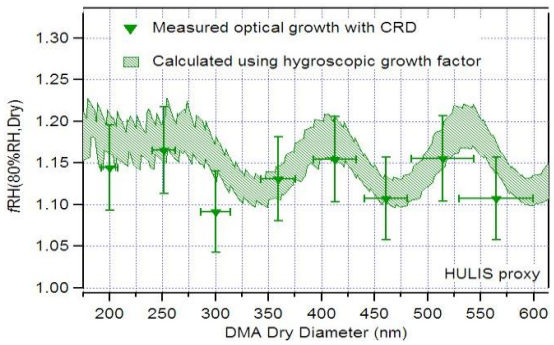

Figure 1. Size dependence of fRH$_{ext}$(80%RH,Dry) for IHSS Pahokee peat at 532 nm. The shaded areas represent the theoretical size dependence calculated from the measured growth factors from the SMPS.

We found either a moderate linear slope or no dependence of fRH(%RH,Dry) with size for absorbing substances in contrast to the decreasing exponential behavior with size for purely scattering substances, but no discernible difference could be made between the two wavelengths used. Less than 5% differences were found between the real parts of the RIs derived and those calculated using the volume weighted mixing rule, and the imaginary parts (k) had up to a 20% difference.

The total extinction as a function of distance from the nearest cloud was found to be independent of k of the dry RI of the absorbing aerosols modeled. The single scattering albedo, as expected, decreased with larger values of k, whereas the asymmetry parameter increased suggesting a reduction in the reflectivity of the twilight zone with more absorbing aerosols and a reduction of cloud edge 3D radiative effects.

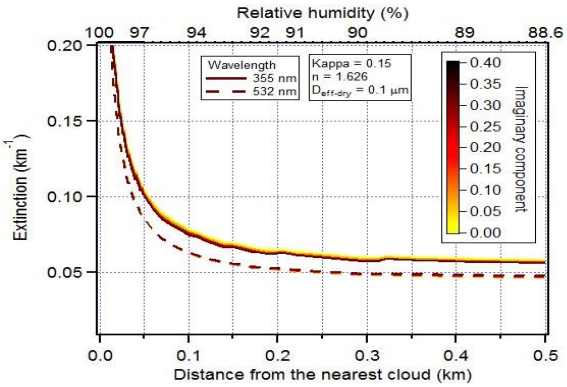

Figure 2. Extinction as a function of distance from the nearest cloud. The hygroscopicity parameter (κ) was set at 0.15, the real part of the RI (n) at 1.626, and the dry effective diameter ($D_{eff\text{-}dry}$) at 0.1 µm. A typical relative humidity field for the marine boundary layer was used. Two wavelengths: 355 nm (solid lines) and 532 nm (dashed lines), are shown. The imaginary component (color scale) was varied from 0 to 0.4.

Various aerosol systems lead to the formation of self-organized fractal-like aggregates of nano-sized primary particles, whose formation mechanisms and morphological properties are not yet fully understood. Over the last few decades a huge effort has been devoted for developing a Transmission Electron Microscopy (TEM) based method for estimating the size distribution and average fractal dimension of collected samples (Koylu et al. 1992, Yon et al. 2011). This widely used method, referred here as the Minimum Bounding Rectangle method (MBR) is based on the multi-scale analysis of an entire aggregate sample. So that, in principle, this method is not suitable for aggregate samples that do not have homogeneous fractal dimension.

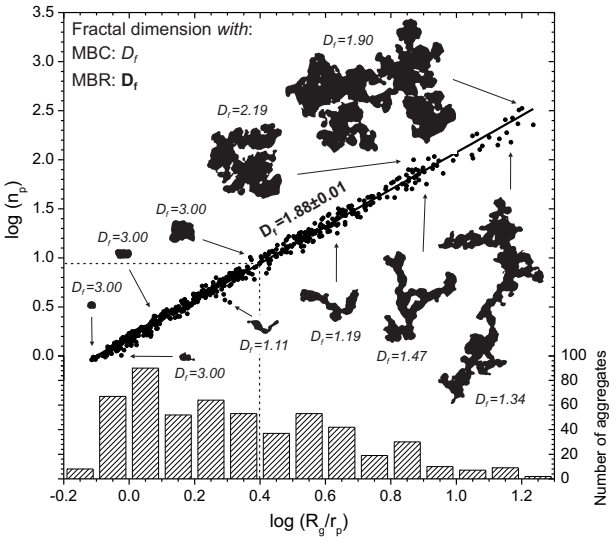

Figure 1. TEM-based analyses of experimental sample of diesel soot. The fractal dimension (D_f) is obtained with the conventional MBR method (average value in bold) and the MBC method (value for each aggregate in italics). R_g,r_p,n_p stand respectively for the radius of gyration, the radius and number of monomers within aggregates

The work we would like to present at the EAC-2012 conference will be focused on solutions to overcome the latter limit (Wozniak et al. 2012). It is will be shown in particular that the average fractal dimension estimated with MBR is severely biased by the smallest aggregates that do not exhibit self-similarity properties. On the other hand, we will detail the principle of a Modified Box-Counting (MBC) method that provides a less noisy estimation for the evolution of the fractal dimension with the size of aggregates, giving at the same time a criterion to reject the aggregates within sufficient self-similarity properties. Tests and validations results will be based on experimental soot aggregates as well as synthetic TEM images produced with a tunable Diffusion Limited Aggregation code (Wozniak et al. 2012).

As an illustration, Fig. 1 shows TEM-based analyses for 543 soot aggregates produced by a diesel flame (Yon et al., 2011). Several results, which will be detailed in the final paper, are presented in this Figure: (i) the number distribution of the normalized radius of gyration of all soot aggregates; (ii) the fractal dimension of the whole sample estimated with MBR method and (ii) typical binarized TEM images of soot aggregates with their fractal dimension estimated by MBC. From a quick view of the binarized TEM images, one may intuit that the smallest aggregates have a significantly greater fractal dimension than the largest ones. If such a correlation exists (i.e. the experimental sample is multi-fractal but not necessarily the aggregate themselves (Vicsek et al., 1990; Kravchenko et al., 2009)), one of the main hypothesizes of the multi-scale analysis is not satisfied. More profoundly, the detection of such a correlation could have major implications for our understanding of nanoparticles aggregation and growing mechanisms. For instance, going back to the results related to Fig. 1, the MBC method clearly show that the fractal dimension of this soot sample is much lower (1.66±0.02) than that the one derived with the MBR analysis (1.88±0.02). This fractal dimensions is, for some extend, in agreement with recent investigations (Chakrabarty et al., 2009).

Electrostatic and diffusion loss of charged nanoparticles in cylindrical tube connections with electric potential difference

D.K. Song[1], W.S. Hong[1] and W.H. Shin[1]

[1]Department of Eco-Machinery Systems, Korea Institute of Machinery and Materials, Daejeon, 305-343, KOREA

Keywords: Charged particles, Electrical mobility, Numerical simulation, Particle losses, Penetration.

Presenting author email: dksong@kimm.re.kr

For the real-time measurement of a detailed size distribution, a differential mobility analyzer (DMA) is widely used to measure size distributions of ultrafine particles.

When measuring the size distribution of atmospheric particles using a DMA, the electrical mobility distribution of particles is obtained, rather than the size distribution. Hence, the so-called reduction or inversion process must be used to derive the size distribution of atmospheric particles from the measured electrical mobility distribution. However, the electrical mobility distribution measured by DMA-CPC or DMA-FCE system is different from the size distribution of the airborne particles, due to the following: diffusional broadening during transport by Brownian diffusion, transport loss caused by inertial impaction, gravitational settling and interception in tube connections, and limitations in the efficiency of instruments for counting the number of particles.

Diffusional losses in particle sampling systems that contain bends and elbows, the detection efficiency of a condensation particle counter and the diffusional transfer function of DMA has been studied by numerous researchers. However, there is no report of any analysis of the phenomenon that electrostatic loss results in a decrease of the penetration of charged particles when they pass through a connection of cylindrical tubes whose electrical voltage differs.

We here present a theoretical and numerical analysis of the effect of the electrode setup geometry on the penetration efficiency of charged particles in transport through a cylindrical tube connection that has an electrical difference. The trajectory of charged particles was analyzed and penetration efficiencies for various cases are presented.

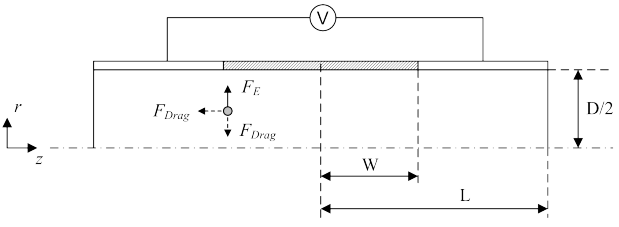

Figure 1 Schematics of cylindrical tube connection with electrical voltage difference.

A cylindrical tube connection that has a voltage difference and is separated electrically by an insulator was modelled (Figure 1), and electrostatic and diffusion loss of charged nanoparticles passing through the connector tube was numerically investigated. To assess the effect of the electrode geometry, various lengths of electric insulator W, tube diameter D, total connection length L and aerosol flow rate Q_a were used when investigating electrostatic loss.

Particle loss was calculated by analyzing particle trajectories and comparison of electrostatic loss for various electrode geometry setups, and Eulerian approach was also performed for solving convective-diffusion equation. We calculated the penetration efficiency for various particle diameters and applied voltages. The range of particle size and applied voltage used in the calculation were 2 – 500 nm and 0.01 – 5 kV, respectively. The ratio W/L of the insulator length to the total length was also changed from 0.1 – 0.4. In the numerical calculations, all particles were assumed to be spherical and singly charged with positive polarity.

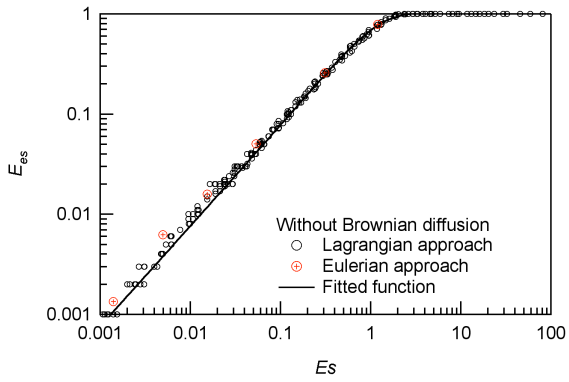

Figure 2 Electrostatic loss of charged particles presented as a function of a non-dimensional parameter, Es.

It suggests that the electrostatic loss can be described as a function of a new non-dimensional parameter,

$$Es = \frac{Z_p V}{U_{avg} W} = \frac{Z_p V}{Q_a W} \frac{\pi D_{tube}^2}{4}.$$

An explicit form for electrostatic loss is provided as a function of Es and given as

$$E_{es} = \frac{1}{1 + \left\{-0.0948 + 1.4137 e^{-0.947 Es}\right\} / Es}.$$

Charge control of particles in air using centrifugal force acting under applied electric field

S. Matsusaka and K. Satoh

Department of Chemical Engineering, Kyoto University, Nishikyo-ku, Kyoto 615-8510, Japan
Keywords: tribocharging, particle charge control, centrifugal contact, electric field.
Presenting author email: matsu@cheme.kyoto-u.ac.jp

When particles are handled in air, their surfaces become triboelectrically charged by coming in contact with walls or solid bodies made of different materials. As a result, charged particles may adhere to walls. If the particles are excessively charged, an electrostatic discharge can occur. Electrostatic forces can be used to control the motion of charged particles, and many such applications have been developed, e.g., electrostatic precipitation and particle separation. To prevent unexpected particle behavior and to improve the process performance, it is necessary to control the charge on the particles. In the present study, we propose a new charge control system for gas-solid pipe flow, which uses centrifugal force produced in an applied electric field, and evaluate the performance of the proposed system both theoretically and experimentally.

The contact charging of particles based on electron transfer depends on the contact potential difference V, which again depends on several factors, e.g.,

$$V = V_c - V_e - V_b + V_{ex} \quad (1)$$

where V_c is the potential difference caused by the surface work functions; V_e, image charge effect; V_b, space charge effect; and V_{ex}, applied electric field effect. To obtain the charge q as a function of the number of collisions n, we use a continuous quantity as follows:

$$\frac{dq}{dn} = k_c CV \quad (2)$$

where k_c is the charging efficiency and C is the capacitance between contact surfaces. Solving Eq. (2) with initial conditions $n = 0$ and $q = q_0$, we obtain the following exponential equation:

$$q = q_0 \exp\left(-\frac{n}{n_0}\right) + q_\infty \left\{1 - \exp\left(-\frac{n}{n_0}\right)\right\} \quad (3)$$

where q_∞ is the equilibrium charge. When the particle concentration is sufficiently low, $V_b = 0$, and q_∞ is expressed as

$$q_\infty = k_1 E_{ex} + k_2 V_c \quad (4)$$

where k_1 and k_1 are constants. Therefore, the equilibrium charge can be controlled by the applied electric field.

Figure 1 shows a schematic of the charge control system. Particles dispersed in air were charged using an inverted truncated cone-shaped device with inner and outer electrodes. Particles introduced into the device in a tangential direction from the top flow spirally downward and exit from the bottom. The particles came in contact with the side wall because of the centrifugal force acting in an electric field and became charged. The diameter of the particles was 80 μm, and their surface was coated with different resins to induce a positive or negative charge. The performance of the charge control system was evaluated by estimating the specific charge of the particles. Experimental results showed that the particle charging efficiency of a single system was approximately 90% and that of a combination of two charge control systems was 98%–99%.

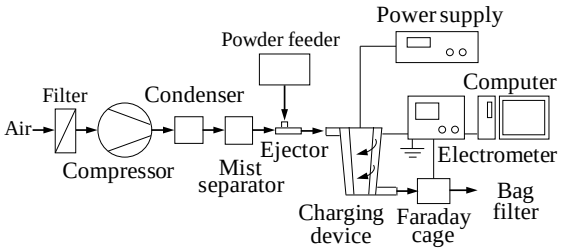

Figure 1. Charge control system.

Figure 2 shows that the specific charge varies with the applied electric field and type of resin. This figure also indicates an interesting feature: the relationship between specific charge and applied electric field can be classified into two categories, linear (Eq. (4)) and nonlinear.

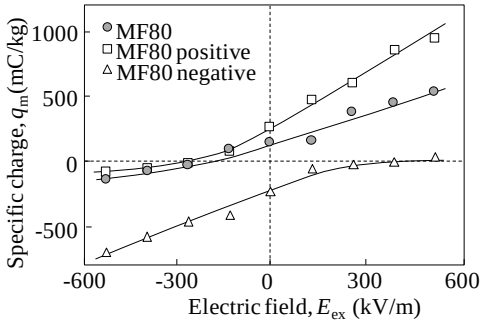

Figure 2. Effect of applied electric field on specific charge of particles.

Data inversion and calibration of a particle number concentration monitor

L. Hillemann[1], A. Zschoppe[2]
[1]Institute of Process Engineering and Environmental Technology, TU Dresden, 01062 Dresden, Germany
[2]Topas GmbH, Oskar-Röder-Str. 12, 01237 Dresden, Germany
Presenting author email: lars.hillemann@tu-dresden.de

The concentration of particle matter in ambient air is quantified in air quality monitoring networks. The classical mass-based methods are more and more completed by number-based methods. This enables to quantify the concentration of submicron particles, which especially show adverse health effects (Peters *et al*, 1997). In the European project UFIPOLNET a particle number concentration monitor has been developed, which combines an unipolar corona-jet charger, a DMA and an aerosol electrometer to measure the particle number concentration in six size classes from 20 to 800 nm.

Data inversion

The raw data measured by the number concentration monitor is the rate of particle-bound charge measured as electrical current versus the classifier voltage $I(U)$. Objective of the data inversion is to derive from these raw data the distribution of the number concentration versus the particle size $c_n(d)$. The analysis of the inverse problem delivers the connection between $I(U)$ and $c_n(d)$ by the charge distribution $f(d,n_e)$, the transfer function of the DMA $\Omega(Z(d,n_e),U)$ and the inlet flow Q if losses can be neglected.

$$I(U) = \int \mathrm{e} Q \sum_{n_e} f(d,n_e) n_e \Omega(Z(d,n_e),U) c_n(d) \mathrm{d}d \quad (1)$$

Due to the stepwise variation of the classifier voltage and the indication of the concentration in discrete size channels the inversion problem can be written in matrix notation.

$$\mathbf{I} = \mathbf{K}(\mathbf{U},\mathbf{d})\mathbf{C}_n \quad (2)$$

The kernel data can be calculated from the charge distribution by

$$K(U,d) = \mathrm{e} Q \sum_{n_e} f(d,n_e) n_e \Omega(Z(d,n_e),U) \quad (3)$$

or derived experimentally in calibration measurements.

The data inversion algorithm bases on the Tichonov regularization and minimizes the third differences of the concentration vector. The regularization parameter is fixed and was chosen empirically.

Calibration

Objective of the calibration of the number concentration monitor is to determine the values of the kernel matrix $\mathbf{K}(\mathbf{U},\mathbf{d})$. This is done in a parallel measurement of the monitor and a reference method, typically a SMPS or DMPS. The raw data of the monitor and the concentration data of the reference system are stored in the columns of the matrices **IM** and **CM** respectively. From these matrices the kernel matrix is derived by minimization

$$||\mathbf{K} \cdot \mathbf{CM} - \mathbf{IM}||_2 \Rightarrow Min \quad (4)$$

This minimization can be decomposed, which enables the calculation of the rows of the matrix separately. Fig. 1 shows a kernel matrix derived by this method.

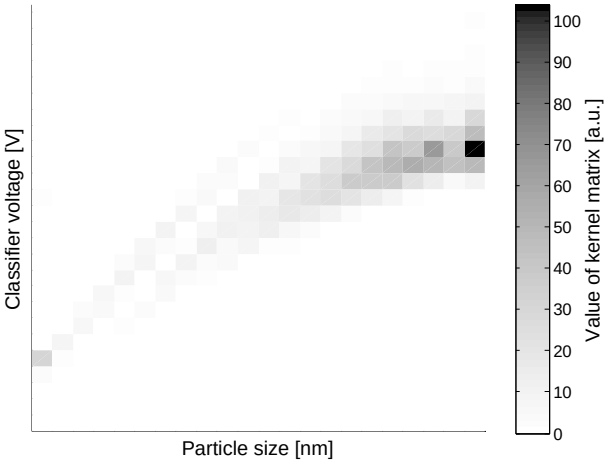

Figure 1: Kernel matrix of the particle number concentration monitor.

Structured chain-like aggregates by coagulation of charged particles

L. Knobel[1] and H.-J. Schmid[1]

[1]Chair of Particle Technology, University of Paderborn, Paderborn, 33098, Germany
Keywords: structured aggregates, unipolar charging, coagulation, charged particles
Presenting author email: lena.knobel@upb.de

Intention is to build a chain-like aggregate with alternating sequence of different materials.

Application could be a lamellar structured polymer with new properties. The structure is to be reached by adding the chain, structured nanoparticle aggregates during polymerization.

The structure of the aggregate will be realized by mixing a positively charged aerosol flow with a negatively charged aerosol flow which consists of another material. To realize the chain shape, the coagulation process needs to be faster than the neutralization by recombination in the contact point. Therefore the materials need to be dielectric. To slow down the charge mobility on the surface as well as in the bulk phase, temperature and humidity conditions have to be adjusted.

Chain-like structures were realised by e.g. Kasper *et al.* (1980) based on magnetic dipoles. DallaValle *et al.* (1954) showed formation of chain aggregates of ammonium chloride particles depending on the charge of the particles. Gutsch (1995) investigated the coagulation of sodium chloride particles forced by multi-stage bipolar charging by simulation and experimentally. Concurrent results showed the decreasing of the form factor (to the point of long-chain aggregates) by increasing the charges of the particles. The simulation results showed even the alternating structure of the oppositely charged particles.

To realize the structure with two different materials, two aerosol flows will be charged unipolar in each case in another polarity by corona charger. An advantage of the unipolar charger is the higher number of charges on the particles.

After forming doublets the impact of the opposite charged particles on the coagulation time will decrease (Figure 1). In order to keep the characteristic coagulation time short particle concentration and temperature have to be adjusted.

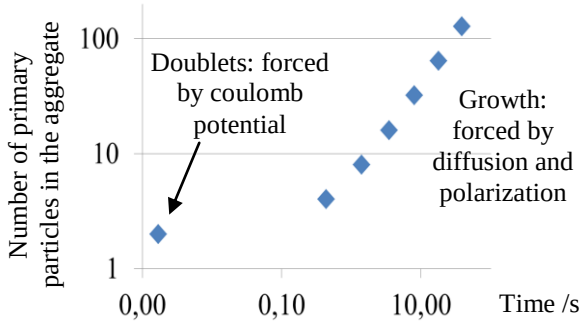

Figure 1: Coagulation time of charged 100 nm particles with an initial particle concentration of 10^{14}/m³

The particle materials, which are first investigated, are silicon dioxide and aluminium oxide. Both are synthesized in a hot wall reactor. The liquid precursors will be evaporated and fed to the process flow. Preliminary for the following coagulation we need at first spherical primary particles. The particle concentration is limited by the synthesis of those particles, because the characteristic coagulation time needs to be much longer then the characteristic sintering time. Figure 2 shows the maximum concentrations and production rate based on the facility design and the calculation of the sintering time by Kirchhof (2008).

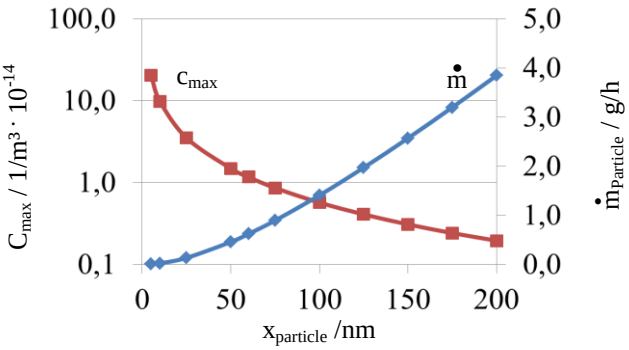

Figure 2: Max. particle concentration and production rate for SiO_2 dependent on the primary spherical particle size, residence time: 900 ms, T= 1700 °C

Downstream of the high-temperature kilns the streams will be charged unipolar separately from each other. The next step is the mixing for the coagulation process.

The analysis of the complex structure in dependency of particle charge, particle size and residence time can only be done by simultaneous application of different measurement technics like mobility analysis, measurement of chargeability (Wang *et al.*, 2011), low-pressure impaction and image analysis.

The charging process will be monitored by a Faraday Cup Electrometer in combination with a Condensation Particle Counter.

Influence on the bipolar stationary charge distribution

L. Knobel[1], A. Jain[2] and H.-J. Schmid[1]

[1]Chair of Particle Technology, University of Paderborn, Paderborn, 33098, Germany
[2]Department of Chemical Engineering, Indian Institute of Technology, Bombay, India
Keywords: bipolar charging, charge distribution, SMPS, charger downstream
Presenting author email: lena.knobel@upb.de

The prediction of the aerosol charge distribution in a bipolar ion environment is an essential part of the mobility analysis. The Fuchs theory (1963) is a widely-used method to calculate the distribution. The temperature, mass of gas molecules, ion mobility and ion mass are necessary independent input parameter. The species of the ions is again influenced by trace gases, humidity, aging time and ionisation energy. The last point is not physically understood jet, but experimental results suggest a difference in the charge distribution (e.g. Lee *et al*., 2004)

The Wiedensohler approximation (1988), derived from the Fuchs model, is a widely-used method in mobility analysis. However, it relies on fixed input parameters.

The first part is a sensitivity analysis on the Fuchs calculation to determine the range of the resulting charge distribution depending on the input parameters and to determine the dominating parameters. It is shown that, in the free molecular regime the charge process is driven by the mobility and in the near-continuum regime it is driven by the mass.

Lots of different values for the ion mobility are known by measurements from the literature. Based on these values for the mobility and the adapted values for the mass by the Kilpatrick relation (1971), we calculated the possible results for the fraction of singly charged particles. The results pointed out, that the mobility difference between negative and positive ions in the near-continuum regime is more important than the absolute values of the mobility. Figure 1 shows four cases for varied mobility differences. The dashed line in the middle shows the result for equal mobility of positive and negative Ions. The three other values for the mobility difference are chosen by reasonable values of the literature. The green line presents the values chosen by Wiedensohler (1988) for his approximation.

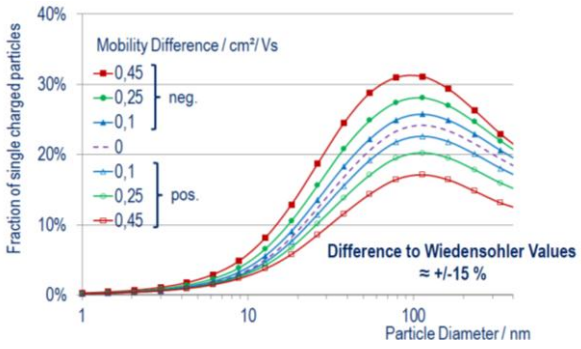

Figure 1: Effect of the mobility difference

The range of the variation is significant and should be taken into account when analysing results from measurements with a SMPS system.

The second part was about the development of the charge distribution downstream of the charger. Hoppel *et al.* (1990) calculated the modification of the ion concentration downstream of the charger and emphasize the non-equilibrium character of the charge distribution, because of not dispensable pluming.

We expanded this calculation. To describe first the ion concentration a coupled population balance for ions and particles were solved along a tube. The following effects were taken into account for the ions: Recombination, charging of particles, electrostatic dispersion, convection and diffusion. In the model the particle flux is driven by dispersion and convection. Particles with the charge of -2 to +2 were examined. The boundary conditions for the model case were selected based on the conditions in a conventional SMPS system.

An interesting aspect is the decay of ion concentration dependent on the initial ion and particle concentration. Based on this result the modified charge probability was calculated. Figure 2 shows, that for the application of the SMPS this effect is negligible.

Break-up of charged ionic salt solution droplets at super-Rayleigh limits

Asit Ray and Kuo-Yen Li

Department of Chemical Engineering, University of Kentucky, Lexington, KY 40506, USA
Keywords: droplet charge limit, evaporation, solute precipitation
Presenting author email: akray@engr.uky.edu

Evaporation of neutral solvent from a charged solution droplet causes reduction in the droplet size, and as a result the charge density at the droplet surface increases. Ultimately, the charge density level attains a critical limit where the droplet becomes unstable resulting in the formation of smaller progeny droplets from the break-up of the parent droplet. The break-up process lowers the charge level below the instability limit, but continual evaporation causes the droplet to break-up intermittently. The charge density level at which droplet break-ups occurs is known as the Rayleigh limit, which has been confirmed by numerous experiments. We have examined the charge stability limits of single evaporating microdroplets of ionic salt solutions. Single charged droplets were suspended in an electrodynamic balance, and a resonance-based light scattering technique was used to determine the size and the size change of a droplet at a charge instability induced break-up. The dc voltages required to gravitationally balance the droplet prior to and following the break-up were used to calculate the charge level and the charge loss at the break-up. We have examined diethylene glycol (DEG) and triethylene glycol (TEG) droplets containing lithium chloride as well as calcium chloride at varying concentrations.

Our previous studies [Li et al. (2005) and Hunter and Ray (2009)] on single component droplets and droplet doped with ionic compounds, such as ionophores or ionic liquids, show that droplet break-ups occur at the Rayleigh limit, and the concentration of ions in a droplet has no effect on the charge limit. The results also show that the fractional charge loss increases, while the mass loss decreases as the ion concentration in a droplet increases. Through an analysis we have shown that the presence of nonuniform ion distributions in a droplet enhances the electrical conductivity at the droplet surface, and established that the charge-to-mass ratio of progeny droplets is proportional to the conductivity at the surface of the parent droplet. The results of the present study on DEG and TEG droplets containing ionic salts show that droplet break-ups occur at significantly higher charge levels than the Rayleigh limit, and droplets can remain stable at charge levels greater than three times the Rayleigh limit. The charge limit at a break-up depends on the salt concentration in a droplet and increases as the concentration increases. During evaporation the salt concentration in a droplet increases due to the reduction in the size, and when the droplet undergoes multiple break-ups we observed that the charge limit of the succeeding break-up always exceeds that of the prior break-up due the concentrating effect of the salt. As long as the salt concentration in a droplet remains below the saturation point, the observed charge limit increases linearly with the salt concentration and approaches the Rayleigh limit at low concentration levels. Between the salts, lithium chloride has more pronounced effect on the charge limit than calcium chloride. Even though the observed charge limit increases with increasing salt content when the salt concentration in a droplet exceeds the saturation value, the dependence of the charge stability limit on the concentration changes considerably due to the precipitation of solute at the droplet surface. In addition, we also observed that the fractional mass loss at a droplet break-up is below the detection limit (i.e., about 0.03%) of our measurement technique. The fractional charge loss at a droplet break-up increases with increasing charge stability limit, and each break-up results in the reduction of the droplet charge to a level lower than the Rayleigh limit. We developed a model to explain the observed behaviour.

Performance of ^{85}Kr, Soft X-ray and AC Corona Charging Sources for Particles <20 nm

J.J. Swanson[1], A.M. Boies[1], A. Collins[2]

[1]Department of Engineering, University of Cambridge, Cambridge, UK, CB2 1PZ

Aggregates consisting of clusters of primary particles are ubiquitous in ambient and industrial aerosols. Soot emitted by Diesel engines or biomass burning is a primary source of aggregates in the atmosphere. Similarly, spherical particles are generated in the laboratory for calibration or synthesis. In many cases, measurement of these particles depends on the knowledge of the distribution of charges they have acquired, either naturally or from a "neutralizer." Variations in neutralization techniques may lead to different charging characteristics and other parameters such as particle size, shape, composition, concentration, and ambient air properties impact the charging process.

The objective of this work is to evaluate the performance of different neutralization techniques. In a typical neutralizer, particles pass through a cloud of ions and acquire a steady state distribution of charges that is nearly symmetrical [1]. Many techniques are available to generate these ions but this work focuses on radioactive sources (^{85}Kr, NRD, Inc), x-rays (3087 Soft X-ray Charger, TSI, Inc [2]), and corona discharge (1090 Electrical Ionizer, MSP Corp). These methods differ in the way they ionize surrounding N_2 and O_2 molecules. The de-facto standard, ^{85}Kr, emits highly energetic beta particles. Similarly, the X-ray Charger generates energy x-rays that peak in energy at ~6 keV. The Electrical Ionizer uses corona discharge operated with AC voltage to generate positive and negative ions. For all cases, ions are generated in equal proportions to achieve a near symmetric charge distribution.

To better quantify the impact of neutralization technique for particles <20 nm, our measurements have focused on the following phenomena.

- Particle charged and neutral fractions
- Particle generation due to photochemistry & radiolytic effects and electrode erosion
- Direct charging of individual particles

Measurement of the particle charged fraction provides an indication as to whether the aerosol is charged according to the assumed equilibrium charge distribution. The charged fraction (f_C), which is a function of particle size (D_p), is the summation of the singly, doubly, etc negatively and positively charged particles, where *n* is an integer index representing the number of charges:

$$f_{C,D_p} \equiv \sum_{n=-\infty}^{-1} f_{n,D_p} + \sum_{n=1}^{\infty} f_{n,D_p}$$

Likewise, the neutral fraction, f_{0,D_p}, is $1 - f_{C,D_p}$. It can be measured by taking the ratio of neutral particle concentration of the given size D_p (N_{0,D_p}) and the total particle concentration of size D_p (N_{T,D_p}):

$$f_{0,D_p} = \frac{N_{0,D_p}}{N_{T,D_p}}$$

A schematic of the apparatus used to measure f_{0,D_p} is shown in Figure 1. A DMA is used to classify a mono-mobility aerosol. The classified particles traverse a bipolar charger to reach an equilibrium charge state. An electrostatic precipitator (ESP) is used to remove all the charged particles by applying a high voltage and a condensation particle counter (CPC) downstream is used to measure neutral concentration ($N_{0,D}$). The total concentration is measured by turning off the ESP.

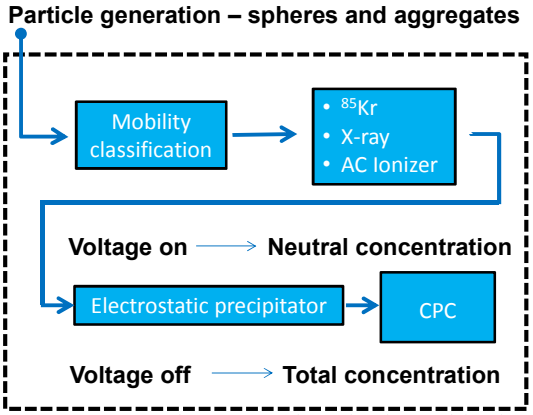

Figure 1. Apparatus used to measure charged and neutral fractions

Additional experiments were performed to investigate the formation of particles during neutralization due to the ionization of molecules into reactive species followed by nucleation and condensation (formation of radiolytic particles), as well as the direct charging for particles, rather than molecules. These effects depend on ambient air and trace gas chemistry. Overall, results obtained from these measurements provide further insight into the nature of particle charging for very small particles.

Abstract

The performance of ESP and generation of the corona discharge is influenced by many parameters. Particle charge is influenced by electrical resistivity that influences the particle collection efficiency. However, not many studies were about measuring the effect of electrical resistivity of particles. Various types of electrostatic precipitator were set up in this study. The objectives of this research included studying the characteristic of two different electrical resistivity of particles (polydispere NaCl and monodisperse PMMA) and discussing corona onset voltage, particle charge, collection efficiency, ozone concentration and filter quality of different types of ESP. The experimental results indicated that the lowest value of particle penetration was obtained for the Point-Plate ESP. The penetration of PMMA of 1.7μm was 0.19%, 9.4% and 64.66% for Point-Plate, Plate-Wire and Flate-Plate, respectively. The particle charge was measured under the same ESP and it was found that the particle charge of PMMA was lower than NaCl because the higher electrical resistivity of particles was difficult to be charged. However, the corona current of Point-Plate ESP was higher than other types of ESP that resulted in generating higher ozone concentration.

Experimental

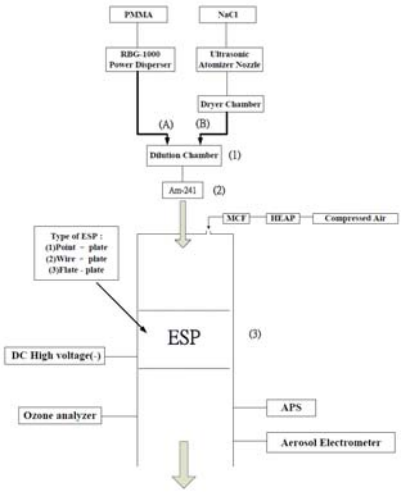

Figure 1. experimental set-up.

The experimental set-up, shown in figure 1, experimental apparatus included three major systems, i.e. The aerosol generator, the discharge electrode and collector system, and the aerosol measurement system, etc.

Results and Conclusions

The results show that the input current increased as the input voltage increases. Besides, the point-plate had largest input current than wire-plate and flat-plate of discharge electrode of ESP based on the same input voltages (figure 2).

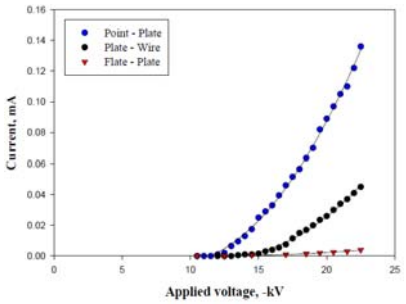

Figure 2. Input voltage vs. current of different discharge electrodes.

And it suggested that the particle charge and removal efficiency (Figure 3) of PMMA were lower than NaCl because the higher electrical resistivity of particles was difficult to be charged (Navarrete et al.,1997).

However, the corona current of Point-Plate ESP was higher than other types of ESP that resulted in generating higher ozone concentration (Viner et al., 1992; Jaworek et al. 2007).

*E-mail: h.wasisto@tu-braunschweig.de

Recently, there is increasing demand for air quality monitoring equipments to assess the release of airborne nanoparticles (NPs) to the environment due to the wide-spread use of nanotechnology. From the previous research, MEMS-based cantilever resonators are proven to highly contribute to the development of low-cost and compact sensors for monitoring ~20 nm airborne carbon NPs mass with a mass sensitivity of 8.33 Hz/ng (Wasisto *et al*, 2012). However, the NPs are still trapped on the whole cantilever surface, including its supporting frame which can definitely reduce the sampling efficiency because of their deposition location. Meanwhile, the most sensitive location of cantilever sensor for detecting the micro/nano-sized particles is its free-end (Dohn *et al*, 2005). The use of electrostatic forces is found to be the most effective method to position airborne charged particles (Tsai *et al*, 2007). Therefore, motivated by the need of high-sensitive mass detection of NPs adhered to the microcantilever on a selective area, a method of electrostatic-directed deposition of NPs by using a *p*-*n* junction patterned Si substrate is investigated and analyzed in this work.

Results

The cantilevers are successfully fabricated using a Si bulk micromachining process. The selective patterned area (*p*-type Si) for NPs collection is located close to the cantilever free-end and is formed by boron diffusion. A self-built miniaturized NP sampler is integrated with the patterned Si cantilever during 15-min TiO_2 aerosol sampling in the chamber having concentration of ~3500 NP/cm^3 (V = 1 m^3, T = 23 °C, rH = 30 %, P = 1 atm) (Fig 1). The aerosol consists of positively and negatively charged NPs. Upon reverse bias, an additional electric field is established in the charge depletion zone. From SEM images, a high number concentration of positively charged TiO_2 NPs with diameter of 6 to 523 nm is clearly deposited uniformly on the *p*-type Si region, indicating that positively charged particles were being repelled by *n*-type Si region and attracted to the *p*-type Si region (Fig. 2). A positive voltage of the NP sampler tube has also created additional electrostatic forces which push the positively charged NPs down to the substrate and keep the negatively charged NPs away from the substrate. In regard to the NP sampler flow rate of 0.68 l/min, the NP collection efficiency of 0.457 % is obtained. Further tests with the other types of aerosol will be addressed.

Post-corona diffusion charging versus radial ion profile in axisymmetric arrangement

Jidenko Nicolas[1], Alonso Manuel[2] and Borra Jean-Pascal[1]

[1]Equipe Décharges Electriques et Aérosols du Laboratoire de Physique des Gaz et des Plasmas (UMR 8578 CNRS – Université Paris-Sud Orsay, F-91405) SUPELEC, Plateau de Moulon, F-91192, Gif-sur-Yvette, France
[2]National Center for Metallurgical Research (CSIC), Gregorio del Amo, 8. 28040, Madrid, Spain.

Keywords: aerosol charging, diffusion charging, charge distribution, corona discharge

This work addresses the comparison of measured and calculated charge distributions in a post-discharge unipolar charger. The main objective is to evaluate the range of charging conditions (Ni.τ products, as time integrated ion densities Ni on particle trajectories) induced by radial and axial decreasing ion densities.

The negative corona discharge occurs around a needle of 100 µm radius in air at atmospheric pressure (Trichel 1938). Ions are extracted from the discharge gap using a 1-2 lpm gas flow rate through a hole in the anode plane. The charger operates with ion and aerosol flow velocities ratio between 0.1 and 2 that controls the ion radial profile. The charging zone has been designed to limit ion and aerosol losses.

A model developed for aerosol and ion mixing (Alonso et al. 2009) is used for the evaluations of Ni profile, mean Ni.τ product and charge distributions in realistic conditions using Fuchs' theory (Fuchs 1963) in the transition regime (30-300 nm). The zone of mixing is axisymmetric. Radial and axial profiles of ion density are stationary. The model calculates these profiles taking into account diffusion, space charge effects (for ion and particle) as well as the evolution of the charge level of particles.

Ni.τ products and the decrease of ion density along the charging zone have been characterized by current measurements at different locations. The related mean Ni.τ product is $6 \cdot 10^{12}$ s.m^{-3}. This value fits with calculation within 10 %.

The average particle charge and aerosol charge distributions are measured and compared to calculations. In that respect, aerosols of controlled size (related to DMA voltage) and concentration (controlled by the furnace temperature and maturation time after furnace) are injected in post-discharge.

Aerosol losses through the charger are determined with the CPC. Maximal aerosol losses are reached for smallest particles tested and remains below 10 % for a charge fraction of 40 % at 10 nm.

The neutral fraction is defined using the CPC after an electrostatic precipitator to collect charged aerosols. Aerosol charge distributions are obtained from mobility spectra measured with a Radial Differential Mobility Analyser (RDMA).

Previous estimation for flat radial ion density profile with decreasing axial density has proven that the radial profile has to be taken into account. Indeed, the measured charge distribution is broader than the calculated one with less than 8 % difference in population of each charge level, when neglecting the radial ion density profile.

Then, taking into account the calculated radial ion profiles, figure 1 shows the evolution of the calculated charge distribution for particles of 30 nm along the charging zone that will be compared with measured charge distributions.

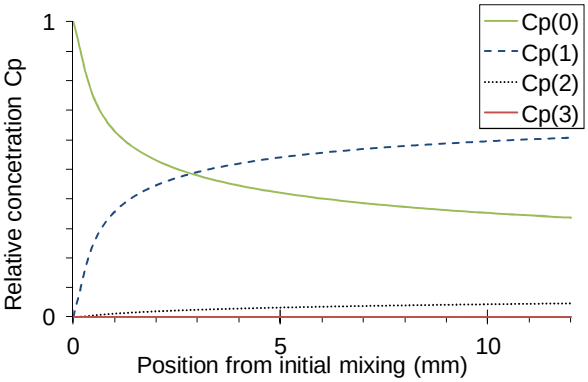

Figure 1. Evolution of the charge distribution for particles of 30 nm along the charging zone.

Measured charge distributions will be compared with the calculated ones at different location in the charging zone, for different radial ion density profiles induced by flow different velocity ratio at constant initial ion density and reversely.

nicolas.jidenko@u-psud.fr

Numerous aerosol processes are based on the charging of aerosol by ions (filtration, size measurement, electrostatic agglomeration …) (Intra 2011). The present work focuses on diffusion charging in short time (below 50 ms). The final aim is to measure the time evolution of the aerosol size distribution with a frequency of 10 Hz. The short charging time is thus required to preserve the temporal information. The ions are produced by an electrical discharge in air at atmospheric pressure and the aerosols are charged in post-discharge to prevent from the destabilization of the discharge due to the collection of aerosol on the electrode when the aerosol is injected in the discharge (Borra 2006).

Two scientific aspects are presented. The first one is the optimization of the ions extraction from the corona discharge and the evaluation of the charging conditions (Ni.τ product which is the critical parameter for diffusion charging). The second one concerns the charge-diameter relation including the influence of aerosol concentration on this relation.

The discharge occurs around a needle of 50 µm radius. The discharge current (-30 µA) is typical of the negative corona regime (Trichel 1938, Goldman et al. 1978). Ions are extracted from the discharge gap through a hole in the anode by convexion. Only a small fraction (about 1 %) of the discharge current is extracted from the discharge. To increase the ion flux, three processes have been studied: the distribution of the ion in the discharge gap, the electro-collection in the extractor by self repulsion and re-collection below the anode.

The charger has been designed to control the charging time below 50 ms. The originality of the charger lies on the strong heterogeneity of the ion density that decreases by 4 orders of magnitude in 50 ms. Indeed, the loss of ions to the walls by electrostatic repulsion requires high initial ion densities to achieve aerosol charging in the short charging time.

The product Ni.τ is defined by integration of the density of ions along the trajectory of the particles obtained by measuring the ion current in post-discharge. The product Ni.τ depends on the ion extraction on the one hand and hydrodynamic conditions of ion-aerosol mixture on the other hand, affecting the ion density profile in post-discharge and the path particles. The estimation of the mean Ni.τ is $2{\cdot}10^6$ s.cm^{-3}.

Under these conditions, the average charge levels are measured on calibrated aerosol size (10 nm - 1 micron) and concentration (10^3-$3{\cdot}10^5$ cm^{-3}). In our charging conditions, the ion density is very heterogeneous; we have highlighted the lack of ions per particle for aerosol concentration higher than 10^9 m^{-3} (cf. figure 1).

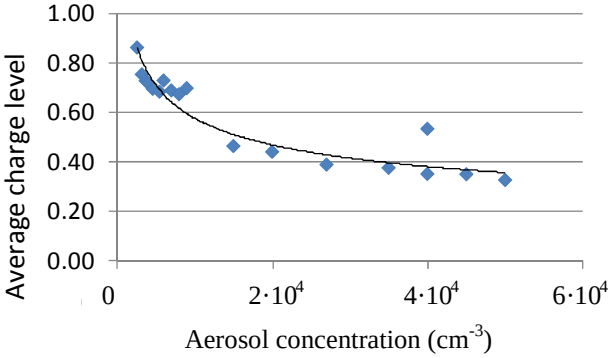

Figure 1. Number of charge per 100 nm particle for a given Ni.τ product of $2{\cdot}10^6$ s.cm^{-3}

The average charge level per particle decreases with the concentration of aerosol, despite constant initial ion density and charging time. Indeed, the charging laws are only valid when in very a large excess of ions per particle (Fuchs 1963). In this experiment, this is only true at the entrance, but this is no longer the case at the end of the charging zone. The numbers of ion per particle evolve from 10^5-$2{\cdot}10^4$ with the aerosol concentration at the entrance but fall down to 10 to 2 at the end of the charging zone. Hence, this effect of aerosol concentration on charge level can be attributed to different real Ni.τ that can be related to a faster decrease of ion density due to collection on the particle for higher aerosol concentration. The estimation of the real Ni.τ product using Fuchs' theory gives Ni.τ between of $3{\cdot}10^5$ and $8{\cdot}10^5$ s.cm^{-3}.

These values are in the same order of magnitude but smaller than the one estimated by ion current measurements without aerosol ($2{\cdot}10^6$ s.cm^{-3}) and account for the maximal aerosol concentration for any post-discharge aerosol charger.

Atmospheric small-ion mobility downwind and upwind of AC high-voltage power lines

M.D. Wright[1,2], A.J. Buckley[1], J.C. Matthews[1,2] and D.L. Henshaw[1,2]

[1]H H Wills Laboratory, School of Physics, University of Bristol, Bristol BS8 1TL, UK

Keywords: Ions, ion mobility, corona discharge, particle charging.
Presenting author email: matthew.wright@bristol.ac.uk

Diffusion charging of atmospheric aerosols is chiefly governed by the mobility and concentration of small-ions. Near to corona-emitting high voltage power lines (HVPLs), a higher ion mobility may lead to enhanced aerosol charging and possibly a higher particle deposition efficiency in the lung (Fews *et al*, 1999). Several previous studies report elevated small-ion concentrations near to AC HVPLs (e.g. Jayaratne *et al*, 2008). Ion mobility measurements have been made near DC lines (Suda and Sunaga, 1990) and from corona sources in the laboratory (Alonso *et al*, 2008). We present measurements of ion mobility upwind and downwind of AC HVPLs in the Bristol, UK area.

Positive and negative ion mean mobilities at 8 HVPL sites were calculated from mobility spectra obtained using Gerdien-type Aspiration Condenser Ion Mobility Spectrometers (ACIMS, Fews *et al*, 2005). Where possible, two ACIMS were used to measure at upwind (UW) and downwind (DW) sites simultaneously. Laboratory intercomparison of the mobility response of each ACIMS (Figure 1) showed reasonable agreement, and was used to correct data obtained in the field. 28 individual measurements were made on 17 days. Wind speed and direction were measured and used to estimate transit times from HVPL to measurement location.

Figure 2 shows DW against UW mobility for positive and negative ions, with mean values given in Table 1. Of 28 (negative) and 27 (positive) individual measurements, only 5 (negative) and 4 (positive) did not show an increased mobility DW compared to UW. Ion mobility for both polarities was higher DW than UW of high-voltage power lines by ~15%, implying that aerosol charging may occur faster, and reach higher peak levels, than if typical background mobilities are assumed. The ratio of negative/positive mobility was 1.32 UW and 1.27 DW. The mobilities reported here are higher than in some previous studies, possibly due to lower than expected airflow through the ACIMS. However, the relative response of the two devices (Figure 1) suggests that the DW/UW ratio was not affected.

Ion mobility is related (in a non-trivial manner) to ion mass and composition. Higher mobilities are often taken to imply that ions are newly-produced. However, most previous studies report that 'ageing' of ions is expected to terminate within a few seconds. In these measurements, transit times from the line to site ranged from 22−290 s, implying that the ageing process may take longer than previously thought, a finding also reported by Luts *et al* (2011), and/or that the components of the cluster are smaller at creation and remain so despite chemical ageing. However, measurements here on 8 days at more than one DW site show no significant difference between mean DW/UW mobility ratios at different transit times from the line. Thus, the present data suggests, but does not provide solid evidence for, further growth at ages > 20 s.

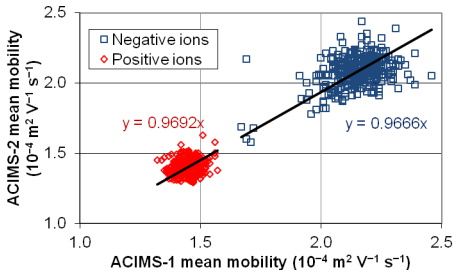

Figure 1. Results of laboratory intercomparison between two ACIMS for positive and negative ions.

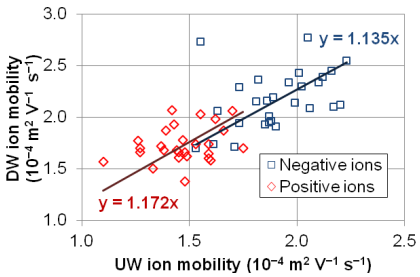

Figure 2. Scatterplot showing individual data for DW against UW mobility. DW=UW shown as dashed line.

Table 1. Mean mobilities DW/UW for each polarity

	Mobility (10^{-4} m^2 V^{-1} s^{-1})		Ratio
	UW	DW	(DW/UW)
Positive	1.47	1.73	1.18
Negative	1.90	2.17	1.14

Charging and collection of fine mists from a wet scrubber using activated oxidation catalysts

Bangwoo Han, Hak-Joon Kim and Yong-Jin Kim

Environmental and Energy Systems Research Division, Korea Institute of Machinery and Materials, Daejoen, 305-343, Korea
Keywords: Carbon fiber, Dielectric film, Electrostatic precipitator, Recovery
Presenting author email: bhan@kimm.re.kr

Wet scrubbers spraying fine water droplets into gas streams have been widely used to remove toxic or odorous gases in many industrial places such as food waste disposal facilities or semiconductor manufacturing factories. Fine white mists generated via the rapid condensation of humid air at the outlet of the wet scrubber can be one of main sources of civil appeals from the residents near the places. Therefore it needs to remove fine visible white mists generated at the chimney of the facilities or the factories. Recently, to improve the performance of the wet scrubbers, spraying water has been activated via electric oxidation catalysts (Chung et al., 2009). The electric activated scrubbing water contains acid solvents such as H_2SO_4 and a small amount of metal catalysts. The mists generated from the scrubbers which use these activated solutions need to be collected to minimize the toxic mist emission and restore valuable catalyst metals from the mists. In this study, a two stage non-metallic electrostatic precipitator (ESP) using a carbon fiber charger and a dielectric film collector has been investigated to charge and collect fine mists from the scrubber with the activated liquids containing a valuable metal catalyst. Carbon fiber charger was composed of 16 carbon fiber ionizers (Han et al., 2008) and dielectric film collector was made of parallel aluminum plates coated by polypropylene films (Kim et al., 2010). Scrubber was packed by a lot of 1 inch balls with a height of 1,200 mm and 40% H_2SO_4 aqueous solution with 0.1 M Co as a scrubbing liquid was sprayed. At the downstream of the scrubber the non-metallic ESP was located to remove fine mist particles generated from the scrubber. Mist size distributions were measured by a scanning mobility particle sizer (Model 3936, TSI) and an aerosol spectrometer (Model 1.109, Grimm) at the downstream of the ESP. High voltages of 4-8 kV were supplied to both the charger and collector of the ESP. Particle size and concentration were increased by about 4-10 times due to the sprayed mist droplets after turning scrubber on. Figure 1 shows the average charge number per particle obtained by the carbon fiber charger when the scrubber was operated on and off. The average charge number per particle was linearly increased with the applied voltage to the charger. After operating scrubber on, charge number per particles was increased by about 4 times compared to indoor particles without scrubbing water. It indicates that mist particles have larger sizes compared to indoor particles and can obtain a larger number of charges at the same particle charging condition. These charged mist particles can be easily collected at the dielectric film collector of our ESP system. Particle loss at the charger and collection efficiency at the collector of the ESP were measured for the various applied voltages at the charger and collector at the gas face velocity of 0.25 m/s. Particle loss was in the range of 5-20% at the applied voltage to the charger of 4-6 kV. Collection efficiency of the charger was increased from 92% to 95% by increasing applied voltage to the charger from 4 kV to 6 kV with an applied voltage to the collector of 4 kV. At the applied voltage to the charger of 4 kV, increase of applied voltage to the collector from 4 kV to 8 kV could improve the collection efficiency from 92% to 98%. At the applied voltage to the charger of 6 kV, it could improve the efficiency from 95% to 98.5%. Therefore, applied voltage of 4 kV at the charger seems to be much proper at the point of view of particle loss in the charger. In our further studies, pH variation at the second scrubber located after the ESP and the fraction of Co catalyst at the collector will be investigated to evaluate our system whether our system can properly remove harmful acid mists and collect valuable metal catalysts from the mists.

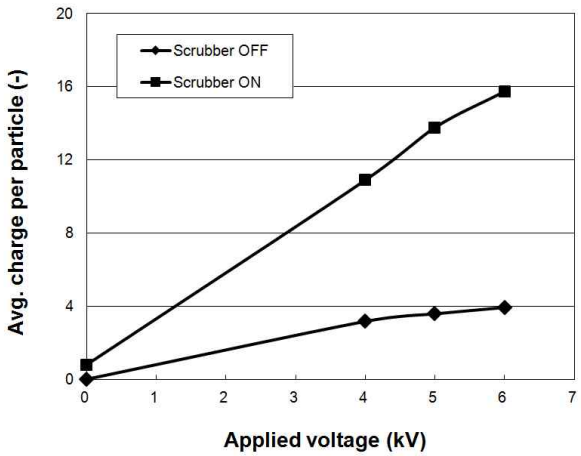

Figure 1. Comparison of average charge number per particle between the indoor particles with scrubber off and the mist particles with scrubber on.

Removal performance of an electrostatic precipitator with edge to plate geometry for particulates in combustion gases for marines

H.J. Kim, B. Han, G.B. Cho and Y.J. Kim

Department of Eco-Machinery System, Korea Institute of Machinery and Materials (KIMM), Daejeon, 171 Jangdong, Yuseong-gu, 305-343, Korea
Keywords: Marine, electrostatic precipitator, particulates, removal.
Presenting author email: diayolk@kimm.re.kr

Even though NO_x and SO_x have been already regulated by international maritime organization (IMO), PMs which are known to be a source of respiratory diseases have not been regulated. However, Due to strong regulation trend on PMs from other machineries such as on and off road combustion machineries such as vehicles, construction machineries, the PMs from marines will be regulated by IMO in the near future.

Generally, to remove particles from combustion engines for on and off load transportation and machinery, DPFs (Diesel Particulate matter Filter) are being widely used. However, the filters have a technical problem to be applied for high volumetric engines such as marines because of significant pressure drop.

In this study, for removal of particles from combustion used in marines, we applied an ESP (electrostatic precipitator) which was generally used for removal of particulates in high volumetric flow rates such as coal firing combustion, and manufacturing industries. Shown in Figure 1, the ESP was one field and two channel geometry with hammer type rappers. The ESP was evaluated with a 12 L diesel engine and a Bunker C boiler with an exhaust gas flow rate of 3000 m^3/hr, based on particle numbers. The concentration was measure by a SMPS (CPC 3076, Classifier 3081, TSI, US), combined with dilutors, and a high voltage power supply of Max. 80 kV/20 mA for negative polarity was used in this study.

Figure 2 shows the particle collection efficiency of the ESP against specific corona power for different combustion conditions. The collection efficiency showed a correlation with a specific corona power which was determined with applied voltage, current, temperature, and flow rate. Specially, with the specific corona power more than 10 W/m^3/min, the ESP achieved high collection efficiency over 80 %, based on number, regardless of types of combustion and temperature. This correlation could be used for a design of the ESP for larger scale of marine diesel engines and boilers. Figure 3 shows the long term PM collection performance of the ESP for different operation conditions such as exhaust flow rate, temperature, and rapping. The collection efficiency was calculated with the total number concentrations measured by a CPC (Model 3076, TSI, US), and it was approximately 95% with the specific corona power of 30 W/m^3/min. This performance was maintained even at high temperature, particle load and flow rate. In particular, during the continuous rapping of 5 min period over one hour, the collection performance was also maintained.

Figure 1. Experimental set-up for this study.

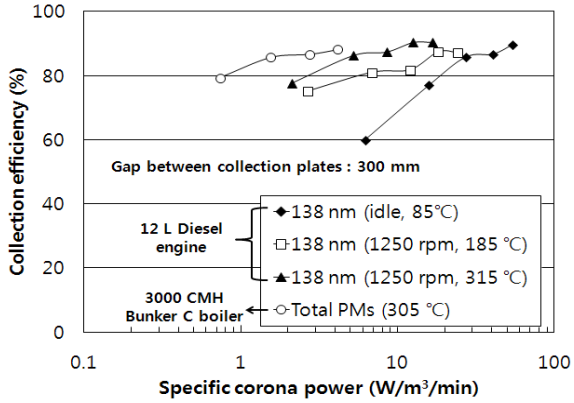

Figure 2. The variation in collection efficiency of the ESP plotted against specific corona power for different combustion conditions.

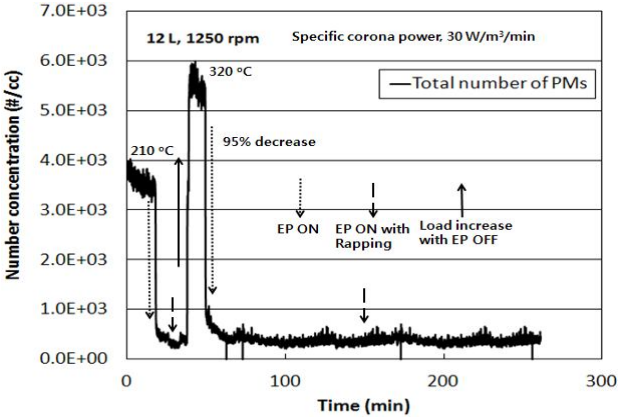

Figure 3. Long term PM collection performance of the ESP.

Enhancement of the filtration performance of metallic foam filter for diesel particulates by electrostatic charging and collection

H.J. Kim, B. Han, G.B. Cho and Y.J. Kim

Department of Eco-Machinery System, Korea Institute of Machinery and Materials (KIMM), Daejeon, 171 Jangdong, Yuseong-gu, 305-343, Korea
Keywords: metallic foam filter, electrostatic, charging, collection, diesel particulates.
Presenting author email: diayolk@kimm.re.kr

In order to decrease both diesel particulate matter (PM) mass and number in exhaust gas from diesel engines, the filtration system with the ceramic DPF (Diesel Particulate Filter) is being on commercialization for light and heavy duty diesel vehicles. Even if the wall flow type ceramic filters, which are coated with metal catalysts, have shown over 90 % filtration performance for the diesel PMs, the DPFs still have problems such as insufficient reliability, excessively high pressure drop at low exhaust temperature, and mechanical crack and failure. To decrease pressure drop and avoid the numerous problems related to DPF, metallic filters as an alternative were developed in Germany and South Korea. However, the filtration systems have shown lower efficiency than DPF especially for removal performance, based on PM number.

To increase particle removal performance of the metallic foam filter for a newly reinforced regulation, based on number of the PMs from diesel engines, a novel metallic foam filtration system assisted by electrostatic charging and collection has been developed. The system was evaluated by comparison with a standalone metallic foam filter and a commercialized DPF filter, using 3000 cc diesel engine with engine dynamo at steady-state engine operation conditions with constant rpms and loads, shown in Figure 1.

The cylindrical diesel PM filtration system in this study was consisted of a novel high voltage electrode which is used for charging particles and imposing electrostatic field to the metallic filter at the same time, and metallic foam filter. Figure 2 shows the curves of corona voltage against current at different temperatures. The curves for the system were moved to the left, and the corona current was higher for the same applied voltage, when the temperature increased. In particular, the sparkover was observed at lower applied voltages at higher temperature. However, the high electrical potential was maintained at the voltage and current up to 16 kV and 1.5 mA even at 300 ^{o}C, due to a special air slit insulation. Figure 3 shows the comparison of the particle collection and pressure drop performance of the filtration system in this study and DFP filter for particles ranged at a peak size of the PMs from the diesel engine, 50 nm. Even though the collection efficiency with only foam filter was 50 % which was much lower than that with the DPF, the pressure drop was significantly lower by a maximum of only 20 % of the DPF. In particular, with the filtration system combined with electrostatic precipitation device, the collection efficiency exceeded over 95% using 10 W/m^3/min, similar to that of DPF.

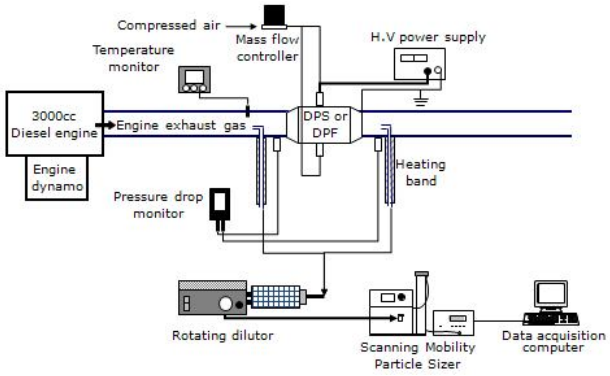

Figure 1. Experimental set-up for this study.

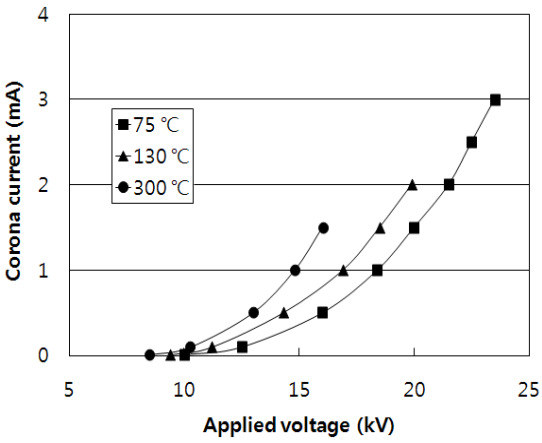

Figure 2. The changes in voltage to current curves plotted for different temperature of the diesel exhaust

Numerical simulations of electrosprays including induced gas flow

A.K. Arumugham[1], J. Grifoll[1] and J. Rosell-Llompart[1,2]

[1]Department of Chemical Engineering, Universitat Rovira i Virgili, Tarragona, Catalonia, E-43007, Spain
[2]Catalan Institution for Research and Advanced Studies (ICREA), Barcelona, Catalonia, E-08010, Spain
Keywords: electrospray, electric wind, numerical simulation, drag force.
Presenting author email: joan.rosell@urv.cat

When aerosol particles move collectively with a net velocity relative to the surrounding gas exert a drag force on the gas which can cause the gas to flow. In electrosprays, this gas motion is induced by the highly charged microdrops moving under the action of electrostatic forces, and can be significant. Because of the difficult experimental accessibility to gas velocity, there are only a handful of reports on this important question, however. In the systems studied by Gomez and Tang (1994) and by Hartman et al. (1999) the surrounding gas velocity was determined to be about 1/3 of the mean droplet axial velocity.

Numerical simulations of electrosprays thus far have neglected the gas flow (Grifoll and Rosell-Llompart, 2012, and works cited therein). In this contribution, we report on our recent efforts to simultaneously compute the droplet and gas motions in steady state. Correct computation of this effect is of paramount importance for the correct numerical simulation of electrosprays, and of multiplexed electrospray systems, and is a requirement in the modelling of droplet evaporation and vapor concentration in electrosprays.

Because the transport equations for each phase (gas and droplets) are coupled, steady state solutions are sought by an iteration procedure using two separate codes. Our droplet dynamics code is based on a 3D Lagrangian model that simplifies the far droplet-droplet electrostatic interactions without any significant loss in accuracy. This coarse-graining scheme, called Lumped Space Charge (LSC) approximation has been proposed recently (Grifoll and Rosell-Llompart, 2012). Our gas flow code seeks steady state solutions to the 2D cylindrical equations for flow vorticity and stream function, modified to include source terms associated to the spray drag. The spray drag force function (force/volume) is a smoothed approximation of the spray drag which is defined piecewise within each of the grid cells used by the flow code. We have assumed that all of the space within the spray is available to the gas, which is approximately valid so long as the volume fraction of the droplet phase is much smaller than unity.

The integration procedure proceeds iteratively as follows. Initially, quiescent gas (zero gas velocity) is assumed and the droplets trajectories are integrated using the LSC code until steady state is reached and about 0.1 seconds of real time data is available. Next, the droplet's velocity and position data are pooled-averaged to compute the corresponding drag force density field, and a steady state gas flow solution caused by this force field is determined. The vorticity and stream function values are then used to define the corresponding gas velocity field. This initial gas velocity solution is then fed to the particle dynamics code, and a new spray configuration is obtained to produce a second estimate for the drag function, from which a second steady gas flow is computed using the gas flow code. The procedure is repeated iteratively until a convergence criterion based on a small predefined difference between the solutions obtained in two consecutive iterations is satisfied.

This methodology is applied to recalculate our previously simulated sprays based on the experimental scenarios of Park et al (2004) comprising droplets of lognormally distributed diameters with count mean of 8.84 μm, and of Tang and Gomez (1994) for a bimodal spray with primary droplets count mean diameter of 32.5 μm. Our methodology can also be useful to simulate systems in which an external co-axial gas flow around the needle is present.

Hybrid QMOM-Orthogonal-Collocation Method: Application to Aerosol Dynamics under Coagulation

M. Arias-Zugasti

Departmento de Física Matemática y de Fluidos, UNED, Madrid, 28040, Spain
Keywords: Coagulation, Aerosol evolution, Aerosol fundamentals.
Presenting author email: maz@dfmf.uned.es

Spectral methods, as Orthogonal Collocation, are an extremely accurate and stable numerical tool for solving partial differential equations. However, this kind of numerical methods is restricted to cases where the dependent variables are very smooth functions. In many cases this condition limits the applicability of spectral methods in aerosol science (in particular in aerosol dynamics under coagulation). In the present work it is shown that a possible way of solving that difficulty is by using time-dependent mappings, based on the dynamics of the region of interest, defined as the region in state variables space where the distribution function is mainly located. This strategy relies on information on the dynamics of that region, which can be defined in terms of the moments of the aerosol's distribution function. Hence, the Quadrature Method of Moments (QMOM) (see McGraw 1997) seems the ideal tool to calculate the dynamics of the region of interest, since the information that this method provides is all that is needed to track the position and size of the region of interest and, on the other hand, QMOM is extremely efficient and its applicability range is extremely broad.

In the case of aerosol dynamics under coagulation, a difficulty that arises when time-dependent mappings are used to solve the General Dynamic Equation (GDE) is that, in general, the coagulation kernel in terms of the mapped variable depends explicitly on time. This difficulty appears as a consequence of the time-dependent mapping, even if the coagulation kernel in terms of the physical variable (e.g. particle size) does not depend on time. Thus, in order to solve the GDE in terms of the mapped variable one needs to re-calculate the integrals that define the coagulation term at every time step. In principle this is too expensive (time-consuming) task, which makes this strategy un-practical. However, this difficulty can be avoided solving the GDE using orthogonal collocation and computing the coagulation term by means of the Fast Algorithm (Arias-Zugasti 2006, 2012). As shown in Arias-Zugasti (2006, 2012), the use of the Fast Algorithm factors the dependence of the coagulation term on the spectral basis used on one hand, and on the coagulation kernel on the other hand. This solves the former numerical difficulty, since by means of the Fast Algorithm the orthogonal collocation expansion of the coagulation term can be computed as the product of the coagulation kernel evaluated at the collocation abscissae, times a set of N integrals that only depend on the spectral basis used (N is the number of functions used in the spectral basis), but not on the coagulation kernel. Since the spectral basis does not depend on time, these integrals can be pre-calculated, thus enabling the efficient evaluation of the coagulation term, even in cases of time-dependent kernels. The present method enables the numerical integration of the GDE from an arbitrary initial condition until the self-preserving size distribution function is reached.

This hybrid QMOM-orthogonal collocation strategy, enabled by the Fast Algorithm, is totally general. I.e., it is not restricted to: (*a*) any particular form of the coagulation kernel, (*b*) the spectral basis used, or (*c*) the conservation law that relates the state variables of the emerging particle to those of the colliding particles. This method has been successfully used in recent studies on the dynamics of Brownian coagulation in expanding gases (Rosner and Arias-Zugasti 2011), the coagulation induced by thermophoresis in the case of non-Brownian particles (Rosner and Arias-Zugasti 2011a) and the thermophoresis-modified coagulation of Brownian particles (Arias-Zugasti and Rosner 2011b, Rosner and Arias-Zugasti 2011c). It is also shown that this method can be extended to the case of multivariate distributions, regardless of the number of state variables and their conservation properties under coagulation. On the other hand, it is shown that the Fast Algorithm leads to the correct evolution equations of the moments of the distribution, which explains its accuracy and stability.

Photophoresis – the forgotten force

Helmuth Horvath

University of Vienna, Faculty of Physics, Aerosol.and Environmental Physics
Boltzmanngasse 5, 1090 Vienna, Austria
Presenting author email: Helmuth.Horvath@univie.ac.at

Particles illuminated by a beam of light having sufficient flux density can move in various directions under the influence of the light. Since light is the cause for the motion, the expression photophoresis has become common. Preining (1966) gives a concise description of the important factors influencing photophoretic motion: *"This motion can depend on the illumination, colour, structure and shape of the light beam, on pressure and composition of the gas, on the particles size, shape and material, and on additional fields such as electric, magnetic, and so on"*

The momentum transferred by photons hitting a particle and absorbed or deflected obviously exerts a force on a particle. Except for extremely intense radiation this direct photophoresis (radiation pressure) is of minor importance in aerosol science and can be neglected. The indirect photophoretic force, as treated below, is much stronger, but needs the presence of gas molecules which are always available in an aerosol.

On a microscopic scale, the gas molecules impact on the surface of an aerosol particle and are reflected. The reflection can be specular, diffuse, or with accommodation. For a particle moving through a gas, the molecules impacting at the front side are reflected with a higher velocity compared to the back side. This asymmetry in velocities leads to a momentum transferred to the particle and causes the friction force acting on the particles when moving through a gas.

Reflection of gas molecules at the particle's surface with accommodation is of special importance for photophoresis. A particle which absorbs (visible of IR) radiation is heated to a higher temperature T_p than the temperature T_g of the surrounding gas. A gas molecule hitting the particle's surface can acquire some of the thermal energy of the hot particle and be emitted with a velocity corresponding to a higher temperature, T, compared to the surrounding gas. The probability of taking up additional thermal energy is characterized by the accommodation coefficient $\alpha = (T - T_g)/T_p\text{-}T_g)$. With $\alpha = 0$ for no and $\alpha = 1$ for full accommodation. The value of α depends on both the material forming the particles as well as the surface structure.

If the accommodation coefficient of the surface of the particles is $\alpha > 0$ and the particle is heated by light, a photophoretic force can act on the particle. Two different possibilities have to be distinguished:

(a) Constant accommodation coefficient but variation in surface temperature. This e.g. occurs for an illuminated light absorbing particle. The surface of the particles is warmer than the backside; molecules at the side facing the radiation source leave the surface faster, resulting in a force away from the light source (positive photophoresis). For a slightly absorbing particle the maximum absorption may be at the backside, resulting in a motion towards the light source (negative photophoresis). The direction of the photophoretic force is determined by the direction of the radiation and is almost independent on the orientation of the particle.

(b) Variable accommodation coefficient on the surface but constant temperature. At the location of higher accommodation coefficient the molecules are reflected with a higher velocity resulting in a thrust on the particle similar to the jet of an airplane. The direction of the force on the particle is determined by the orientation of the particle and independent on the direction of the illumination (body fixed force). Upon change of the orientation of the particle the direction of the force changes likewise. Since all particles perform Brownian rotation, the net force is zero. If an orientating torque acts on the particle, the photophoretic force will predominantly be in one direction, thus the average photophoretic force will be nonzero. The orientation can be due to inhomogeneous distribution of the mass on the particle in the gravitational field, or magnetic or electric dipoles in the corresponding field.

(c) Obviously a combination of (a) and (b) is possible.

The photophoretic force depends on many factors: Flux density of radiation, particle size and optical properties, mean free path of the gas molecules, gas pressure, thermal conductivity of gas and particle, temperature of gas and particle, asymmetry of the particle, strength of external fields. Generally the photophoretic force reaches a maximum value for particle sizes comparable to the mean free path of the gas molecules. Despite these many influencing factors, a theory of photophoresis could be developed (Rohatschek 1955, 1995).

Positive photophoresis can be used as a tool for on line separation of absorbing and non absorbing particles. Particles are illuminated by an intense laser (808 nm), obtain a velocity into the direction of the light and perpendicular to the flow velocity due to the photophoretic force and can be collected in a secondary

flow (Haisch *et al*. 2008). Also photophoretic particle trapping and levitation is possible.

In the stratosphere and mesosphere the air molecule's mean free path is between 1 and 100µm due to the lower pressure thus photophoresis can occur for all particles found there. Since an irregular particle or one with a magnetic moment has a preferred orientation in the gravitational or magnetic field, gravito- of magneto-photophoresis are important. This has been proven experimentally (Jovanovic 2005). The existence of layers of particles in the stratosphere and mesosphere can be explained by photophoresis, as well as the transport of soot particles in the atmosphere (Cheremisin *et al*., 2005, 2011, Pueschel *et al*. 2000).

Photophoresis is an important force involved in planet formation. In a gas rich, optically thin circumstellar disk the motion of particles ranging from 1 µm to 10 cm will be dominated by photophoresis, moving the particles opposite to gravity to a distance from the star, where the gas density reaches a value at which photophoresis equals all other forces at work. Thus the formation of ring like structures of dust distribution around a star can naturally be explained (Krauss and Wurm, 2005) and the formation of protoplanets is significantly influenced by photophoresis (Wurm and Krauss, 2006).

For fighting global warming by geo-engineering, particles should be positioned in the stratosphere or mesosphere, which reflect sunlight and remain suspended as long as possible. The photophoretic force can be very helpful, since a long residence time can be achieved this way. A particle optimized for this purpose can be a 10 µm disk with a layer of Al_2O_2 at the top, Al in the middle and $BaTiO_3$ at the bottom with a micro-magnet attached to it (Keith 2010).

For completeness it is mentioned, that the term photophoresis is also used for motion of hydrocolloids illuminated by a laser beam. In that case actually it is the radiation force, which makes the particle migrate (Helmbrecht *et al*. 2007).

Session SS03S1O. Source apportionment

PMF vs CMB for source apportionment of PM: advantages, limitations, complementarity of the two models explored by applications at different types of environments

Compliance with the tougher regulations of ambient particulate matter (PM) in the European Union will require detailed and quantitative information about the sources of PM. Such information can be provided by source apportionment studies based on determination of the chemical composition of PM and application of receptor models (RM). These RM can be applied to on-line measurements or off-line PM sampling. Off-line PM sampling is developing largely because of the ease of implementation, especially by air quality networks throughout Europe. From the off-line chemical characterization of PM, different RM have been proposed in the literature (see review of Viana *et al.*, 2008), including the Molecular Marker - Chemical Mass Balance (MM-CMB) and multivariate statistical models, e.g. Positive Matrix Factorization (PMF).

MM-CMB is commonly based on the organic speciation of PM while PMF is typically applied to major components, metals and traces elements. Given differences between the two models (mass balance or statistical analysis) and the chemical speciation used, identified sources and estimated contributions may be different and intercomparisons of these two models are necessary. Just a few of these intercomparisons have been published so far (Ke *et al.*, 2008 ; Shrivastava *et al.*, 2007). In this work, the two models were applied on the same set of PM10 samples collected in various types of environments and seasons, representing various sources and chemical composition of PM: urban background, urban kerbside, rural and alpine valley sites in France and in Switzerland.

Results obtained in the urban background site of Zurich (Switzerland) and in the rural site of Payerne (Switzerland) for the estimation of PM10 show a reasonable agreement between the two models (Fig. 1) particularly in winter and confirm the estimated contributions. Differences are observed in summer for vehicular emissions due probably to an underestimation of this source by CMB (organic tracers of this source are lower than limits of detection in this season). Estimations of secondary inorganic (sulphates and nitrates) and organic aerosols (SOA) are almost equivalent despite the method of estimation: in MM-CMB they are indirectly estimated while in PMF they represent some individual factors (containing inorganics and SOA in same factors).

The presentation will also cover comparisons of the estimation of OC and EC in various types of environments. From these comparisons, MM-CMB seems to be more adapted to primary organic sources and source apportionment of OC. PMF allows estimation of a greater number of inorganic sources but by reconstructing the total mass of PM it can overestimate the fraction of each source. All this will be discussed in the presentation focusing on the complementarity of the two models.

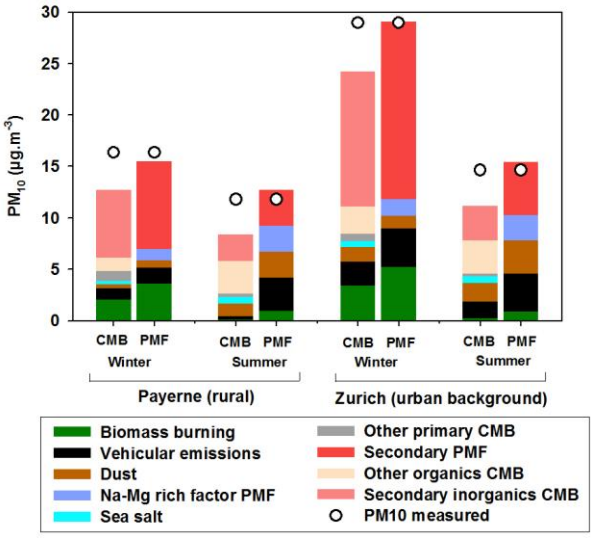

Figure 1. Contributions to PM10 estimated by PMF and MM-CMB in Zurich and Payerne.

C. Piot and L. Polo thank the Région Rhône-Alpes for their PhD grant. The activities at the Swiss sites were supported by the CCES- IMBALANCE and by the Swiss FOEN. Campaigns in France were supported by the MOCOPO program funded by the French Ministry in charge of Transport or studies of AASQA, and several activities were funded by ADEME.

The identification of sources is one of the prerequisites for the implementation of the Air Quality Directive (AQD). It provides scientific support to the development and periodic revision of air quality plans and short term action plans and to the quantification of categories with special status like long range transport, natural sources and winter road salting and sanding.

The suitability of receptor models (RM) for the apportionment of pollutant sources in the implementation of the AQD is testified by the amount of published studies in 2005 and 2010 in correspondence with the entry into force of new provisions for PM10 and PM2,5, respectively.

In recent years, Member States were requested to provide official estimations of source contribution to the Commission like the quantification of natural sources in 2006 and PM_{10} time extension reports in 2009 (Fragkou et al., 2011). These experiences have shown that although this kind of methodology is used by about 60% of the European experts involved in source apportionment there is a considerable variability in the methodological approaches and adopted tools. Furthermore, there are critical steps that require strict quality assurance standards and skilled practitioners (e.g. identification of the appropriate number of sources).

In order to foster harmonization in this field, the JRC has promoted a number of interconnected initiatives linked to FAIRMODE. One of those was to set up a group of experts with skills in different areas to assess RM methodologies and propose common criteria and procedures for source apportionment studies. The information collected was summarized in a document which is intended to serve as a basis for a common Receptor Model Technical Protocol (RMTP).

The RMTP is addressed to different kinds of users: Policy makers and managers interested in the output of RMs for development of mitigation measures, air quality experts and scientists unfamiliar with these techniques, and RM practitioners involved in the model execution and interpretation of results.

In order to address such heterogeneous readership the document was designed to be accessible at different levels. The RMTP is organized in three sections:

- an introduction to present the methodology to the unskilled reader, illustrating its capabilities and recommending when and how to use it.
- a core section concerning the most common RM methodologies for source apportionment with in-depth analysis boxes for more experienced readers. The section is structured in 13 chapters following, as a check list, the logical steps to accomplish a source apportionment study. The first chapters deal with preliminary activities like the evaluation of the study area, collection of existing information and experimental design. In the following chapters data collection and data treatment are discussed. The section includes also chapters regarding specific aspects of widely used methodologies like CMB, Factor Analysis, and PMF. The evaluation of test performance and reporting are discussed in the last part of this section.
- the third section of the document was conceived to give an insight on the capabilities and the possible future trends in RM methodology. It consists of four chapters dealing with advanced, innovative techniques for which ready- to-use tools are already available or under development: trajectory analysis combined with RM, constrained and expanded models, AMS data processing, and the aethalometer model.

The document includes a number of annexes to provide additional and practical information on specific topics, and examples.

Application of PMF to the Source Apportionment of Polycyclic Aromatic Hydrocarbons

Roy M. Harrison[1,2], Eunhwa Jang[1] and Mohamed S. Alam[1]

Presenting author email: r.m.harrison@bham.ac.uk

The fact that polycyclic aromatic hydrocarbons comprise a large number of individual compounds emitted in different proportions by their various sources offers many opportunities for application of source apportionment methods. Historically, source apportionment of PAH has generally been based upon the use of diagnostic ratios but recent reports, e.g. Galarneau (2008), have cast doubt on this approach. Problems include the frequently large number of contributory sources and the very significant chemical reactivity of some PAH. Nonetheless, application of Principal Component Analysis has yielded valuable insights into the major sources of PAH in urban air (Harrison et al., 1996; Mari et al., 2010).

Positive Matrix Factorisation (PMF) is generally recognised to be a more powerful technique than PCA as it uses weighting and is constrained not to produce negative factors. For this reason, PMF has been applied to several large databases of PAH concentrations measured in the United Kingdom and has yielded valuable outcomes which challenge the conclusion of Katsoyiannis et al. (2011) that "atmospheric sources of PAH in the UK are probably not dominated by any single clear and strong source type, so the mixture of PAHs in air is quickly 'blended' away from the influence of the few major point sources which exist and further weathered in the environment by atmospheric reactions and selective loss processes.".

An example of the results shown in Figure 1 is a factor enriched in benzo(b)naph(2,1-d)thiophene whose abundance declined rapidly after 2004 coincident with the reduction in the sulphur content of motor fuels. This factor is associated with diesel vehicle emissions whose profile has changed as a result of the changing fuel composition.

Other identified sources include wood combustion, gasoline vehicles and steel industry emissions, and further refinements to the methods may yield additional insights.

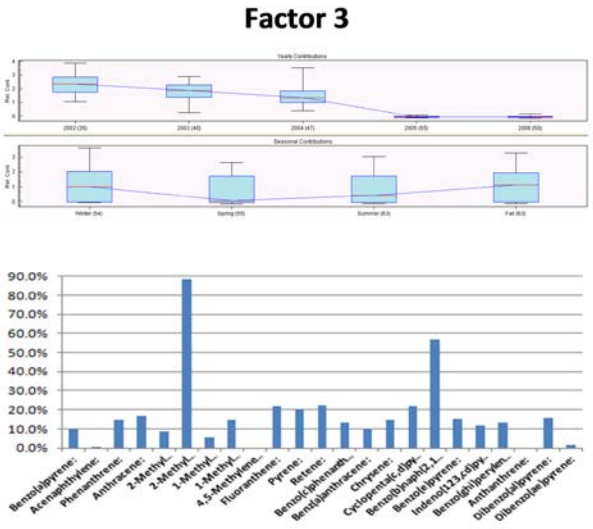

Figure 1. Factor profile and temporal variation in a factor related to diesel emissions.

To develop effective mitigation strategies to reduce concentrations of particulate matter its origin needs to be established. To identify and apportion observed PM concentrations to source categories, a statistical receptor model (Positive Matrix Factorization (PMF)) is often applied to comprehensive experimental data sets. Although this technique provides general categories, it cannot cope with non-linear components. A complementary detailed source attribution study with a chemistry transport model (CTM) is therefore recommended to gain further insight in the origin of PM.

For the CTM LOTOS-EUROS a new module was developed that tracks the origin of primary as well as secondary aerosol components in each modeled process. The source apportionment module was validated with dedicated simulations. It enables to quantify the source contributions of a set of sources at a computational effort of 20% compared to performing a "source off/on" scenario based assessment. Moreover, the module is mass conserving and provides the source attribution under one chemical regime, which is not the case for a source apportionment based on scenario simulations.

The new module was used to establish the source attribution of PM10 and PM2.5 in the Netherlands at a SNAP 1 level, distinguishing between national and foreign sources, for the period 2007-2009. Based on modelled PM, 70-80% of PM_{10} and 80-95% of $PM_{2.5}$ in the Netherlands is estimated to be man-made. About 1/3 of anthropogenic PM_{10} is of Dutch origin and 2/3 originates in foreign countries. For $PM_{2.5}$, a Dutch share of 30% was found. These figures change with location, with highest domestic contributions in the densely populated western part of the country. During peak episodes, natural sources are less important than under normal conditions, whereas especially emissions from road transport and agriculture become more important.

To evaluate the quality of the source apportionment the model results were compared to mass concentration measurements throughout Europe. To gain further insight in the quality of the source apportionment a study was set up to compare the model results to those obtained by PMF. Experimental data sets on PM_{10} and $PM_{2.5}$ from the Netherlands, Belgium and Germany were collected and a combined PMF analysis was performed for 23 sites. The analysis resulted in a 7 factor solution. Three of these factors were identified as industrial process emissions, fossil fuel combustion in general and heavy oil combustion. The latter is indicated by V/Ni tracers (Fig. 1). To compare the model results to the PMF a new LOTOS-EUROS simulation was performed that discriminates between major fuel types. Emissions from industrial process emissions as well as agriculture are classified as unknown. The model results enable a large number of analyses, such as assessing the source contributions as function of modelled PM10 mass concentration (Fig. 2) and its components.

Comparison of the model and PMF results are on-going and will be presented. Besides using the PMF factors special attention is given to tracer concentrations for different sources. First results indicate that modelled international shipping contributions are too high. Anthropogenic sodium contributions are low on average, but both the model and the PMF analysis indicate higher non-marine sodium contributions in the Ruhr area and during days with high PM10 concentrations.

Multilinear engine 2 applied to long-term on-line data of non-refractory submicron aerosol in the city of Zurich

F. Canonaco[a], J. Slowik[a], U. Baltensperger[a], A.S.H. Prévôt[a]

[a]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: AMS, PMF, ME2, ACSM
Presenting author email: francesco.canonaco@psi.ch

The role of aerosols in the atmosphere is of pivotal importance, because they affect climate (Forster *et al.*, 2007), human health (Peng *et al.*, 2005), ecosystems, e.g., acidification (Matson *et al.*, 2002), and visibility (Watson, 2002). These effects are controlled by particle concentration, composition, and size, which are in turn governed by sources and formation processes. Thus, the identification and quantification of formation mechanisms and sources is of high priority. However, this task is complicated due to the complexity of particle composition.

Long-term monitoring of aerosol composition provides a powerful tool for the analysis of the effects described above. This approach enables elucidation of the seasonal variability of different aerosol constituents, which is not possible with shorter-term campaigns. Long-term measurement records also allow for evaluation of emissions control strategies. Furthermore, long-range, mesoscale, and local air quality models can be improved through comparison with long-term datasets. Finally, the existence of long-term sampling records at a given site provides a framework for the interpretation of datasets from short-term intensive measurement campaigns.

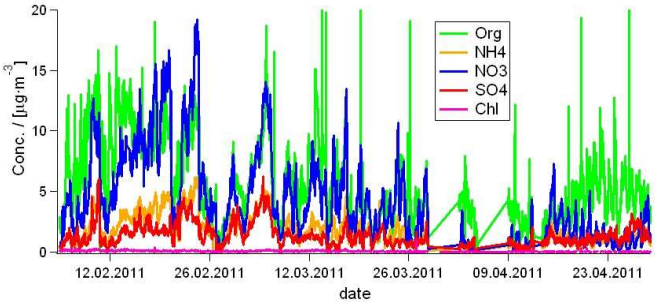

Figure 1. Preliminary time series of the ACSM including SO_4, NO_3, NH_4, Cl and organics. For the sake of simplicity the figure comprises only the winter data.

We present measurements of submicron aerosol composition from an aerosol chemical speciation monitor (ACSM, Aerodyne Research, Inc.) deployed in downtown Zurich. The ACSM yields quantitative mass spectra of the non-refractory aerosol component with an averaging period of 15 minutes. These are the first full year measurements in Europe using this technique. As shown in Fig. 1, the ACSM is capable of resolving inorganic species such as NH_4, SO_4, NO_3, Cl, and the organic fraction. The data can be further deconvolved in order to identify and apportion the inorganic and organic fraction to important sources and processes.

There are several possible techniques for the deconvolution of a data set. In particular positive matrix factorization (PMF) is extensively used for this purpose. However, the multilinear engine 2 (ME2) comprises more advantages compared to PMF. The user has the possibility to run ME2 in the normal PMF algorithm allowing the engine to model the factor solutions or imply constraints on single parts of the factors or to the factors themselves (Paatero, 1999). The use of constraints is justified in many cases, e.g., if the source contributions are known in advance or if an unconstrained model does not lead to plausible ambient results at all.

Therefore, the aim of this work is to exploit the multiple advantages of ME2 on a large dataset, in particular on the obtained data from downtown Zurich during the full year 2011. For this purpose we implemented a user-friendly interface in the software IGOR wavematrics which might be shared in the next future with other environmental science groups.

During the winter period, PMF did not succeed in resolving the factors probably caused by the high correlation of various components due to the prevailing meteorology, similar to Lanz et al. (2008). ME2 was therefore effectively applied on the full winter period, i.e., between January and April using different constraining techniques.

We will discuss identification and source apportionment of AMS and ME2 data at an urban site over the full year of 2011. Aerosol composition and source apportionment will be used to investigate the seasonal variability of specific emission sources and processes in the city of Zurich.

Aging fingerprints on the carbon functional groups in 2-stroke scooter exhaust particles with STXM/NEXAFS

The physical state and the microstructure of individual particles with a typical, complex chemical composition is an important issue in assessing the significance of aerosols. It has been shown that oxidative degradation of reactive organic compounds may be controlled by the morphology of the particles they are contained in. Despite of its scientific relevance, the number of studies relating aerosol morphology and microstructure from an individual perspective with atmospheric physicochemical processes is still scarce. The light scattering and absorption properties of internally mixed and possibly mixed phase aerosol particles strongly depend on their phase state and their microstructure (Zhang *et al.*, 2008).

Recent results suggest that the emissions of organic compounds from scooters are much higher than from other vehicles (Chirico, 2008). In addition, secondary organic aerosol (SOA) from 2-stroke scooters can be distinguished by aerosol mass spectrometry from that of diesel vehicles, wood burning or alpha-pinene oxidations products (Heringa *et al.,* 2011). These findings prompt the scientific motivation to study in detail the microstructural changes associated to the photooxidation processes of scooter emissions. Thus, the present study seeks the identification of distinctive changes to the carbon functional groups in individual particles from 2-stroke scooter experiments at the PSI mobile smog chamber at different degrees of aging.

The aging experiments were performed in the new mobile smogchamber of the PSI Laboratory of Atmospheric Chemistry under UV-light. Samples collected at different stages during an experiment were analyzed offline using scanning transmission X-ray microscopy (STXM) and near edge X-ray absorption fine structure spectroscopy (NEXAFS), which allow the retrieval of spatially resolved information about carbon functional group composition and the O/C ratio (Vernooij *et al*., 2009). Particle samples were collected by inertial impaction on silicon nitride membrane windows on Si wafers. The wafers were mounted into the standard sample holder fitting into the STXM at the PolLux beamline at SLS. Images and NEXAFS spectra were taken at the carbon and oxygen K-edges in the energy ranges 280 – 320 eV and 520 – 560 eV, respectively.

The carbon K-edge spectra for the 2-stroke scooter exhaust particles before and after photooxidation exhibited clear changes. The main distinguishing features are found at the peak energies of the C 1 s→π* transitions of aromatic (285.2 eV), phenolic or ketone carbon (286.7 eV), the carboxylic carbon (288.3 eV), and the aliphatic and/or aromatic carbon (292 eV). The aromatic fraction was predominant in the structure of the recently formed particles. As the particles were processed, there was a pronounced decrease in the aromatic fraction and a corresponding gradual increase in the phenolic and carboxylic groups. Particles within 1-2 hours of photooxidation showed significant particle to particle variation, representing a variety of stages between the unprocessed and heavily processed spectra. However, the changes in the particle internal structure were homogeneously developed and no coatings were found. Similar spectral changes, but to a much lesser extent, were observed in a previous study with wood burning and diesel vehicle exhaust (Zelenay *et al*., 2011).

Considering the different thermal behaviour of wood-burning and diesel emissions for ^{14}C-based source apportionment of elemental carbon

S. Szidat[1,2], Y.L. Zhang[1,2,3], G. Ciobanu[3], P. Zotter[3], N. Perron[3,4], M.C. Minguillón[3,5], L. Wacker[6], U. Baltensperger[3], and A.S.H. Prévôt[3]

Keywords: Source apportionment, ^{14}C, carbonaceous particles, elemental carbon, wood combustion
Presenting author email: szidat@iac.unibe.ch

Radiocarbon (^{14}C) analysis is a powerful tool to help apportion the sources of carbonaceous aerosols (Szidat *et al*, 2006), due to its ability to differentiate between contemporary and fossil emissions. Since elemental carbon (EC) and organic carbon (OC) may have different origins, source apportionment of both fractions separately (as opposed to only total carbon, TC) provides additional valuable information. However, this strategy requires complete chemical separation of OC and EC, which cannot be achieved for ambient samples due to the indeterminate transition between both fractions (Minguillón *et al*, 2011).

We present an optimized procedure for the isolation of OC and EC for ^{14}C analysis conducted with a commercial thermo-optical OC/EC analyser. In particular, we show how different conditions of temperatures and carrier gases influence the separation of OC and EC and the ^{14}C results of the removed carbon fractions. An optimized thermo-optical protocol (Swiss_4S) with four steps was developed to isolate only the carbon fractions of interest (i.e. OC and EC) with minimized biases from charring and premature EC oxidation. For the isolation of EC for ^{14}C analysis, the thermal treatment is applied to water-extracted filters, as this substantially reduces charring by removal of water-soluble organic and inorganic compounds. For monitoring positive and negative biases of EC, the laser transmission signal of the OC/EC analyser is used.

The Swiss_4S protocol involves these consecutive four steps:

1. Combustion in pure O_2 at lower temperature for separation of OC for untreated filters and water-insoluble OC (WINSOC) for water-extracted filters without any premature EC evolution
2. Combustion in O_2 at intermediate temperatures
3. Further heating in helium; steps 2 and 3 yield mixtures of refractory WINSOC and non-refractory EC aiming at complete OC removal before step 4
4. Complete oxidation of the remaining refractory EC in O_2

In addition, water-soluble OC (WSOC) is determined by subtraction of the water-soluble fraction of TC from complete TC.

Optimum temperatures and durations were investigated for all steps in order to confine the reaction for OC within steps 1-3 and for EC within steps 2-4. This was possible with maximum EC recoveries for step 4 of 70-85%. Although the ^{14}C analysis of CO_2 from step 4 already gives a good indication of EC sources, it cannot provide the full information of all emissions. As wood-burning EC tends to be less refractory than diesel EC, ^{14}C analysis of step 4 alone may underestimate the wood-burning contribution. Additional ^{14}C analyses of step 1 (WINSOC) and steps 2+3 (mixture of refractory WINSOC and non-refractory EC) eliminate this bias and allow a full source apportionment of EC.

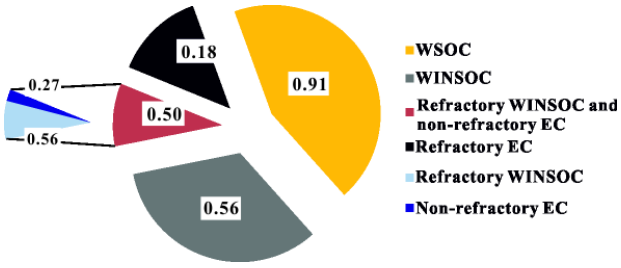

Figure 1. Composition of different carbon fractions of the carbonaceous aerosol (pies) and their ^{14}C signature (numbers) based on the Swiss_4S separation protocol for a typical winter sample.

Figure 1 presents an example of this approach. Whereas the refractory EC from step 4 reveals a more fossil ^{14}C signature (fraction of modern, f_M, ranging from 0 for fossil to ~1.1 for non-fossil emissions; Szidat *et al*, 2006), the less-refractory fraction of EC shows a substantially larger contribution from wood burning. For this sample, the f_M value for the total EC is determined to be 0.23 from isotope-mass balancing. Consequently, the analysis of step 4 alone would underestimate the wood-burning contribution by ~20% so that the more comprehensive approach presented here is required for correct ^{14}C source apportionment.

Keywords: Positive Matrix Factorization, gross errors, data errors
Presenting author email: hopkepk@clarkson.edu

Gross data errors may seriously distort the results of source apportionments based on speciated particulate measurements. The worst effects are due to data where a very small value (zero or practically zero) and a very low uncertainty estimate are mistakenly reported for one or several measurements.

Visual screening of such errors by the user is not practical. Both the time and the training for such work are missing. Also, the so-called *Robust Mode* in program PMF often fails, especially with points where an unrealistically small uncertainty was specified.

High-leverage values

The mathematical concept of *Leverage* (L) indicates how powerful any data value is in commanding the fitted value to be close to itself. If L=100%, then the fitted value cannot deviate from the measurement. In contrast, L=0% means that the measured value has no effect at all on the fitted value.

Figure 1 illustrates a least squares fit of a straight line to five points, two of them having high leverage.

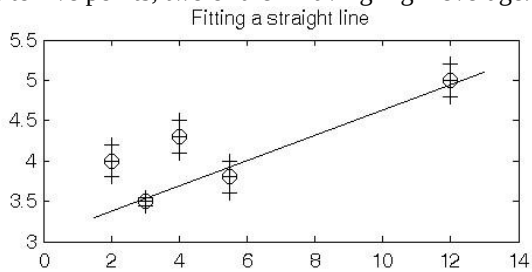

Figure 1. Least-squares fit to a line illustrating points with high leverage.

The second point has very small uncertainty (short error bar). Its power overrides that of its neighbors. The last point has a "long lever" for forcing the fitted line. Both points have almost L=100%. In practice, points 2 and 5 control the position of this least squares line.

A high-leverage value has excessive influence on the outcome of any factor analysis (FA). Omitting or accepting one such point may significantly change the results. The whole idea of source apportionment is to determine the normal or repetitive patterns of particulate matter (PM) concentrations. High-leverage points contradict this idea. Thus, it is advantageous to source apportionments to eliminate high-leverage values from the data matrix.

The following is a simplification of an algorithm that has been successfully used against high-L points. First, run PMF in the customary way. Then compute L values for all data points in the matrix. Identify all matrix elements whose L values exceed a chosen limit, e.g. L>25%. Downweight all these high-L elements by a large coefficient, e.g. by 100. Finally, rerun PMF.

Edge outliers

Figure 2 illustrates real data from PM measurements. One point is on the wrong side of the invisible "fence" or *Edge*. This *Edge Outlier* point may be caused by a gross error in SO_4 (too large value) or in NH_4 (too small value). Alternatively, it might also be caused by a transient or local source of acidic SO_4

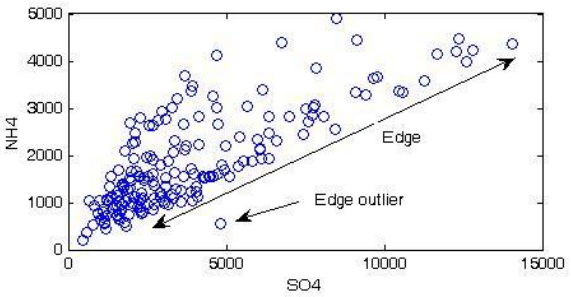

Figure 2. Plot of ammonium and sulphate ion concentrations illustrating an edge outlier.

Clean edges, without outliers, are valuable for determining a realistic rotation of the computed factors. Edge outliers often force the PMF model to a wrong, unrealistic rotation, preventing identification and evaluation of sources. Thus, one wishes to eliminate edge outliers, even if their causes remain unknown.

In this work, an algorithm is developed for automatic detection and downweighting of edge outliers.

Avoiding false rejection of good values

On rare occasions, good matrix elements may have high leverage. This effect may occur when some values have been measured by an enhanced technique so that uncertainties of such values are exceptionally low. The investigators must be aware of such special conditions. They have the option to declare some data "untouchable" by the high-leverage algorithm.

Unusual natural conditions may create a "good" edge outlier. This would happen if a source is always active, except during a rare interruption. For the traffic source, such an interruption might be caused by heavy snowfall, so that all roads are blocked by the snow. Good data corresponding to such special conditions should be declared untouchable by the edge outlier algorithm.

Practical results

In this talk, examples will be shown for real data where the two types of errors have been identified and eliminated.

Detailed chemical characterization of PM and COV, and source apportionment near a French highway

L. Polo[1, 3], C. Piot[1, 2], A. Charron[3], J. Cozic[1], B. Temime-Roussel[4], N. Marchand[4], J.L. Besombes[2] and J.L. Jaffrezo[1]

Contact email: polo@lgge.obs.ujf-grenoble.fr

The relation between exposure to ambient fine particulate matter (PM) and human mortality is now well established, particularly in the roadway proximity. Further, Hoffman et al (2009) showed the link between long-term residential exposure to high level of PM and coronary atherosclerosis. Improving air quality for reducing morbidity and premature death has become an urgent need. In spite of the evolution of vehicle motorization, the PM_{10} level has not been decreasing proportionnally in urban environments during the last decade (Harrison, 2008). The characterization and quantification of traffic emissions are still poorly known for the French motor vehicle fleet. These emissions involved exhaust and non-exhaust emissions (i.e. road-traffic like re-suspension of road dusts, from brake, tyre and road-surface-wear, from the corrosion of vehicle components…). The PM_{10} emissions related to traffic can represent up to 60% non-exhaust emission (Bukowiecki, 2010). A detailed chemical characterization of exhaust and non-exhaust traffic related emissions is still needed.

In order to characterize the chemical composition of traffic sources, detailed measurements were performed in the vicinity a suburban highway characterized by regular traffic congestions in Grenoble-Echirolles (France). Measurements were simultaneously conducted at an urban background site (Grenoble-Les Frênes), 2.5km away. This two weeks campaign took place in September 2011 within the MOCOPO and PM-Drive programs. PM_{10} and Volatile Organic Compounds (VOCs) were sampled on a 4h basis at the two different locations. In addition, high time resolved measurements (HR-ToF-AMS, PTR-ToF-MS, MAAP, SMPS…) were performed at Grenoble-Echirolles. At the same time, the traffic on the highway was recorded with a high temporal resolution (loops and systems allowing vehicles identification).

HR-Tof-AMS has been used to measure the concentration and chemical composition of the non-refractory submicron aerosol. Figure 1 presents the temporal evolution of two well-known fragments derived from AMS measurements: mz 57 (mostly $C_4H_9^+$) and m/z 44 (mostly CO_2^+), considered as markers of HOA associated with fuel derivatives emissions and OOA associated with secondary organic aerosol respectively. The mz 57 fragment follows clear daily cycles highly correlated with traffic and BC (MAAP). The evolution of mz 44 is completely different, and is well related with that of ions from secondary origins like sulfate, nitrate, and ammonium. A strong link also exists with the weather pattern during this two-week campaign. These first results allow already a distinction between the traffic emissions and others sources, which is a good foundation for this study.

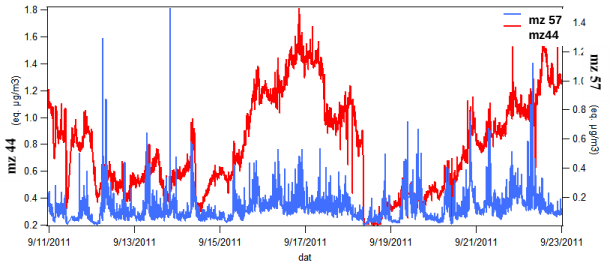

Figure 1: Temporal evolution of the fraction m/z 57 and m/z 44 at Echirolles (France)

Off-line sampling allows the detailed chemical characterization of aerosols notably the organic speciation with the aim of research of source tracers and determination of chemical fingerprints of large chemical families (hydrocarbons, PAH, saccharides…). About eighty compounds have been quantified. Further, a large array of trace metals was also measured on these filters. From these results, both the Chemical Mass Balance (CMB) and Positive Matrix Factorization (PMF) models will be used in order to apportion the contribution of influential sources including non-exhaust traffic emissions. These results will be presented and compared with on-line data and with traffic.

L. Polo and C. Piot thank the Rhône-Alpes Region for their PhD grants. Campaigns in France were supported by the French Ministry in charge of Transport (MOCOPO program) and by the French Environmental agency ADEME (PM-DRIVE program).

Soot aerosol – hard nuts to crack for an analyst

R. Niessner

[1]Institute of Hydrochemistry, Chair of Analytical Chemistry, Technical University of Munich, Marchioninistrasse 17, D-81377 München, Germany
Keywords: soot, chemistry, electrical conductivity, health effect, morphology, reactivity
Presenting author email: reinhard.niessner@ch.tum.de

Soot is emitted from many sources all around the world. There is common consensus about the harmfulness of ambient or occupational soot exposure. Ca. 30 % mass of aerosol sampled in urban areas is consisting of soot. The role of soot aerosol on radiation budget, thus influencing climate forcing, is heavily discussed among climate scientists.

But what is "soot"? Are there special properties with soot particles, which are unique, and can be used for proper identification, characterisation, and quantification? So far, there does not even exist a reference material for soot, not to mention a procedure to generate such soot aerosol in a representative way for mimicking where it comes from: incomplete combustion.

Obviously, one has to consider the situation where soot is an actor. In the presentation different features of soot are discussed:

- *cardiovascular health effect*: results of experiments with a still beating heart perfused by blood serum enriched with flame-derived soot, in comparison to other nano-engineered materials, are shown.
- *carbon particle morphology*: high resolution TEM measurements show the individual types of soot, ranging from completely mixed to well ordered nano-crystallinity, depending on history of formation.
- *electrical conductivity* of soot is the latest soot sensor priciple. Conductivity is dependent on nano-crystallinity and twinned metal oxides attached.
- *photoelectron emission* under X-ray stimulation. ESCA spectra reveal distinct differences among different soot types because of surface chemistry.
- *photon absorption* can be probed threefold: the subsequent heating up of individual carbon particles can lead to photon emission (*laser-induced incandescence*), may causes subsequent optoacoustic effects (*photoacoustic soot sensor*), or undergo photophoretic movement (*thermo-photophoretic velocimetry*).
- *chemical reactivity*: is very important for current and future diesel exhaust aftertreatment. *Thermally programmed oxidation (TPO)* reveals a huge span among various types of soot – from completely inert graphite up to highly reactive spark discharge soot. Again, the degree of nano-crystallinity governs the scene: best probed by *Multi-wavelength Raman microspectroscopy.*

Organic Emissions from Modern Small Scale Wood Combustion Appliances – Chemical Characterization and Toxic Potential of Fine Particulate Matter

J. Orasche[1, 2, 3], J. Schnelle-Kreis[2], G. Abbaszade[2], H. Hartmann[4],H. Ruppert[1], R. Zimmermann[2, 3]

Keywords: ambient aerosols, health aspects of aerosols, PAH, wood combustion
Presenting author email: juergen.orasche@helmholtz-muenchen.de

In this century the use of renewable energies is enforced by many European countries. In Germany an effort was started to replace even nuclear power plants. The new energy mix must involve next to solar power, wind power and geothermal power also energy crops and wood for generation of heat, electrical power and gaseous and liquid fuels. But the combustion of wood for residential heating or in biomass power plants is accompanied by considerable emissions of particulate matter (PM) with particle sizes in the fine (< 2.5 µm) and ultrafine fraction (< 100 nm). So it is now discussed which part of energy supply can be solved by wood combustion. How much additional PM will be generated and how dangerous are the effects of generated PM to human health? Moreover the release of high amounts of different organic species is responsible for a lot of not well known chemical processes in the atmosphere. In order to further investigate the impact of wood combustion on atmospheric processes and human health and to apportion the contribution of wood combustion to ambient PM concentrations a comprehensive characterization of source emissions is essential.

Therefore an investigation was done to study the emissions of state of the art small scale wood combustion furnaces under different firing conditions. Additionally emissions from straw combustion were studied. A detailed characterization of organic species of PM of all combustion systems was done by filter sampling and analysis by in-situ derivatization thermal desorption gas chromatography time-of-flight mass spectrometry (IDTD-GC-TOFMS) (Orasche, 2011).

An approach was done to estimate toxicity of the emitted PM by the content of polycyclic aromatic hydrocarbons (PAH). It is based on the proposal of the German Research Foundation (DFG) that the health risk is proportional summarised by different PAH with different health risk potentials (Greim, 2008). Although this tool has been developed to estimate work place exposure this approach can be transferred for assessing health effects associated with PAH in wood combustion PM. This allows a rough but fast comparison of different furnaces by determination of toxic equivalents (TEQ) and emission of PM.

Best results were obtained by combustion of wood pellets in a modern pellet boiler (PM = 4 - 9 mg MJ^{-1}, TEQ = 0.01 - 0.03 µg MJ^{-1}). On the opposite of the emission scale the toxic potential of common log wood stoves were found to be about 1000-fold higher (PM up to 119 mg MJ^{-1} and TEQ up to 27 µg MJ^{-1} during the inflaming phase – Fig. 1)!

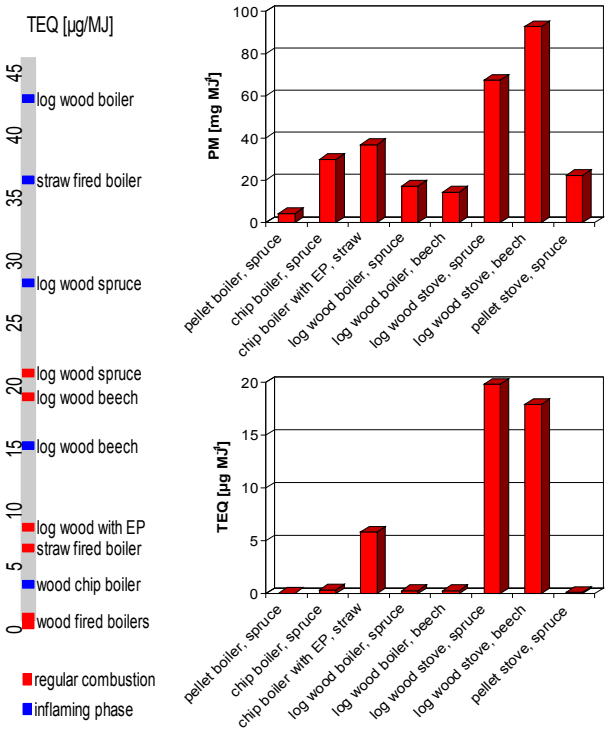

Figure 1. Right: Comparison of emissions from different types of wood combustion during regular combustion (EP = electrostatic precipitator). Left: toxicity scale of the wood combustion systems by the toxicity of released PM distinguishing inflaming phase (blue) and regular combustion (red).

This work was supported by the Federal Ministry of Science and Culture, Lower Saxony, Germany.
The health effects of organic compounds in aerosols are currently investigated in the framework of the Virtual Helmholtz Institute HICE (www.hice-vi.eu).

Presenting author email: Erik.Nordin@design.lth.se

Combustion of biomass fuels for residential heating is considered to be a climate friendly option and is increasing globally. However, this implies potentially increased emissions of aerosol particles. $PM_{2.5}$, which is to a large extent comprised by combustion generated particle matter, co-varies with cardio vascular diseases (Kocbach Bølling *et al.*, 2009). The composition of biomass combustion aerosol can be divided into three main components, soot, alkali salts/ash and organic aerosol and is determined by combustion conditions like oxygen supply and temperature as well as the fuel. Soot and organic aerosol are a result of poor combustion conditions and are considered to be more harmful to human health than ash particles produced under optimal combustion conditions (Kocbach Bølling *et al.*, 2009). A combustion cycle for example in a wood stove can emit episodes of poor combustion even when the overall combustion is relatively complete. The start-up phase is very sensitive to flash-over which results in air-starved conditions with emissions of soot and polycyclic hydrocarbons. The aim of this paper is to study the change in aerosol properties due to different combustion conditions and phases using on-line aerosol measurement techniques.

A total of five combustion cases were studied using three residential wood combustion appliances; *i*) a conventional wood stove operated with high burn rate *ii*) a conventional wood stove operated with nominal burn rate, *iii*) a modern pellet burner operated under optimal conditions *iv*) a novel pellet reactor operating on optimal conditions *v*) a novel pellet reactor operating under air starved conditions. Mean flue gas and particle characteristics from the combustion cases are shown in table 1.

Table 1: Particle characteristics and gas concentrations.

Case	O_2 (%)	CO (mg/MJ)	Total conc. (#*10^7/cm^3)	Org (mg/MJ)
i	9.3±5,4	3020	2.7±1.1	9.4
ii	11.8±2,4	2590	1.6±0.8	8.6
iii	8.2±1.0	110±38	8.4±0.4	0.32
iv	11.1±1.2	120±67	6.1±0.2	0.45
v	5.3±2.0	700±1390	3.0±0.8	6.5

The aerosol from the combustion appliances was diluted 1000-3000 times to concentrations relevant for ambient air before sampling. A high resolution aerosol mass spectrometer (HR-TOF-AMS, Aerodyne research Inc.) was used for size resolved composition of compounds vaporised at 600°C. A scanning mobility particle sizer (SMPS) was used for mobility size distributions (10-600 nm) and an aerosol particle mass analyser operated downstream a differential mobility analyser and an optional thermodenuder (DMA-TD-APM) was used to determine the mass mobility relationship and assess the size dependent organic mass fraction. Particles for TEM analysis were collected using an electrostatic precipitator. For highly transient conditions like the start-up phase the time-resolution of the APM is not sufficient. By utilizing a relationship in (DeCarlo *et al.*, 2004) that the effective density is the ratio between the vacuum aerodynamic diameter (AMS) and mobility diameter (SMPS), the effective density can be derived by from SMPS and AMS size distributions. Combining this method with APM measurements will give novel and detailed information about the aerosol composition in all phases of the combustion cycle.

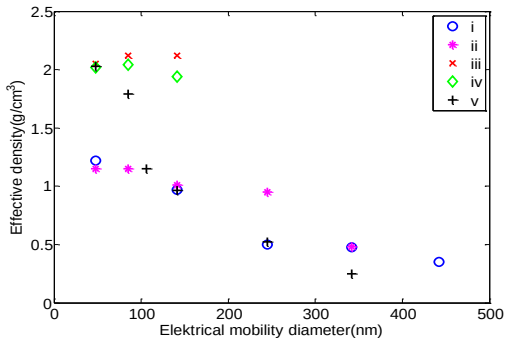

Figure 1: The effective density

The effective density from DMA-APM measurements (figure 1) gives an indication of the particle shape and composition. Salt aerosols have a relatively high effective density, which does not change with increasing mobility diameter, due to their spherical shape. Soot particles on the other hand have a lower effective density which is decreasing with increased size, due to their agglomerated shape.

Impact of iron content on structure and thermo-chemical characteristics of multicomponent soot aerosol

H. Bladt[1], J. Schmid[1], E. Kireeva[2], O. B. Popovicheva[2], N. P. Ivleva[1] and R. Niessner[1]

[1]Chair for Analytical Chemistry, Technische Universität München, Munich, 81377, Germany
[2]Skobeltsyn Institute of Nuclear Physics, Moscow State University, Moscow, 119991, Russia
Keywords: combustion aerosol, metal, contamination, SEM/EDX, Raman microscopy, soot reactivity.
Presenting author email: bladt@tum.de

Soot aerosol which is a major pollutant in the atmosphere of urban areas often contains not only carbonaceous matter, but also inorganic material. As specifically iron contaminations can be derived from various sources, e.g. impurities in heavy fuel oil or lubricating oil used for shipping, engine wear or fuel-borne catalysts, they can be frequently found to a high content in ambient aerosols (Moldanová et al., 2009). Thus, our research focuses on iron species and their impact on the chemical and physical properties of soot.

We studied in-depth the change of composition, structure and oxidation reactivity of laboratory-produced soot of various iron content. For this purpose, iron-containing soot aerosol was generated in a propane/air diffusion flame. By adjusting the doping amount of iron pentacarbonyl to the flame, soot types without Fe addition and with various iron content were produced. Additionally, diesel flame soot without and with ferrocene addition was combusted to give further soot types without and with iron contamination. Scanning Electron Microscopy and Energy-dispersive X-ray Spectroscopy (SEM/EDX) were combined with cluster analysis (CA) to characterize the individual particles by separating them into definable groups of similar chemical composition representing the particle types in dependence of the iron content in soot. Raman Microspectroscopy (RM) and Infrared Spectroscopy (IR) were applied for the structural investigation of the carbonaceous soot structure as well as the characterization of hydrocarbons and iron species. For the analysis of the soot oxidation reactivity, Temperature-Programmed Oxidation (TPO) and Desorption (TPD) were applied and the temperature of maximum CO and CO_2 emission T_{max} throughout the TPO experiment was used as criterion for soot reactivity (Schmid et al., 2011).

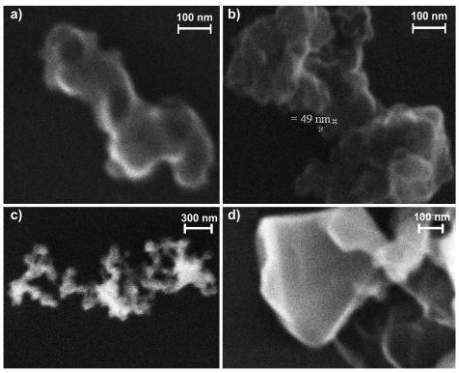

Figure 1. SEM images of different particle types: "typical soot" (a), "elemental carbon" (b), "oxidized soot" (c) and "soot with iron oxide" (d).

Individual soot particles are classified by combined SEM/EDX and CA into four different groups according to their elemental composition in dependence of iron content: "typical soot", "elemental carbon", "oxidized soot" and "soot with iron oxide" (Fig. 1).

Moreover, it could be demonstrated, that iron is most dominantly present in the form of amorphous Fe (III) oxide that crystallizes upon the thermal treatment of soot to form hematite α-Fe_2O_3. Iron contaminations do not change the soot microstructure significantly, but doping of the flame with iron pentacarbonyl impacts the hydrocarbon composition.

Soot oxidation reactivity strongly depends on the content of the catalyst iron, as T_{max} follows an exponential decay with increasing iron content in soot (Fig. 2). Thus, especially at low iron contents, soot reactivity increases significantly with increasing iron content. For iron contents above ~30 % (m/m), soot reactivity cannot be enhanced by further increase in iron content.

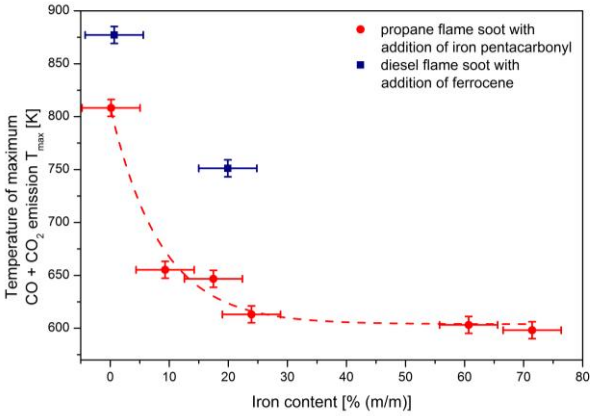

Figure 2. Relation of T_{max} and iron content in soot.

Our results of the thermo-chemical characterization of laboratory-produced internally mixed iron-containing soot raise severe questions on the applicability of commonly used thermo-optical techniques for the quantification of organic carbon (OC) and elemental carbon (EC) in ambient aerosol samples contaminated with inorganic compounds.

Aerosol particles play important direct and indirect roles in climate. Particles composed of black carbon (BC) are key absorbers of radiation in the atmosphere, thereby affecting planetary warming, circulation patterns and cloud formation (Ramanathan and Carmichael, 2008). By acting as condensation or ice nuclei, BC particles may enhance cloud formation. Conversely, they may inhibit cloud formation or precipitation by radiative heating within-cloud.

The climate effects of BC depend on its degree of oxidation and on the presence of heterogeneous coatings. These in turn vary between different BC sources. For example, emissions from sulphur-rich coal combustion may lead to sulphate-coated BC, affecting the radiative and cloud effects mentioned above. To determine the importance of such effects, field measurements need to describe BC according to its source and mixing state.

In order to characterize the composition and coating of BC aerosols, the Aerodyne Soot Particle Aerosol Mass Spectrometer (SP-AMS, Onasch et al. 2012) has been developed based on the original AMS (Jayne et al., 2000). This new instrument complements other BC-measurement techniques by providing information on the chemical composition of BC particles and their coatings in real time. In the SP-AMS, BC particles are vapourized by a continuous-beam laser operated at 1064 nm. The resulting vapour is then ionized by electron impact at 70 eV; ions are then mass-analysed within a high-resolution time-of-flight chamber. In this study, the SP-AMS was also operated with a 600°C tungsten vapourizer positioned directly behind the laser. With the laser switched on or off, the SP-AMS detected either both refractory and non-refractory species (laser on), or non-refractory species only (laser off).

The SP-AMS was employed in the laboratory to characterize five different BC types along with a suite of mass- and optically-based instrumentation. The BC sources were: propane-flame soot ("CAST", Jing Ltd.), graphite-spark-generated soot ("GFG", PALAS GmbH), a commercial carbon black ("Regal Black", REGAL 400R pigment black, Cabot Corp.) and fullerene soot (Sigma-Aldrich Corp.). The CAST propane burner was operated under two different regimes, fuel-lean ("black" soot) and fuel-rich ("brown" soot).

The mass spectral signatures of these five BC types were analysed and compared with the goal of identifying mass spectral characteristics unique to each sample. As an example, the ratio of signals at mass-to-charge ratios (*m/z*) +12 to *m/z* +36 are shown in Figure 1 below for three BC types: GFG, CAST black (fuel-lean) and CAST brown (fuel-rich) soot. For these three types, the slopes of a linear-regression fit were 0.85, 0.57 and 0.95, respectively. When the SP laser was switched off so that particles saw only the 600°C vapourizer, the signals at *m/z* +12 and *m/z* +36 fell to zero for all three samples. The results therefore demonstrate a distinct chemical structure of BC for these three soot types.

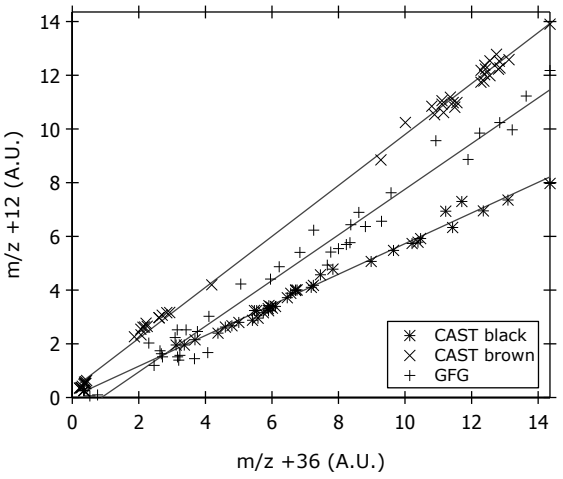

Figure 1. SP-AMS signal at *m/z* 12 and *m/z* 36 for graphitic soot (GFG), and two types of propane flame soot: CAST black and CAST brown. Error bars omitted for clarity.

In this presentation, similarities and differences between the mass spectra of five BC types will be detailed, supported by independent measurements of soot mass and optical properties (SP2, APM, MAAP, nephelometer, PSAP). The results provide a reference against which ambient measurements of BC may be compared.

Fine particle emissions from combustion sources have gained attention recently due to their climate effects and adverse effects on human health. Here the effects of fuel quality, boiler type and control devices on particle emissions from energy production by combustion and some other industrial sources (Lind et al., 2007) are reviewed. Several fossil and biomass based fuels are used for energy conversion processes. Here we consider coal, peat, heavy fuel oil, biomass and waste derived fuels and their effects on fine particle formation in boilers. Boiler types considered are pulverized combustion, bubbling fluidized boilers, circulating fluidized boilers, grate fired boilers, gasification-combustion boilers, small scale combustion (Ruusunen et al., 2011; Hytönen et al., 2009; Kaivosoja et al., 2012) appliances and oil burners. The emission control devices have the most important effect on particle matter (PM) emissions. Several PM removal devices are used like multicyclones, scrubbers, electrostatic precipitators, fabric filters with and without sulphur removal. Measurements have been performed for boilers with fuel power from few kW up to several hundred MWs. Extensive chemical and physical characterisation methods are used to understand the role of different species on emissions. Understanding all these factors helps us to design the energy production units to meet the emission regulations and to assess the environmental fate of different alternatives in energy production.

Presenting author email: kane.n@aist.go.jp

The accident of Fukushima Dai-ichi nuclear power plant, triggered by the great Tohoku earthquake and Tsunami that hit eastern Japan on March 11, 2011, released a large amount of radioactive materials into the environment. Although the radioactive particles have been collected by use of High-Volume air sampler in numerous sites, the activity size of radionuclides and their mixing state with other aerosol components have not yet been reported since the occurrence of the accident. We thus have started the sampling of size segregated aerosol at Tsukuba City, Japan, located 170 km south of the plant since 28 April, 2011.

A low-pressure cascade impactor (12-stages plus backup filter, Tokyo Dylec LP-20) was operated on the fourth-floor balcony of a building in Tsukuba. As impaction substrates, aluminium foil sheets were used for the first and third samples (LPI-AIST-1 and 3), and quartz fiber filters (Pallflex 2500 QAT-UP) were used for the second and fourth sample (LPI-AIST-2 and 4). As the backup filter, a quartz fibre filter was placed after the 12th stage. The radioactivity of ^{134}Cs and ^{137}Cs in aerosols collected at each stage were determined by gamma-ray with a high sensitivity Germanic detector. After the gamma-ray spectrometry analysis, the ionic species in the aerosols were extracted from one-fourth of the substrates into ultra-pure water and were determined by ion chromatography

The activity size distributions of ^{134}Cs and ^{137}Cs in aerosols measured from the first sample (LPI-AIST-1) reside mostly in the accumulation mode size range and showed the double peak structure. These activity size distributions almost overlapped with the mass size distribution of non-sea-salt sulfate aerosol. From the results, we can regard that sulfate is the main transport medium of these radionuclides, and re-suspended soil particles that attached radionuclides were not the major airborne radioactive substances by the end of May, 2011 (Kaneyasu *et al*., 2012).

Temporal changes in the Activity Median Aerodynamic Diameter (AMAD) of ^{137}Ce and the Mass Median Aerodynamic Diameter (MMAD) of non-seasalt (nss.)SO_4^{2-} are listed in Table 1. From the three sample sets analyzed so far, we can recognize two aspects on the size of radiocesium: (a) AMADs of ^{137}Ce are monotonously increasing with time, and (b) AMAD of ^{137}Ce are almost the same as MMAD of nss.SO_4^{2-} in the first two samples. In other words, the activity size distribution of the first two samples follows the mass size distribution of nss.SO_4^{2-}, while this character diminishes in the latest (LPI-AIST-4) aerosol sample. These suggest that the radiocesium included in sulfate aerosol had become a minor contributor to the airborne radionuclides by that time, and the re-suspended soil dust that attached the radiocesium has started to replace the position. This is probably caused by two factors: the direct emission of radiocesium from the damaged plant had almost halted, and the transport of radioactive materials from the plant was depressed by weather conditions.

During the Chernobyl nuclear accident in 1986, Bondietii *et al.* (1988) conducted a successive extraction experiment of radionuclides from aerosols collected on glass-fiber filters (aerodynamic diameter < 0.41 μm) in Tennessee, USA, with water, 0.01M HCl, and 0.1 M HCl. Their results indicated that water-extractable fraction of $^{134, 137}$Cs were less than 25%, and those of non-extractable fraction to 0.1 M HCl were above 30%.

We then conducted the successive extraction experiment of radiocesium from the aerosol deposits on the aluminum sheet substrate (8th stage of LPI-AIST-1, 0.5–0.7 μm in aerodynamic diameter) with water and 0.1M HCl. In contrast to the relatively insoluble property of Chernobyl radionuclides, those in aerosols collected at Tsukuba are exceedingly water-soluble (~100%). This may reflect the difference in the nature of the Chernobyl and Fukushima accidents, of which the former exposed the damaged reactor core directly to the ambient air whereas the latter did not. The possible formation mechanism of sulfate-radiocesium internal mixing particles will further be discussed in the presentation.

Table 1. Comparison of ^{137}Cs AMAD and nss.SO_4^{2-} MMAD of aerosols collected in Tsukuba, Japan, after the Fukushima accident.

Sample ID	Sampling period	^{137}Cs AMAD (μm)	nss.SO_4^{2-} MMAD (μm)
LPI-AIST-1	Apr.28– May 12	0.54	0.53
LPI-AIST-2	May12– May 26	0.63	0.63
LPI-AIST-3	May 26–Jun.9	under meas.	under meas.
LPI-AIST-4	Jun.9 – Jul.19	0.89	0.66

Environmental Impact of Fukushima Fallout in Southeast Spain

F. Piñero-García, J. Drożdżak and M.A. Ferro-García

Radiochemistry and Environmental Radiology Laboratory (LABRADIQ), Department of Inorganic Chemistry, University of Granada, Granada, 18071, Spain
Keywords: Nuclear Reactor, Accident, Radioactive Aerosols, Back Trajectories.
Presenting author email: franciscopigar@ugr.es

The aim of this research is to study the impact of the Fukushima fallout in Southeast Spain. Based on backward and forward trajectory, the movement of the radioactive cloud toward Southeast Spain was reconstructed. Furthermore, the transfer of fission products to different matrixes was studied.

On March 11th, 2011, an earthquake of magnitude 9.0 occurred in the Pacific Ocean near the east coast of Japan (epicenter 38.32ºN-142.37ºE), followed by a tsunami. As consequence, the backup diesel generators of Fukushima Dai-ichi nuclear plant were dangerously affected. The lack of electrical power subsequently caused extensive damage to the reactor cooling system. Subsequent explosions inside the reactors projected fission product (^{131}I, ^{132}I, ^{132}Te, ^{134}Cs, ^{137}Cs) into the atmosphere. Fifteen days after, traces of the Fukushima nuclear accident, was detected at Southeast Spain.

Samples of aerosols, rainwater and food, were taken in Granada, Spain, from March 11th to April 19th. Air samples were collected weekly by an air pump with two filters. Aerosols were collected in AAWP04700 cellulose filter, 4.7 10^{-2} m diameter and 0.8 μm size pore. The ^{131}I was collected in a CP-100 Radioiodine Sampler with activated charcoal traps for gaseous iodine. Dry and wet deposition was collected weekly using a slightly tilted stainless steel tray, 1m^2, connected to a 50L vessel. After the rainfall, samples of food, vegetables and cheese, were taken to check the transfer of the fission products from the atmosphere to the human food chain.

Some of experimental values found were; the highest concentration of ^{131}I in air (gas 2.63±0.12 mBq/m^3 and aerosols 0.82±0.08 mBq/m^3) was detected between March 23 and 30 and in rainwater samples (1.10±0.16 mBq/L) between March 30 and April 6. In addition, the maximum concentrations in air of ^{134}Cs (0.10±0.03 mBq/m3) and ^{137}Cs (0.09±0.02 mBq/m3) were measured between March 30 and April 6. ^{131}I remains mainly in gaseous form during transport due to activity levels for the gaseous fraction (2.6-0.4 mBq/m^3) were always higher than particulate fraction (0.82-0.14 mBq/m^3). After rainfall on April 3rd, 131I concentrations fell by 33.5% as a result of the scavenging of the atmosphere. The ratio ^{131}I/^{137}Cs, was similar in different countries, suggesting a quick movement of the radioactive cloud around the world (Manolopoulou, 2011). In addition, the high level of the ratio confirms that the fallout was rich in ^{131}I.

After the nuclear accident the air masses transported the radioactive cloud from Fukushima toward the Pacific Ocean and northern Japan in the direction of the Arctic Ocean, Canada and northern USA. Subsequently, polar maritime air masses, which had been originated as continental air masses over North America, moved the radioactive plume toward the Atlantic Ocean on the way to southeast Spain (Figure 1), (Piñero-García et al 2012). However, the rainfall and the change in the air mass origin (polar and arctic air masses passing over the British Isles and Western Europe, and Mediterranean and European Continental air masses), from April 16 to April 19, decreased the activity of radioactive fission product to background levels.

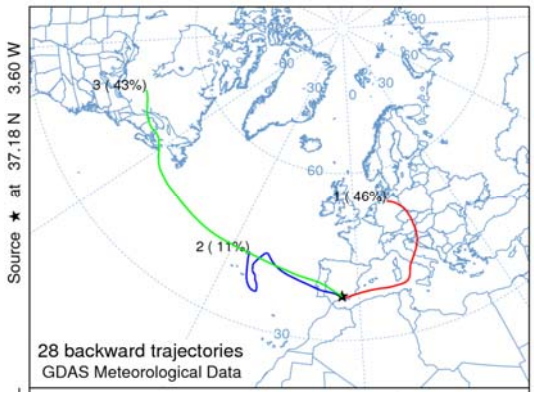

Figure 1. This is a representative air mass origin during Fukushima fallout exposure over Granada, Spain.

The concentrations of fission product detected in southeast Spain due to Fukushima fallout are so low that there is no impact on human health or the environment. Furthermore the Annual Limits on Intake (ALI), calculated for ingestion of food was 130±30 nSv/y, 0.013% of the annual effective dose limit for members of the public, 1mSv/y. Therefore the ingestion of vegetable and cheese, in Southeast Spain after the nuclear accident does not represent any risk to human health.

In summary, this research shows the importance of the climatic events in the evolution of the Fukushima fallout, and the importance of environmental radiology laboratories for nuclear safety in the world.

The Spanish Nuclear Safety Council (CSN) supported this work.

Atmospheric dispersion and ground deposition induced by the Fukushima Nuclear Power Plant accident at local scale: simulation and sensitivity study

I. Korsakissok[1], A. Mathieu[1] and D. Didier[1]

[1]Institute of Radiation Protection and Nuclear Safety, Fontenay-aux-roses, 92262 Cedex France

Presenting author email: irene.korsakissok@irsn.fr

On March 11th 2011, an earthquake of magnitude 9.0 occurred off northeastern Japan, causing a tsunami and damaging the Fukushima Daiichi Nuclear Power Plant (FNPP1). As a result, radioactive products were released in the atmosphere. During the emergency phase, the Institute of Radiation Protection and Nuclear Safety (IRSN) was asked to provide its expertise on the plume dispersion and radiological consequences, in support of the French Government. Since then, the institute has been working on improving its assessment of the environmental contamination (Mathieu *et al*, 2012).

Understanding the formation process of highly contaminated areas cannot be achieved through measurements only. Indeed, many devices (radiation and meteorological monitoring stations) had been damaged by the earthquake and tsunami and were unavailable. Thus, improving atmospheric dispersion simulations remains a key issue. This paper presents the evolution of atmospheric and ground activity simulated at local scale (within 80 km of FNPP1), sensitivity studies and comparisons with environmental monitoring data.

IRSN's Gaussian puff model pX is used for the simulations. Dry deposition is modelled through apparent deposition velocities (cf. Table 1), and the scavenging coefficient is given by $\Lambda s = \Lambda_0 \times p_0$, with $\Lambda_0 = 5 \times 10^{-5}$ h/mm/s and p_0 the rain intensity in mm/h.

Table 1. Deposition velocities used in the simulation

	Particles	Organic iodine	Gaseous iodine
v_d (m/s)	2×10^{-3}	1×10^{-4}	7×10^{-3}

The source term was evaluated using available information on the reactors status (pressure, water level) and events chronology (ventings and explosions). 73 isotopes were included. Additional information was inferred from air dose rate measurements at local and Japan scales, to help determine each release's time and duration and the quantity of each radioisotope. However, the source term remains a key uncertainty.

The meteorological data used are ECMWF forecasts at 0.1° resolution, with a 3-hour time step. At this resolution, the model fails to reproduce the complex orography, leading to uncertainties in the wind fields. Thus, wind observations at FNPP1 are used during crucial time periods. Since wet deposition is a key process in the contamination, rain radar data at a 10-minutes time period are used to model the precipitations.

The reference simulation was carried out using the aforementioned deposition and scavenging values. The release height was split between 50 m above the ground (70% of the emission) and 150 m (30 % of the release). The results compare well with gamma air dose rates measured in Fukushima prefecture (cf. Figure 1).

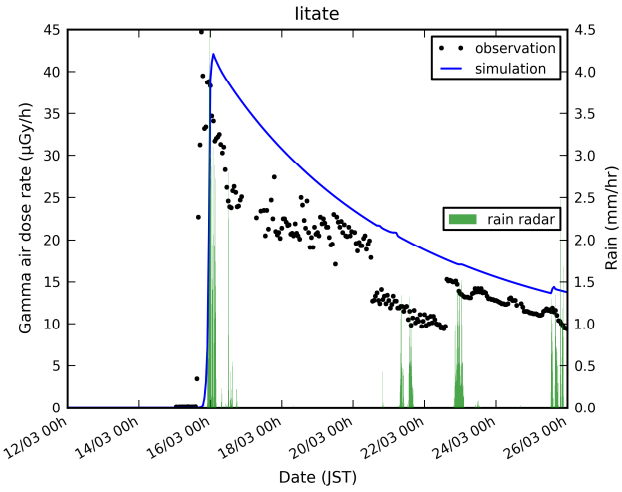

Figure 1. Comparisons between gamma air dose rate measured (dots) and simulated (line) at Iitate (about 40 km north-west of FNPP1).

Additional simulations are used to evaluate the results sensitivity to some parameters, such as the release height, the isotopic composition (e.g., proportion of noble gas in the release), the deposition and scavenging constants, and the dispersion parameterizations. A particular focus is made on the wet deposition process, which is probably responsible for the formation of the north-western high dose rate zone. Gamma air dose rate data are used to evaluate a simulation ability to forecast (1) the plume arrival time, (2) the peak intensity and (3) the deposition rate. Ground deposition measurements are used as a complement to this analysis.

Acknowledgements: the meteorological forecasts used in this work have been provided by Météo-France. The source term evaluation was done in collaboration with D. Corbin and J. Denis (IRSN).

In spring 2010 the Icelandic volcano Eyjafjallajökull erupted high loads of pyroclastic material into the atmosphere. The eruption cloud reached heights between 4 and 7 km. The volcanic ash advisory centre London, the responsible institution for making forecasts of ash coming to Europe, decided the complete shut down of the air traffic over wide parts of Europe for a sequence of days.

From April 13th to 20th there was a stable high pressure system over the Atlantic Ocean. Thus, a rather constant air flow from north-west to south-east prevailed over Europe in the upper and middle troposphere. Due to that the volcanic ash was transported from Iceland over the UK to Central Europe. Furthermore, the weather conditions were sunny, dry, and stable, preventing the ash from being mixed throughout the atmosphere or from being washed out by precipitation. These weather conditions led not only to long range ash transport but also to high PM10 concentrations in the boundary layer from other sources. Thus the question arises whether the volcanic ash contributed to the high PM10 levels near ground or if the reason for the high PM10 concentrations measured by the ground based stations has to be found elsewhere.

The aim of this paper is to give a review of some of the findings of the ground based measurements, model calculations, and remote sensing in Central Europe during the volcanic event two years ago, with focus on Germany, France, and Great Britain.

A large variety of modelling results on the dispersion of the Eyjafjallajökull plume over Europe can be found in the recent literature. They all showed that the ash plume reached the air space over Central Europe and these findings compare rather nicely to satellite pictures, Lidar measurements, and measurements from aircrafts. In the present paper as an example EURAD and Chimere model simulations will be presented.

With regard to lidar and satellite measurements, we will concentrate on the findings by the German Weather Service, the Met Office and of the volcanic ash advisory centre in Great Britain.

As an example for the ground based measurements, we will show the findings of Germany and France. To figure out whether and to what extend the elevated PM10 concentrations are influenced by the transported volcanic ash the PM10 samples were analysed for heavy metals, chloride, nitrate, sulphate, and ammonium. The composition was compared with the one of the erupted material as measured by Óskarsson (2010). An additional indicator for volcanic material is the occurrence of elevated SO_2 concentrations and of unusual particle shapes that can be detected by scanning electron microscope analyses.

The results of the ground based observations in Germany and France are quite similar. There was volcanic ash that reached the surface, especially at the Black Forest as well as in the Alsace region (Colette et al., 2011, LUBW, 2010), where part of the sampled particles have the same chemical composition than the erupted material. Thus about 25 $\mu g/m^3$ of the PM10 can be ascribed to volcanic ash there, in good agreement with long-range transport modelling studies. Nevertheless in other places, for example in North Rhine-Westphalia (LANUV), the volcanic ash fraction contributed merely about 5 $\mu g/m^3$ to the PM10 burden in the latter regions.

This shows that a combination of all existing methods and a close collaboration should be used to predict the impact of future events.

Desert dust events, volcanic eruptions and soot emissions from forest fires are natural events that emit large amount of particles into the atmosphere. Depending on their magnitude, such event can yield sometimes air travel disruption at a local or continental scale. Beside the large amount of emitted material, airborne particles bear also in common some traces of radionuclides, either of natural or anthropogenic origin (table1).

During the first three days of the Eyjafjallajökull eruption in April 2010, roughly 200 million tonnes of basaltic tephra (Gudmundsson, 2010) having a uranium concentration close to 2 ppm (Schleicher, 2012) were emitted into the atmosphere. This corresponds to *ca.* 400 tonnes of uranium and 1300 tonnes of thorium (assuming a 3.3 Th/U ratio). Most of those particles were deposited close to the volcano on soil having the same specific activity level. Moreover, a large plume spread over northern Europe. In France, IRSN conducted measurements of ^{210}Po, known as a specific tracer of volcanic plumes (Nho et *al.* 1997). Results were in the range of the north hemisphere background level (~ 50 µBq/m^3), excluding a specific volcanic contribution at ground level. This was also consistent with Lidar detections showing that the plume remained mainly at around 1 km a.g.l. over France before being so diluted that the signal became too weak to be measured.

Desert sandstorms are responsible for the transport of hundreds million tonnes of particles a year. Most atmospheric nuclear bomb tests where performed in the northern hemisphere and yielded to a latitudinal dependent deposition with maximum rate between 30 et 50° of North latitude. Wind eroded clay and silt particles have trapped small traces of former deposited anthropogenic long-lived radionuclides. Traces of caesium and plutonium can thus be transported over long distances. This is the case when winds are blowing from Sahara to France. The specific contribution of the French nuclear tests performed in the early 1960's in Sahara cannot currently be distinguished from the global radioactive fallout as the ^{238}Pu/$^{239+240}$Pu, ^{241}Pu/$^{239+240}$Pu and ^{240}Pu/^{239}Pu ratios remain close to ratios characteristic of the global fallout (Masson *et al.* (2010). Additionally, weighted activity levels in Saharan soils (except very close to ground zero test site) are similar to what can be observed in France. Similar observations were noticed in Japan regarding sandstorm originating from East Asian arid areas (Hirose, 2007).

Fires in boreal forests may also act as a diluted and widespread source that can redistribute up to 10% of formerly deposited radionuclides still present in the forest litters, or that have migrated into biomass. In summer 2004, fires occurred in territories contaminated by the Chernobyl fallout in Belarus, Ukraine and western part of Russia. Airborne ^{137}Cs, normally at trace levels, was slightly enhanced during eastern wind conditions over France (Piga, 2010). Apart from forest fires, usual biomass burning for heating purposes or agricultural practices can slightly affect its current background level at local and regional scales. This is especially the case during winter as shown by Bourcier *et al.* (2010) using simultaneous ^{137}Cs and Levoglucosan determinations.

Table 1: Comparison of some radionuclide amounts (Bq) emitted to the atmosphere by natural events

	^{137}Cs	^{238}U
Sahara desert export (*per* year)	10^{12} Bq	10^{12} Bq
Eyjafjöll 2010 eruption (first 3 days)	not concerned	5.10^{12} Bq
Europe and Russia forest fires export (*per* year)	10^{13} Bq	n.d.

Despite the amounts of released or re-emitted radionuclides, airborne levels remains after dispersion at trace levels (~ 1-50 µBq/m^3) and of no concern for public health.

Eyjafjallajokull volcanic dust characteristics from LIDAR data and in-situ aerosol size distributions

Massimo Del Guasta[1], Paolo Cristofanelli[2], Angela Marinoni[2], Paolo Bonasoni[2]
[1]Institute of Applied Physics (IFAC) CNR, Via Madonna del Piano 10, 50019 Sesto Fiorentino (Italy)
[2]Institute of Atmospheric Science and Climate (ISAC) CNR,Via Gobetti 101, 40129 Bologna,(Italy)

Keywords: volcanic dust, LIDAR, light scattering, depolarization
Presenting author email: m.delguasta@ifac.cnr.it

In this experiment the LIDAR backscatter and depolarization of Eyjafjallajokull volcanic dust measured continuously at 532 nm at IFAC CNR (60 m asl, Sesto Fiorentino, Italy) are compared with calculated quantities derived from aerosol observational activity in high mountain site during the period 18-22 May 2010.

The simulations rely on aerosol size distributions that are continuously measured by means of DMA and Optical counters at the O. Vittori Mt. Cimone station, Italy (MTC, 2165 m asl), which is located 50 km away from the IFAC LIDAR site. Different dust compositions and aspect ratios were considered in the simulation..

A closure experiment was then attempted by comparing the calculated and measured LIDAR quantities at the altitude of MTC. The goal is to improve the derivation of the characteristics of volcanic dust with the synergic use of LIDAR and mountain-site aerosol data.

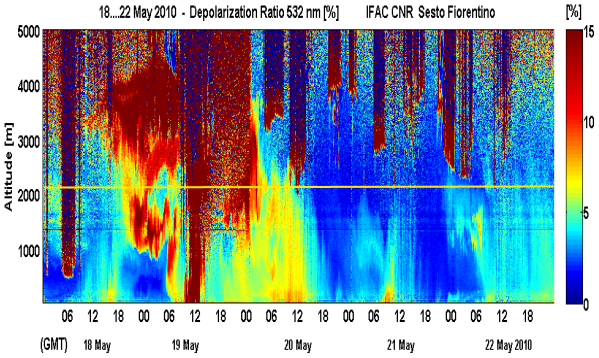

Figure 1. The LIDAR depolarization of the volcanic plume of 18-22 May 2010 at Sesto Fiorentino (Italy). The altitude of the MTC station is line-marked

Optical simulations

The scattering properties of volcanic dust were simulated at 532 nm by assuming axisymmetric spheroids with the refractive index of Obsidian, Basaltic glass, Basalt and Andesite (Pollack et al.,1973). The scattering simulations were performed by means of the "Null Field method with discrete sources" approach to T-matrix developed by Doicu *et al*. (2006).

The final results of simulations were LIDAR quantities, such as depolarization, calculated for randomly-oriented particles of different sizes (0.01-20 um), composition and aspect ratios (1.2<AR<2). LIDAR depolarization is a powerful indicator of the presence of non-spherical particles: simulations showed that large volcanic spheroids can depolarize less than small ones, and that 15-17% depolarization is expected from large volcanic spheroids, regardless of their shape and composition (Fig.2).

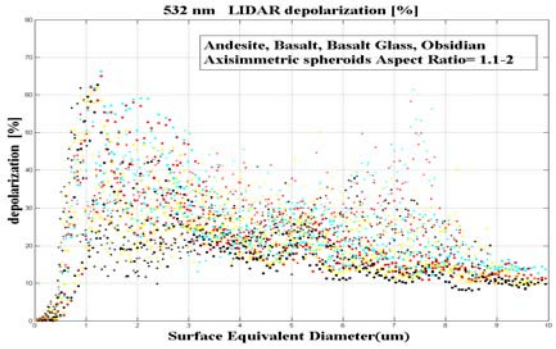

Figure 2: LIDAR Depolarization as obtained from simulations with different dust composition

Comparison with in-situ aerosol information

IFAC LIDAR data and MTC in-situ aerosol size distributions (0.01-20μm) were both analysed for the Eyjafjallajokull cloud of 18-22 May, 2010. LIDAR quantities were calculated from MTC size distributions by splitting them into three lognormal modes. The LIDAR backscatter and depolarization were calculated by using the Mie theory for the two small modes, and the T-matrix results for the third, dust mode. All the different, simulated ash compositions and aspect ratios were considered. The calculated LIDAR quantities were compared with the measured ones for the altitude of MTC (2165 m) (Fig.1).

A closure experiment was thus carried out in order to show, as suggested e.g. by Hervo *et al*.,(2012) the benefits of the synergic use of LIDAR data and aerosol data from high mountain sites in deepening our knowledge about volcanic dust.

Eyjafjallajökull volcanic ash number concentration retrieval at Lyon (France) with a UV-polarization Lidar

G. David[1], B. Thomas[1], A. Miffre[1] and P. Rairoux[1]

[1]Laboratoire de Spectrométrie Ionique et Moléculaire, CNRS UMR 5579, Université Lyon 1, Villeurbanne, 69622, France

Keywords: remote sensing, volcanic particles, number concentration

Presenting author email: amiffre@lasim.univ-lyon1.fr

The volcanic ash particles released from the Eyjafjallajökull 14th April 2010 eruption caused a six days airspace closure over Western Europe. After long-range transport, volcanic ash aerosols were aged and highly dispersed with irregularly shaped volcanic ash particles, mixed with sulfate particles (Schumann et al., 2011). We have traced these non-spherical volcanic ash particles with a sensitive and accurate UV-polarization Lidar at Lyon (France), at the border of the airspace closure, after advection over more than 2,600 km. We then applied this field measurement to develop a new methodology (Miffre et al., 2012b) to remotely evaluate the volcanic ash particles number concentration in the troposphere, with high sensitivity and accuracy. It only requires a single Lidar laser wavelength and it is ash particles specific, which is new (Miffre et al., 2012b).

The spatial and temporal dispersion of the volcanic ash cloud at Lyon is displayed in figure 1 from April 17th to 20th 2010, between 0.5 to 7 km, by representing the particles parallel backscattering coefficient $\beta_{p,//}$. Between 3 and 7 km, an unusually high backscattering coefficient is observable in a thin filament, tilting into the low troposphere, in nice agreement with FLEXPART ash numerical dispersion model and 7-days air mass back-trajectories (Miffre et al., 2012a), showing evidence of volcanic ash presence above the Lidar station.

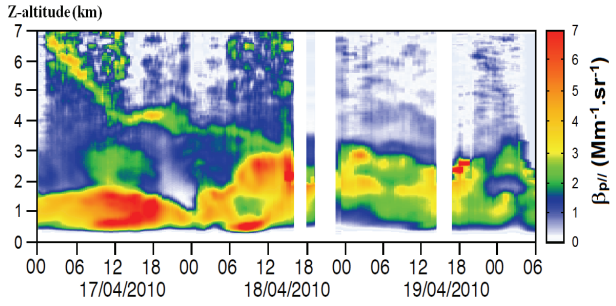

Figure 1. UV-Lidar time-altitude map of the particles parallel backscattering coefficient $\beta_{p,//}$ at Lyon (France).

Since the perpendicular Lidar channel is, by construction, only sensitive to non-spherical particles backscattering, it is in this study volcanic ash particles specific. As volcanic ash particles are detected on both Lidar polarization channels, the volcanic ash particles backscattering coefficient β_{ash} can be determined as follows (with obvious notation for $\beta_{p,\perp}$):

$$\beta_{ash} = \beta_{ash,\perp} + \beta_{ash,//} = \beta_{p,\perp} (1 + 1/\delta_{ash}) \quad (1)$$

The volcanic ash depolarization ratio $\delta_{ash} = 40.5 \pm 2$ % has been determined from laboratory scattering matrix measurements on volcanic ashes, mechanically sieved to remove the largest particles, as after long-range transport (Muñoz et al., 2004). Then, at altitude z, the volcanic ash number concentration N_{ash} has been retrieved from the β_{ash}-definition ($N_{ash} = \beta_{ash} / \langle (d\sigma/d\Omega)_{ash} \rangle$), by computing the size-averaged ash backscattering cross-section $\langle (d\sigma/d\Omega)_{ash} \rangle$, using Muñoz's ash particles size distribution and refractive index, assuming surface equivalent spheres, while including sedimentation processes (Schumann et al., 2011). $\langle (d\sigma/d\Omega)_{ash} \rangle$ is hence known with 15 %-uncertainty. Figure 2 displays vertical profiles of $\beta_{p,//}$, $\beta_{p,\perp}$ and N_{ash}. The sensitivity and accuracy of our Lidar enable to distinguish different volcanic ash layers. Moreover, the retrieved N_{ash}-values well compare with in-situ optical particle counter measurements (Schumann et al., 2011).

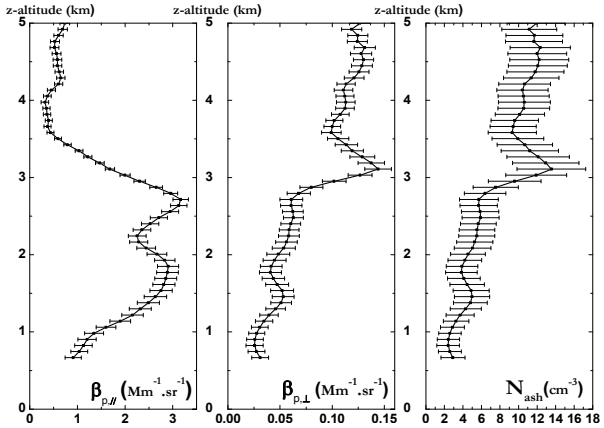

Figure 2. Vertical profile of $\beta_{p,//}$, $\beta_{p,\perp}$ and N_{ash} on April 19th at 0 h UTC at Lyon (France).

The presentation will detail our field observation of the Icelandic volcanic ash cloud at Lyon, in nice agreement with FLEXPART ash numerical dispersion model (Miffre et al., 2012a, Eyjafjallajökull Special Issue). Then, we will point out the robustness of our N_{ash}-retrieval methodology (Miffre et al., 2012b), which is new and easily applicable to other volcanic ash events as only one Lidar wavelength is required.

We thank A. Stohl's group for providing FLEXPART ash numerical dispersion model, CNRS and Région Rhône-Alpes for financial funding.

Presenting author email: zamin.kanji@env.ethz.ch

Aerosols can cool or warm the atmosphere directly via interaction with incoming solar radiation (aerosol direct effect), or via their ability to act as cloud condensation or ice nuclei (IN) and thus play a role in cloud formation (indirect effect). The physical properties of aerosols such as size and solubility as well as chemical composition can influence their behavior and fate in the atmosphere. Ice nucleation is known to be especially sensitive to surface properties. Ice nucleation taking place via IN is termed as heterogeneous ice nucleation and can take place via deposition (ice forming on IN directly from the vapor phase), condensation/immersion (freezing via formation of the liquid phase on IN) or condensation (IN colliding with supercooled liquid drops).

Motivation for quantifying ice formation in the troposphere is many-fold. First, to understand the hydrological cycle since ice is the primary initiator of precipitation forming clouds. Second, the tropospheric budget of water vapour, an especially active greenhouse gas is strongly influenced by ice nucleation and growth. Third, ice surfaces in the atmosphere act as heterogeneous surfaces for chemical reactions of trace gases (e.g., SO_2, O_3, NO_x). Being able to quantify ice formation rates and ice surface concentrations allows an accurate calculation of trace gas budgets in the troposphere. This work addresses how mineral dust particles chemically aged from O_3 exposure influence deposition and immersion mode freezing under tropospherically relevant temperature (**T**) and relative humidity (**RH**) conditions.

Ice nucleation measurements were conducted using home-built chambers of the thermal gradient continuous flow diffusion principle capable of measuring immersion freezing (Lüönd *et al.*, 2010) (IMCA) and deposition freezing (Stetzer *et al.*, 2008) (PINC). In IMCA an ice optical depolarization detector was used to discriminate between frozen and liquid drops, whereas an optical particle counter was used to detect ice crystals in PINC. Poly-disperse samples of sub-micron diameter kaolinite and Arizona test dust were aerosolized in a stainless steel chamber and allowed to age for 15 – 90 minutes in known amounts of O_3 in the range 0.4 – 4 ppmv under dark conditions at ~298K. Destruction of O_3 was observed due to initial rapid decline of concentrations beyond background decay upon addition of dust particles to the aerosol tank. Deposition and immersion mode freezing experiments were conducted for both particles exposed to O_3 and unexposed particles.

Results for deposition mode freezing of kaolinite particles at RH_i = 130% are shown in Figure 1. It is observed that exposure to low levels of O_3 marginally enhance the ice active fractions as function of T. In contrast, when high O_3 concentrations are used for the ageing process, the ice active fractions are significantly repressed.

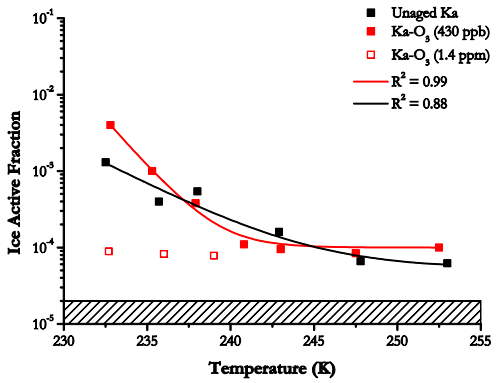

Figure 1. Ice active fraction as a function of T for kaolinite particles quoted at RH with respect to ice of 130%. The hashed region indicated the instrument background.

Ozone is known to react at surface sites of mineral dusts, including kaolinite (Karagulian and Rossi, 2005) to produce oxygenated surface species. It is possible that these surface species lower energies of ice germ formation for ice nucleation on the kaolinite surface. In contrast, when higher O_3 concentrations are used, the active surface species are chemically destroyed or physically occupied by adsorbed O_3, therefore making active sites for ice nucleation unavailable. Similar trends in ice nucleation behavior were observed for immersion freezing.

The results imply that mineral particles exposed to low ozone concentrations for longer periods of time in the atmosphere could have a significantly different ice nucleation behavior depending on the particle history compared to untreated particles typically used in laboratory measurements. These are the first results to show an inhibition of freezing in the immersion mode due to chemical ageing of aerosol particles.

Presenting author email: tclarke@soest..hawaii.edu

The world's largest stratus deck over the South East Pacific (SEP) was a study target for the VOCALS (http://www.eol.ucar.edu/projects/vocals/) experiment in October 2008. Aerosol-cloud interactions were one major goal of several ship and aircraft studies including results from 14 flights of the NCAR C-130 aircraft reported here. Each flight covered about a 1000 km range with multiple profiles and legs below, in and above the Sc deck.

Strong aerosol sources along the coast of Chile were expected and found to influence cloud condensation nuclei (CCN) in coastal clouds. However; "rivers" of elevated CO, black carbon (BC) associated with combustion aerosol effective as CCN at <0.3%S were also common in subsiding free troposphere (FT) air overlying the extensive Sc deck for over 1000km offshore (Shank et al., 2012). This subsidence brought in aerosol from sources over the western Pacific as well as South America. Observed entrainment of this aerosol appeared linked to cloud related turbulence. When present, entrained combustion aerosol increased the CCN in the marine boundary layer (MBL) (Fig.1) leading to decreased effective radius compared to clouds in "clean" MBL air advected from the South Pacific.

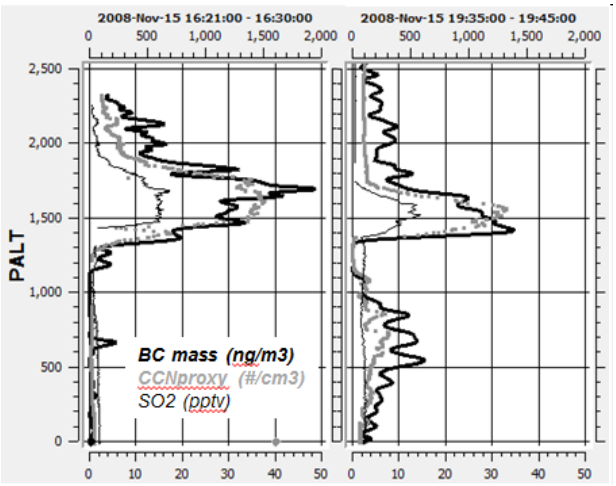

Figure 1. An example from flight 14 on Nov. 15 for descent (left) and ascent (right) ~3hrs later in same location near isolated cloud in an MBL air mass advected with the wind. Combustion plume aloft with elevated BC, SO2 and CCNproxy at 0.2%S (Here non-volatile CN heated to 350C are shown as proxy for CCN at 0.2%S) initially lies above inversion near 1,300m with a clean MBL below. Three hours later (right) plume is lower and about 1/3 is mixed into MBL. This suggests a localized entrainment near this cloud of about 1.4 cm/s and 2-3 times regional expected entrainment values.

Previous modeling results using LES (Wang and Feingold, 2009) show that drizzle in the clean marine boundary layer depletes aerosol and leads to a transition from closed cell convection to the formation pockets of open cells (POC), with much reduced cloud cover. These clean conditions are similar to MBL conditions in Fig. 1 (left) before entrainment of pollution. New, preliminary simulations, with a pollution layer located in the FT above the cloud deck, using measured aerosol size distributions, suggest that entrainment of the pollution aerosol can maintain MBL CCN concentrations and prevent the transition to POC conditions (Figure 2).

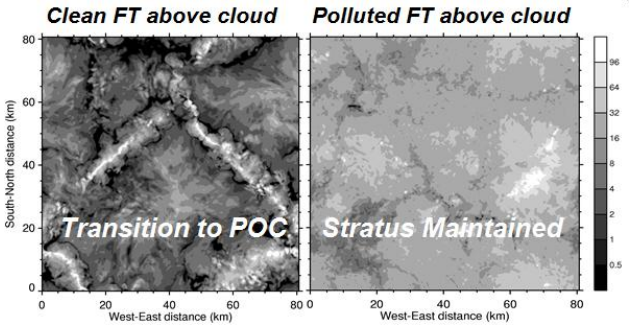

Figure 2. Modeled LES cloud optical depth after 21hr simulation of cloud evolution in clean SC topped MBL resulting in transition to POC (left). Similar model for case with pollution layer located above cloud (Fig. 1, right) showing no evidence of transition to POC.

We hypothesize that such entrainment of pollution and the resulting elevated CCN concentrations in the MBL can help buffer clouds over the SEP against depletion of CCN by drizzle. This may suppress the transition of closed cell to open cell convection, leading to increased lifetimes of Sc clouds that entrain such aerosol. If confirmed by additional ongoing investigations this would be important because increased cloud cover, caused by suppressed POC formation, would have significant regional radiative effects. These are expected to add to but greatly exceed those caused by an albedo increase from associated increases in CCN.

Aerosol cloud interactions of trade wind cumuli
A single cloud contact analysis

F. Ditas[1], B. Wehner[1], H. Siebert[1], R.A. Shaw[2], H. Wex[1], T. Schmeißner[1], G. Roberts[3,4], A. Wiedensohler[1]

Presenting author email: ditas@tropos.de

Aerosol and cloud microphysical properties of trade wind cumuli were observed during the CARRIBA (Clouds, Aerosol, Radiation, and tuRbulence in the trade wInd regime over BArbados) experiment in November 2010 and April 2011. Measurements were performed by the helicopter-borne measurement platform ACTOS (Airborne Cloud Turbulence Observation System, Siebert et al. 2006) with high temporal and spatial resolution. For detailed information about the aerosol instrumentation the reader is referred to Wehner et al. 2011.

A single cloud contact analysis is carried out, providing statistical information about e.g., activation diameter and critical supersaturation (S_{crit}) of each observed cloud. The analysis is based on two different methods: a) deriving the activation diameter by comparison of aerosol number size distributions (NSDs) inside and outside the cloud, b) calculating the fraction of activated particles by comparison of interstitial aerosol and cloud free aerosol number concentration. Simultaneous measurements of cloud microphysical properties allow aerosol – cloud condensation nucleus – cloud droplet number concentration closure studies to evaluate both methods.

Figure 1 demonstrates method a), it shows NSDs inside and outside of a trade wind cumuli observed on Nov. 15th 2010. NSDs under cloud free conditions show a typical bimodal structure, whereas for the NSDs of the interstitial aerosol inside the cloud the accumulation mode is vanished due to cloud droplet activation. The black line indicates the fraction of activated particles (η), the shaded area corresponds to the number of activated particles of $N_{act} = 100$ cm^{-3}. From $\eta = 0.5$ we derive an activation diameter of $d_{p50} = 80$ nm which is close to the Hoppel-minimum of the number size distribution. For particles in this size range a critical supersaturation of $S_{crit} = 0.3\%$ is required to activate to cloud droplets (for ammonium sulfate, 70% soluble fraction).

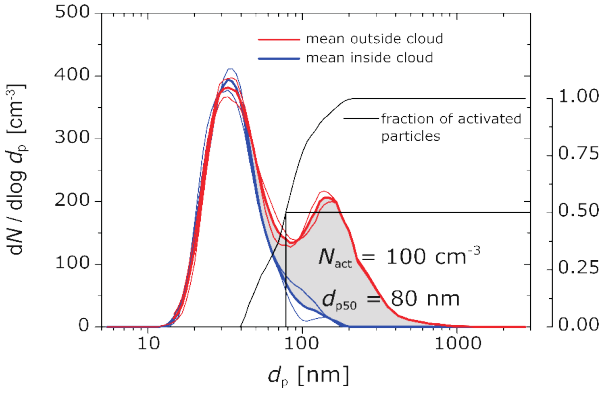

Fig. 1. Aerosol number size distributions inside (blue) and outside (red) clouds. Black line indicates the fraction of activated particles.

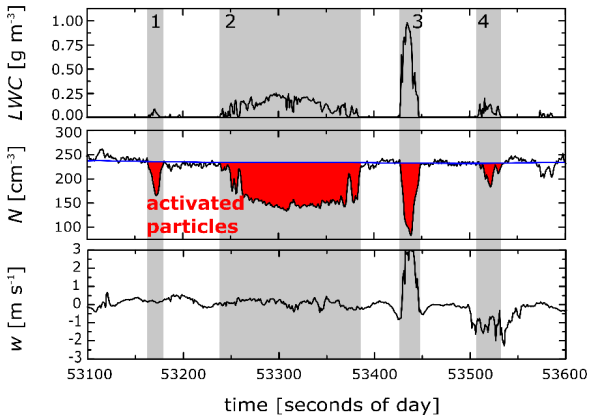

Fig. 2. Time series of liquid water content (*LWC*), interstitial aerosol particle concentration (*N*) and vertical wind velocity during a typical flight leg at cloud level. Grey shaded areas mark 4 cloud contacts, fraction of activated particles is indicated in red.

Figure 2 shows a time series at cloud level and illustrates partly method b). The red area refers to the fraction of activated particles which is related to the activation diameter with the help of integrating the aerosol number - size - distribution. Furthermore, the critical supersaturation is calculated by using Köhler theory. First results of single measurement flights under clean, marine conditions show for actively growing cumuli lowest activation diameter of $d_p = 40$ nm, corresponding to a critical supersaturation of $S_{crit} = 0.7\%$ (for similar chemical properties as used above).

Finally, this analysis is applied to measurement flights of both campaigns in November 2010 and April 2011 covering different meteorological conditions and aerosol types.

Keywords: aerosol cloud interaction, atmospheric aerosols, optical properties, scavenging.
Presenting author email: Ari.Leskinen@fmi.fi

The direct effect of aerosols to radiative forcing arises from light extinction by aerosol particles, i.e. light scattering from and absorption to the aerosols, and it still has a great uncertainty. Evaluation of its magnitude is complicated, because the optical properties depend on the wavelength of the incident light and the angular distribution of the scattered light, which, in turn, depends, e.g., on the size, concentration, and chemical composition of the aerosol particles.

The Puijo measurement station on the top of an observation tower (306 m a.s.l. and 224 m above the surrounding lake level) near the town of Kuopio in Finland has provided continuous data on aerosol-cloud interactions since 2006. Since then the station has been covered by clouds 15 % of the time and is occasionally influenced by e.g. sulphurous compounds and black carbon emitted from local sources. The former are good scatterers of light and the latter absorbs light efficiently.

With a special inlet setup (total and interstitial inlets) and a switching valve system we are able to separate the activated particles from the interstitial (non-activated) particles. This enables us to define the activation properties for aerosol size distribution between 3–800 nm, measured with two differential mobility particle sizers, light scattering at the wavelengths of 450, 550, and 700 nm, measured with a nephelometer (TSI Model 3563) and light absorption at the wavelength of 670 nm, measured with a Multi-Angle Absorption Photometer (Thermo Model 5012).

The level of cloud scavenging depends not only on the aerosol size but also its chemical composition and atmospheric age. We have found that during a cloud event the scattering and absorption values for non-activated particles compared to those for the activated particles are sometimes smaller and sometimes not (Leskinen *et al.* 2012). The decrease is stronger for scattering than for absorption. This may be due to the fact that the absorptive material, e.g. fresh soot, is generally hydrophobic and therefore inhibits activation.

The stronger decrease in scattering results in a decrease in the single scattering albedo (SSA), which is the ratio of scattering to extinction (scattering + absorption). The SSA determines whether an aerosol layer causes net heating or cooling. For example, during two cloud events the SSA dropped from its initial value of 0.80–0.85 to as low as 0.4–0.5, on an average (Figure 1). A similar, but not as intensive, decrease in the SSA was observed by Berkowitz *et al.* (2011) in a foggy situation.

The scavenging is less efficient when the wind blows from the direction of local pollutant sources (the first cloud event in Figure 1) than when it blows from a cleaner sector with no local sources (the second cloud event in Figure 1). A similar observation was done by Sellegri *et al.* (2003) who concluded that the scavenging efficiency in clouds is enhanced by aging of organic species and subsequent mixing.

After the second cloud event the incoming air was clean and the scattering and absorption coefficients decreased to the same levels as during the second cloud. The low SSA values can be explained by the uncertainties in the low scattering and absorption coefficients and by the sensitivity of the SSA to the scattering coefficient value, especially in dry conditions.

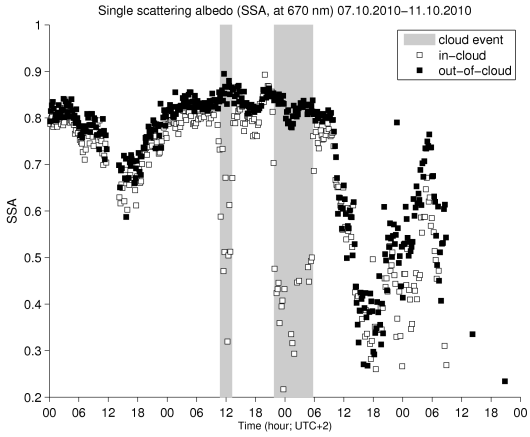

Figure 1. Single scattering albedo (SSA) before, during and after two cloud events at Puijo in October 2010.

Presenting author email: zsofia.juranyi@fhnw.ch

Ambient aerosols are usually complex mixtures of particles with different physical and chemical properties and consequently distinct hygroscopic behaviour. The hygroscopicity of a particle determines its water uptake at subsaturated relative humidity (RH) and influences its ability to form a cloud droplet at supersaturated RH. These processes influence the Earth's climate and the atmospheric lifetime of the particles as well.

HTDMA measurements are widely used and accepted to determine the size-resolved hygroscopicity mixing state of aerosols. Several studies on ambient aerosol were performed where, next to the overall hygroscopicity, the mixing state of the particles was investigated as well. The same hygroscopicity mixing state can be also derived from cloud condensation nuclei (CCN) counter measurements (Su et al. 2010), however it is barely done, and to our knowledge no hygroscopicity closure study was performed that does not only compare the agreement between the average hygroscopicity but also its proper distribution.

The CCN number size distributions covering 10 different supersaturations (0.1-1.0%) and total particle (CN) number size distributions from 10 to 440 nm were measured for a 10-day period during the MEGAPOLI campaign in winter 2010 in Paris. This was achieved by adding a CCN counter (CCNC) in parallel to the condensation particle counter of an SMPS (Scanning Mobility Particle Sizer) system. In addition, the mobility diameter growth factor probability density functions (GF-PDF) below saturation (at 90% RH) at 6 different dry diameters (35-265 nm) were determined from Hygroscopicity Tandem Differential Mobility Analyser (HTDMA) measurements.

Distributions of the commonly used κ parameter (Petters and Kreidenweis, 2007) were derived from both HTDMA and CCNC measurements. The CCNC derived mean particle hygroscopicity was as low as κ=0.14 averaged over all dry particle sizes and decreased with increasing supersaturation (SS) (corresponding to a decreasing dry activation diameter) from 0.09 to 0.24 at SS=1.0-0.1%. During the measurement period the aerosol was often highly externally mixed, HTDMA measurements revealed often bi- or tri-modal GF distributions, and the time dependent average GF values show significant variability as well. As an example, for the 110-nm particles ~80% of the performed scans had more than 1 GF mode and the mean GF varied between 1.1 and 1.48 within the 10 days of measurement.

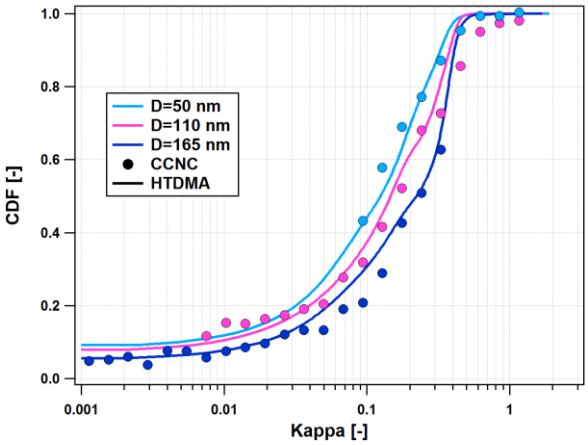

Figure 1. κ hygroscopicity parameter cumulative distribution functions (CDF) at different dry diameters as derived from hygroscopicity measurements.

Figure 1 shows the hygroscopicity (κ) cumulative distribution functions for 3 selected dry sizes (diameter D = 50, 110 and 165 nm) determined for sub- and supersaturation. It can be seen that not only the average hygroscopicity (median κ) but also its distributions agree very well between sub- and supersaturation. Based on these results, we can state that the hygroscopicity mixing state can also be successfully derived from CCN number size distribution measurements and that the assumptions used in the closure such as κ parameterisation, use of the surface tension of pure water were valid.

The success of the closure for this fast-changing, highly externally mixed, complex aerosol also suggests that significant differences between sub- and supersaturation reported in some previous hygroscopicity closure studies, might originate from measurement uncertainties and/or from insufficient time- and size-resolution.

Keywords: ice nuclei, biogenic particles, mixed phase clouds.
Presenting author email: hartmann@tropos.de

Atmospheric observations indicate that heterogeneous ice nucleation in mixed-phase clouds can already occur at a temperature higher than - 20 °C (Seifert *et al.*, 2010). In contrast, laboratory studies showed that, e.g., mineral dust and soot particles, which are two of the major components of ice crystal residues (e.g., Pratt *et al.*, 2009), function as ice nuclei (IN) at lower temperatures. One possible explanation for the observed temperature differences might be the presence of biological particles (one out of three particles have biological origin, Pratt *et al.*, 2009) acting as IN already at temperatures above - 20 °C. Biological particles such as bacteria and pollen possess membrane proteins and non-proteinaceous macro-molecules, respectively, acting as template for ice cluster formation reducing the energy barrier required for ice nucleation. Nevertheless, the dominating freezing mechanism, the properties inducing ice nucleation, and the relative importance of biological particles in the atmosphere are still unclear.

In our study, the immersion freezing behaviour of different size-segregated biological particles is investigated at the laminar flow tube LACIS (Leipzig Aerosol Cloud Interaction Simulator, Hartmann et al., 2011). SNOMAX®, outer membrane vesicles (OMV) and surface material of pollen was used for the analysis. SNOMAX® is considered as convenient surrogate for bacterial IN and contains ice nucleation active proteins. Bacterial strains, here extracted and cultured from rain samples (Temkiv *et al.*, 2011), have the ability to produce outer membrane vesicles, which might also contain ice nucleation active proteins. Surface material washed off from pollen grains (e.g. birch) includes macro-molecules which induce ice nucleation (Pummer *et al.*, 2011).

Figure 1 shows the ice fraction f_{ice} (number of frozen droplets per sum of frozen and unfrozen droplets) as function of temperature for all biological particles investigated. For 800 nm SNOMAX® the freezing curve is very steep in a temperature range from -5 °C to -10 °C and levels off to constant values of about 0.4, i.e., 40 % of SNOMAX® particles are ice active. The ice fractions observed for the OMV containing particles where close to the detection limit (in the order of 1 % and lower). This indicates that only a small fraction of the OMV particles nucleate ice. However, considering the small size of the OMV particles (ranging between 50 nm and 160 nm as shown in Temkiv *et al.*, 2011) it might be possible that compared to SNOMAX®, the significantly reduced IN ability is mainly due to size effects. The IN contained in the washing water of birch pollen grains nucleated ice below -18 °C with f_{ice} curve having a slightly shallower slope than observed for SNOMAX®. About 80 % of the 800 nm particles might include at least one ice nucleation macro-molecule.

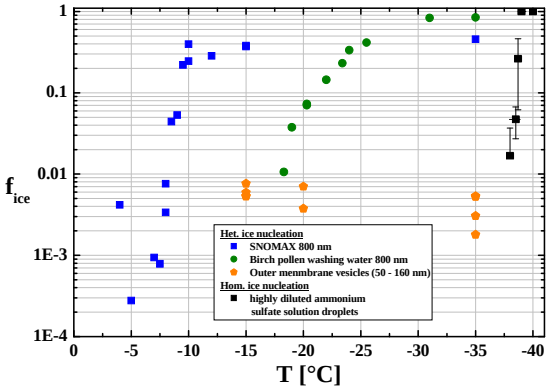

Figure 1. Ice fraction f_{ice} as function of temperature for 800 nm SNOMAX® and birch pollen washing water as well as different sized outer membrane vesicles as well as highly diluted ammonium sulphate solution droplets.

In conclusion, investigating the ice nucleation behavior of quasi monodisperse biological IN, SNOMAX® was found to be the most ice nucleation active substance, followed by the residues of birch pollen washing water. Outer membrane vesicles featured the lowest ice nucleation potential.

Presenting author email: janp@chem.gu.se

Deposition of water on aerosol particles contributes to ice cloud formation in the atmosphere with implications for the water cycle and climate on Earth. Heterogeneous ice nucleation is influenced by physico-chemical properties of substrate particles, but the mechanisms remain incompletely understood.

Here we investigate heterogeneous ice nucleation via deposition mode freezing on graphite and alcohol-covered graphite surfaces. The overall aim is to identify and characterize governing mechanisms in ice formation by deposition freezing, which can be used to guide the further development of a molecular-level description of the process. The investigated surfaces have pronounced hydrophobic and hydrophilic properties. They are simplified compared to systems found in the atmosphere, but display some characteristics that mimic properties of soot, soot coated with organics, and secondary organic aerosol particles. We describe the results from studies of pure water, and water-methanol and water-butanol mixtures at temperatures up to 213 K using elastic helium scattering and light reflection techniques. Surface science experiments at these relatively high temperatures are made possible by the use of a recently developed Environmental Molecular Beam (EMB) method that allows for experiments at pressures up to $\approx 10^{-2}$ mbar (Kong *et al.* 2011; Thomson *et al.* 2011).

We observe that nucleation of ice on a bare graphite crystal becomes increasingly inefficient as the surface temperature decreases below 200 K. The hydrophobic graphite also prevents efficient wetting in this temperature range, resulting in rough ice surfaces (e.g., Figure 1).

Adsorption of a monolayer of methanol on the graphite surface changes it from hydrophobic to highly hydrophilic. The methanol molecules provide sites for efficient hydrogen-bonding of water molecules, which stabilizes water on the surface compared to the bare graphite. Ice nucleation on the hydrophilic surface takes place at lower supersaturations than on the hydrophobic surface, and the adsorbate thus influences the absolute nucleation rate at a given temperature. Pre-adsorption of methanol also results in the growth of smooth crystalline ice (Figure 1) in sharp contrast to the rough ice surfaces grown on bare graphite (Kong *et al.* 2012).

Adsorption of a butanol monolayer results in an ice nucleation efficiency intermediate between the other systems. Butanol forms a highly stable solid layer on graphite. Water does not appear to wet the butanol layer efficiently and the water stability on the surface is lower

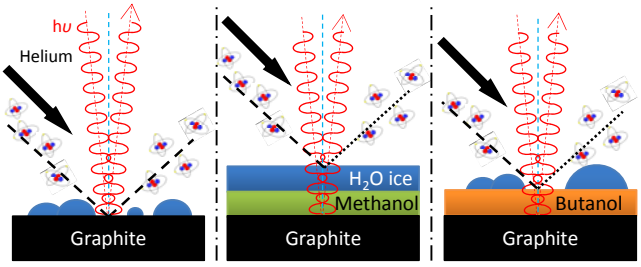

Figure 1. Schematic illustration of ice growth on bare and alcohol-covered graphite surfaces. Elastic helium scattering and light scattering were used to probe ice formation on the substrate.

than on the methanol layer. We conclude that the hydrophilicity of the different investigated surfaces influences the absolute nucleation rate. However, the supersaturation required for nucleation increases rapidly with decreasing temperature, and the overall trend with temperature is similar for all systems.

The combination of the present investigations of carbon-based hydrophobic and hydrophilic systems with existing literature provides us with a sufficient data set to allow us to generalize the behaviour of the deposition freezing process at low temperatures. Although the substrate plays a role, the overall trends with temperature are similar for different surfaces and therefore the explanation for the observed inefficient nucleation at low temperatures must be related to the inherent properties of water. The importance of the results for cloud formation processes in the Earth and Martian atmospheres are discussed.

To understand the formation and evolution of clouds in the atmosphere, airborne in-situ measurements of liquid and ice cloud particle sizes and concentrations are essential. Recently, the particle measurement techniques are under revision to rule out possible scientific misinterpretations due to particle artifacts, i.e. ice crystals shattered or drops splashed at the instruments edges.
Here, we present NIXE-CAPS single droplet and ice crystal measurements in the temperature range between -40 C and 0°C observed at the AIDA cloud chamber, in mixed-phase clouds over the UK during the COALESC field campaign in 2011 and over Northern Canada during the VERDI campaign in 2012. NIXE- CAPS (Novel Ice EXpEriment - Cloud and Aerosol Particle Spectrometer, manufactured by DMT) is a cloud particle spectromete which measures the cloud particle size and phase in the size range 0.6 - 945μm. The AIDA chamber is especially suitable for testing the cloud instrumentation performance without influences induced by aircraft. Comparison of NIXE-CAPS to a number of other instruments such as SMPS, APS, WELAS, SID3, PHIPS and VIPS shows an overall good agreement.

In both the chamber and the natural clouds ice crystals in the size range of 1 to several 100μm are detected. We found that the shape of the ice size distributions mirrors the drop spectra. They are unimodal in nonraining clouds with one cloud drop mode and bimodal in clouds where precipitation sized drops have developed.
The mean total ice crystal number concentration observed in the natural clouds during COALESC agrees well with the number of ice nuclei reported by DeMott et al. (2010), PNAS. On average, the mass of cloud water that is converted to ice increases with decreasing temperature. Slightly below 0°C the clouds were liquid, the highest ice mass fraction is found to be 80%. Complete glaciation is not detected in the stratocumulus mixed phase clouds over the UK.

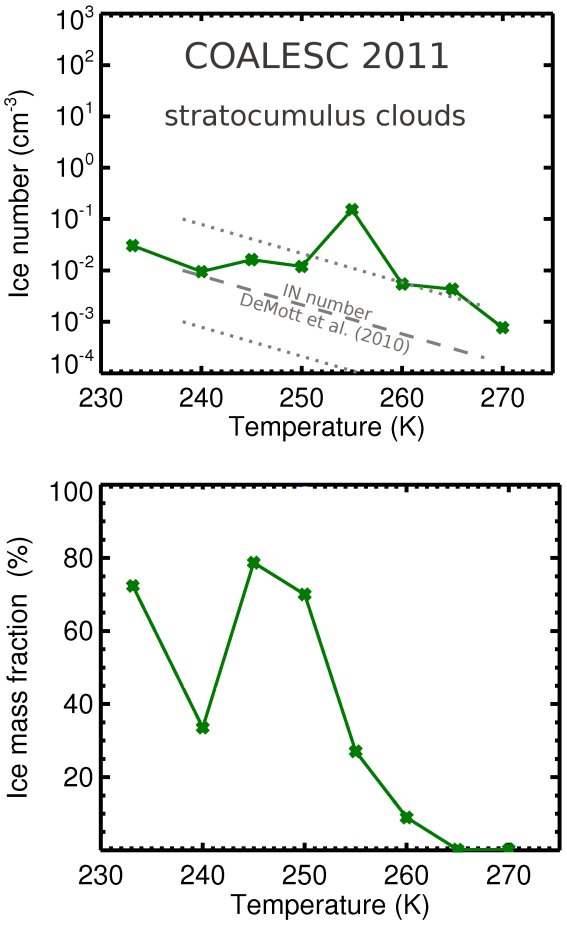

Figure 1: Mean total ice crystal number and ice mass fraction in stratocumulus mixed phase clouds during COALESC 2011 (UK).

Session WG11S1O. Electrical effects

Indirect Photoelectric Diffusion Charging of Aerosols

B. Grob[1] and R. Niessner[1]
[1]Chair for Analytical Chemistry, Technical University of Munich, Munich, Bavaria, 81377, Germany
Keywords: particle charging, particle counting
Presenting author email: benedikt.grob@mytum.de

Black carbon has a big impact on the public health as well as to the climate. Therefore the upcoming exhaust emission standards Euro 5b and 6 for diesel engines include a strict limit of 6.0×10^{11} particles/km of non-volatile particles. To measure the particle emission of engines, complicated measurement set-ups are necessary, which can handle high particle concentrations, prevent coagulation, separate non-volatile and volatile particles and count efficiently particles in the low nanometer-range. The idea of the car manufacturers currently is to use condensation nucleus counters (CNC), which causes many problems due to measurement reproducibility and to their susceptibility to chemical particle composition (Giechaskiel, 2009 and 2011). An alternative is the counting of unipolar charged particles by a aerosol electrometer. However, a unipolar charging method is necessary, which can charge particles in a range of 10 to 100 nm efficiently.

In this study we are using a modified set-up published by Bucholski and Niessner (1991). It consists of an elliptically grooved, electrically grounded alumina block (Figure 1). A UV lamp is fixed in one focus of the ellipse to concentrate the light to the second focus. The aerosol flux is pumped through a quartz tube placed in the second focus. In the medial axis of the tube a metal rod is installed. On the rod a voltage can be applied. The idea is to emit electrons on the metal surface, due to the photoeffect. The photoelectrons can charge directly by diffusion the aerosol particles or form negative ions by attachment processes, which itself collide with the aerosol particles. It was shown that the set-up is working for NaCl particles, with a gold or nickel rod at a wavelength of 185 nm (Bucholski & Niessner, 1991).

The challenge for charging black carbon particles is to find a material for the rod which has a lower work-function then the particle. It has to be avoided to perform the photoelectric charging directly on the particle surface. Additionally the ozone formation has to be prevented, which will take place in a combustion aerosol by radiation with 185 nm photons. Therefore we changed the set-up to a UV lamp of 254 nm and a magnesium rod.

With this method it seems to be possible to charge the particles with a efficiency of over 90% (Figure 2). To prove the system we study several questions like influence of particle size, surface morphology, particle concentration and effect of multiple charging. We think with our approach of the indirect photoelectric diffusion charging we can overcome the disadvantages of the directly photoelectric aerosol charging and we provide an alternative to the particle counting by a CNC.

We present mobility distribution measurements of both positive and negative ions produced by corona discharge under different conditions. Here, the measured mobilities of the corona-generated ions are converted to Millikan-Fuchs equivalent mobility-diameters (Mäkelä et al., 1996). The chemical composition of the ions was measured in parallel with the mobility measurements. The aim was to characterise both the mobility and chemical composition of the ions generated by a corona-needle charger from the Neutral cluster and Air Ion Spectrometer (NAIS, Manninen et al. 2009) with state-of-art instrumentation.

The corona-generated ions were characterized with a high resolution Herrmann Differential Mobility Analyzer (H-DMA), which has nearly monomobile transfer functions (sample to sheath flow ratio ~1:100). The negative corona ions were < 1.6 nm (0.8 $cm^2 V^{-1} s^{-1}$ in mobility) in all the tested gas mixtures (nitrogen, air with variable mixing ratios of water vapour), whereas the positive ions were < 1.7 nm (0.7 $cm^2 V^{-1} s^{-1}$). An Atmospheric Pressure Interface Time-Of-Flight mass spectrometer (APi-TOF, Ehn et al. 2011) was used to measure the mass/charge ratios of corona-generated ions, from which we can find quite accurately (<20 ppm) their exact masses which correspond to certain elemental compositions.

Our results indicate that in the corona discharging process the mobility and the concentration of ions depend both on the corona voltage and on the physical and chemical properties of the carrier gas mixture. The role of the water vapour is pronounced. The chemical composition of corona-generated ions has been observed to depend on the trace gas composition and time for reactions, as one could expect. The results of this study help in understanding the large scattering of ion mobility values given in earlier publications.

The mobility distribution of the positive and negative corona-generated ions, shown in Fig. 1, illustrates the effects of carrier gas and impurities in the sample lines on the size distribution observed during laboratory experiments. Asmi et al. (2009) and Manninen et al. (2011) both used the corona discharger of the NAIS to generate these ions. Basically, the only difference between the experiments is the design of the sample lines and the exact composition of the carrier gas, as the charger current stayed constant in both experiments. In Fig. 1, the black dots represent corona-generated ions carried by filtered compressed air and the gray stars represent ions carried by room air. The room air contains e.g. more water vapour compared to the compressed air.

This result found an agreement with earlier publications and indicated that the mobility and concentration of charger ions generated in the corona charging process depend strongly on the properties and composition of the carrier gas. Therefore, in field conditions the corona-generated ion mobility and composition changes with time when the corona discharger is used to charge the aerosol sample.

Therefore, the corona-generated ions complicate NAIS particle detection in the measurement range which overlaps the mobility range of charger ions. The positive and negative corona-generated ions were smaller than 1.8 and 1.6 nm, respectively, which results in the lower detection limit of approximately 2 nm for the NAIS particle measurements. Thus, particles below a diameter of ~2 nm cannot be reliably distinguished from the corona-generated ions. An efficient filtering of these ions, but not the charged particles, at different operating conditions is essential for achieving the lowest possible size limit for the electrical detection of charged particles.

Study of the corona discharge in the syngas at various gas temperatures and pressure

A. Bologa, H.-R. Paur, H. Seifert and K. Woletz

Institute for Technical Chemistry, Karlsruhe Institute of Technology
Hermann-von-Helmholtz-Platz 1, Eggenstein-Leopoldshafen, 76344, Germany
Keywords: corona discharge, gas composition, temperature, pressure
Presenting author email: andrei.bologa@kit.edu

The use of corona discharge opens broad possibilities for developments in many fields such high temperature / high pressure electrostatic precipitators (HT/HP ESPs'), electrohydrodynamic pumps, heat exchangers, decomposition of toxic gases, etc. (Chang *et al*, 1995, Bologa *et al*, 2011,a).

The corona discharge occurs when a high voltage is applied between two electrodes with substantially different radii of curvature. The charge generation and transport in the gaseous media is one of the key-points of corona discharge which characteristics strongly depend on gas composition, velocity, temperature, humidity and pressure; electrode system geometry; form, value and polarity of applied voltage and electrogasodynamic phenomena in electrode system, etc. (Bologa et al. 2011,b) By gas cleaning in electrostatic precipitators, the corona discharge characteristics depend on particle mass and number concentration in the exhaust gas, particle physical properties, aerosol space charge, loading of the electrode system with precipitated aerosol, etc. The objective of the current work is the study of the corona discharge at various temperatures and pressures in the syngas (a gas mixture which contains varying amounts of H_2 and CO). The 1st purpose is to define the conditions of stable corona discharge which ensure effective charging of particles and their precipitation. The 2nd purpose is to observe the phenomena in the HT/HP syngas in the corona discharge ionizer. The aim is the development of the new type of high temperature / high pressure electrostatic precipitator.

The experimental studies are carried out with a high temperature / high pressure ionizer (Bologa *et.al*, 2011,a,b). The ionizer is installed inside of a high pressure vessel (gas pressure up to 2,0 MPa and temperature up to 500°C). The electrode gap between the high voltage and grounded electrodes is 10 mm. The tests were carried out with two different gas mixtures. The first one contained 25,7 Vol.% H_2; 38,0 Vol.% CO; 18,3 Vol.%CO_2; 0,2 % of CH_4 and rest (17,8 Vol.%) was N_2. The second one contained 40 Vol.% of H_2 and 60 Vol.% of CO.

The current-voltage characteristics of the negative corona discharge in the 1st gas mixture for various temperatures and pressures are presented in the Figure 1 and 2. The corona current by the negative polarity of applied voltage was higher than for positive polarity of applied voltage. At room temperature conditions the increase of gas pressure strongly suppresses the corona discharge (Fig.1). By increase of gas temperature, the conditions of stable corona discharge are extended to higher gas pressures (Fig.2).

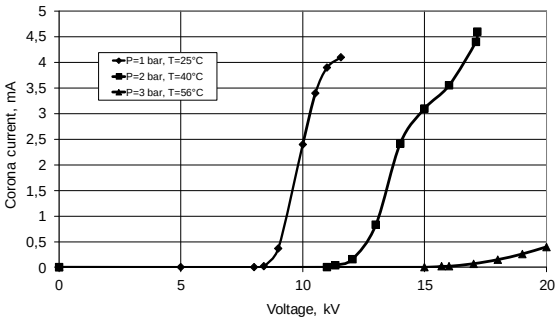

Figure 1 Corona discharge at room conditions.

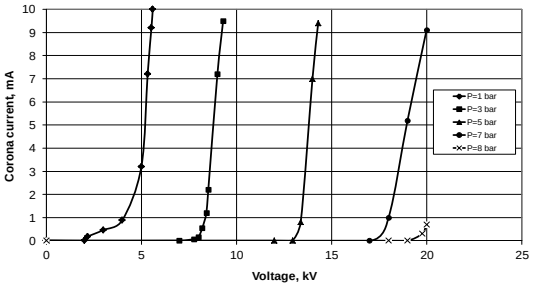

Figure 2 Corona discharge at 500°C.

By the experimental studies the following phenomena were observed. By high temperatures, the application of corona discharge:
(i) can change the composition of the 1st gas mixture. It was observed the increase of CO_2 and corresponding decrease of CO concentrations;
(ii) can provoke the generation of nanoparticles in the ionizer stage from the 1st gas mixture which are precipitated inside of the ionizer under the influence of the electric field forces;
(iii) by special design of the electrodes, in the 2nd gas mixture a large quantity of aerosol can be generated during relative short period of time. By aerosol generation, the decrease of gas pressure inside of the HT/HP vessel was observed.

Stability of the cone-jet mode in electrohydrodynamic spraying

J.L. Castillo, S. Martin, A. Perea and P.L. Garcia-Ybarra

Dept. Fisica Matematica y de Fluidos, Facultad de Ciencias UNED, Madrid, Spain
Keywords: Electrospray, Particle deposition, Deposit morphology, Material synthesis
Presenting author email: jcastillo@ccia.uned.es

Granular materials with a given microstructure may be efficiently prepared via an aerosol route starting with the electrohydrodynamic atomization of a liquid suspension. The liquid is pumped through a needle under the presence of strong voltage differences between the needle and the surroundings. Then, the electrosprayed charged droplets evaporate along their pathway leaving a dry residue that deposits on a collecting plate (Martin et al., 2010a, 2010b). For attaining a highly porous material at the deposit, the collecting plate must be kept relatively far from the electrospray ejecting needle as the solvent must have enough time to evaporate during the flight of the droplets. On the other hand, the efficiency in the capture of the dry particles substantially improves when a negative voltage is applied to the collector plate, leading to an electric field that forces the charged particles to deposit preferentially over the plate. Under these conditions, the intensity of the *electric field at the needle exit* controls the operating mode of the electrospray whereas the strength and homogeneity of the *electric field at the plate* surface determines the deposition features of the charged particles and thus, the morphological properties (bulk porosity, compactness and surface roughness) of the formed deposit (Rodriguez-Perez et al, 2005, 2007).

The electrospray should work in a stable mode to be used as a steady generator of almost monodisperse droplets. A steady cone-jet mode (consisting of a Taylor cone formed at the needle exit and a very thin jet emerging from the cone tip) is only achieved in a range of flow rates and voltage differences.

In the classical electrospray configuration (Cloupeau and Prunet-Foch, 1989) a high positive voltage (V_n) is imposed at the needle and the liquid is ejected at a given flow rate, Q, toward a collecting plate connected to ground. Then, Q and V_n remains as the control parameters and the cone-jet mode is stable in a stability island on the (Q, V_n) space. The borders of the island depend on the liquid properties (electrical conductivity, viscosity and surface tension) and in minor extend on geometrical aspects.

However, other configurations may lead to significant changes in the stability island. Indeed, an opposite polarity at the plate is required when the main objective of the electrospraying process is to collect the charged particles emitted at the needle. This configuration introduces a new degree of freedom in the experimental set-up; that is, the voltage applied to the plate (V_p), with some additional parameters that affect the electric field at the needle exit: the needle-plate distance and the plate dimensions.

The present work (Castillo et al, 2012, Martin et al, 2012) extends previous studies by performing an experimental investigation on the stable cone-jet domain when a voltage is also applied to the plate. For completeness, positive as well as negative polarities of the plate voltage are investigated, showing the changes induced in the range of liquid flow rates compatible with a stable cone-jet mode configuration.

Thus, the stability island corresponding to the electrohydrodynamic spraying of different liquids [a pure liquid (ethanol), a liquid mixture (isopropanol+Nafion®) and liquid suspensions (Pt on carbon nanoparticles in ethanol)] has been experimentally determined. A broader range of liquid flow rates compatible with a stable cone-jet mode is observed. Thus, the two-dimensional cone-jet domain in the classical needle voltage-flow rate diagram (for a grounded plate) is recovered as embedded in the three-dimensional parameter space (Q, $V_n - V_p$, V_p). When the voltage polarity applied to the plate is opposite to the needle polarity, the maximum flow rate compatible with the cone-jet regime is much larger than for an electrically grounded plate. This amplification factor increases with the liquid electrical conductivity. Also, when liquid suspensions (based on Pt/C nanoparticles in ethanol) are electrosprayed, the maximum flow rate is more than twice the value for a grounded plate.

This configuration allows a suitable control of the whole process (electrospray + deposit formation + deposit morphology) and opens the door for preparing new materials as those required for fuel cell electrodes.

Electrospray deposition of nanoparticles onto airborn microparticles

C.U. Yurteri[1], N. Ellis[2], J.R. van Ommen[1]

[1] Delft University of Technology, Faculty of Applied Science, Julianalaan 136, 2628 BL Delft, The Netherlands
[2] University of British Columbia, Chemical and Biological Engineering, 2360 East Mall, Vancouver, BC V6T 1Z3, Canada

Keywords: coating, nano_particles, electrospray.
e-mail: c.u.yurteri@tudelft.nl

Coated particles are common in industrial and pharmaceutical applications. Coating surfaces of micron-sized particles (host particles or carriers) with nanoparticles (guest particles) can set up chemical or biological contact points allowing diagnosis and treatment of respiratory diseases, adding functionalities, such as changing the hydrophobic or hydrophilic behaviour, anti-reflex performance or the catalytic activity. In case of inhalation, nanoparticles can also be more efficiently transported using micro vehicles [1-3].

Coating can be realized via either dry or wet coating techniques. However, dispersing dry nano-sized particles in the former case, and use of liquid solvents and dispersants requiring evaporative removal during dispersion steps in the latter case are among major challenges. A solution for dispersing and directly depositing nanoparticles in one step can be realized by Electrohydrodynamic atomization (EHDA), also called electrospraying, a process where a liquid jet breaks up under the influence of electrical forces. EHDA comes with unique advantages: a narrow droplet size distribution; and self dispersing of droplets due to unipolar charged droplets. Electrospraying suspensions of nanoparticles results in a charged spray of nanoparticles, overcoming the challenges of dispersing and depositing nanoparticles on a substrate.

The charged nature of nanoparticles via EHDA can be utilized to coat host particles charged with opposite polarity by means of tribocharging, field, diffusion, or inductive charging to enhance the efficiency of deposition. Furthermore, mechanical, or electrostatic interactions can also be utilized to combine particles. In the latter case, a bipolar coagulation due to the mutual electrostatic attraction force between the negative and positive charges will take place. Thus, guest particles deposit on the surface of host particles while airborne. Figure 1 is a typical result from such interaction. Once coated, the van der Waals forces keep nanoparticles from detaching from host particles. The coating level is controlled by the interaction time, the concentration of the suspension, and the charge of host particles in the spray.

Several possibilities to accomplish mutual interaction of oppositely charged particles in order to deposit electrosprayed or electrospray formed nanoparticles on micron-sized particles have been studied by our group. By controlling the electrostatic charge of host particles relative to the charge of nanoparticles, the coating quality can be optimized.

We will present results from various process lay-outs and demonstrate a novel approach for continuous production of nanostructured particles. The approach is based on various processes: fluidization, tribocharging, elutriation, and electrohydrodynamic atomization.

Determination of the Transition Regime Collision Rate in the Presence of Potential Interactions from Mean First Passage Time Calculations

Christopher J. Hogan Jr.[1], Ranganathan Gopalakrishnan[1], Hui Ouyang[1]

[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, 55455, USA
Keywords: Coagulation, Diffusion Charging, Transition Regime, Brownian Dynamics
Presenting author email: Hogan@me.umn.edu

The behaviour of aerosol nanoparticles is strongly influenced by collisions between particles (leading to adherence; coagulation), as well as particles with ions (leading to charge transfer; diffusion charging). Complex about these processes is that 1). collision processes for nanoparticles in atmospheric pressure environments occur in neither in the mass transfer continuum nor mass transfer free molecular regimes (they occur in the transition regime), and 2). particle-particle and particle-ion interactions also influence collision rates. Traditionally, the flux matching approach of Fuchs (1963) has been used to predict collision rates in the mass transfer transition regime, and in comparison to experimental results this approach has been shown to be quite successful in the absence of potential interactions. Recent work (Gatti & Kortshagen, 2008), however, reveals that in the presence of strong attractive potential interactions between colliding entities, application of the flux matching approach to collision rate calculation may be problematic. Specifically, in the standard application of flux matching, a limiting sphere concept is employed, whose radius defines the boundary between continuum and free molecular motion. Problematic in the use of this concept is that on the limiting sphere radius, the velocity distribution of particles is not known in the presence of strong potential interactions, and, in the case of strong attractive interactions, completely free molecular motion does not describe well particle motion inside the limiting sphere (Gopalakrishnan & Hogan, 2012).

We describe an alternative approach for the examination of collision rates in the transition regime in the presence of potential interactions between colliding entities: mean first passage time calculations. In this method, the relative motion between colliding entities in the gas phase is monitored by a Langevin equation. From determination of the average time necessary for entities to collide under specified conditions (the mean first passage time), the collision rate is inferred. In conjunction with mean first passage time calculations, it is shown that regardless of the functional form for the potential between colliding entities, the collision rate coefficient, β_{ij}, can be non-dimensionalized as:

$$H = \frac{\beta_{ij} m_{ij} \eta_C}{f_{ij} (a_i + a_j)^3 \eta_{FM}^2} \qquad (1)$$

where m_{ij} is the reduced mass of the colliding entities, f_{ij} is their reduced friction factor, a_i and a_j are the radii of the colliding entities, and η_C and η_{FM} are the potential dependent enhancement factors for the collision process in the continuum and free molecular regimes, respectively. The dimensionless collision rate coefficient, H, is found to depend on the diffusive Knudsen number, $\mathrm{Kn_D}$:

$$\mathrm{Kn_D} = \frac{(kTm_{ij})^{1/2} \eta_C}{f_{ij} (a_i + a_j) \eta_{FM}} \qquad (2)$$

where kT is the thermal energy. As shown in figure 1 for the image potential, provided the potential energy/thermal energy ratio is sufficiently low, mean first passage time calculations reveal a near universal relationship to describe collisions, $\mathrm{H(Kn_D)}$ is found:

$$H = \frac{4\pi \mathrm{Kn_D^2} + C_1 \mathrm{Kn_D^3} + (8\pi)^{1/2} C_2 \mathrm{Kn_D^4}}{1 + C_3 \mathrm{Kn_D} + C_4 \mathrm{Kn_D^2} + C_2 \mathrm{Kn_D^3}} \qquad (3)$$

where C_1 =25.836, C_2 = 11.211, C_3 = 3.502, and C_4 = 7.211.

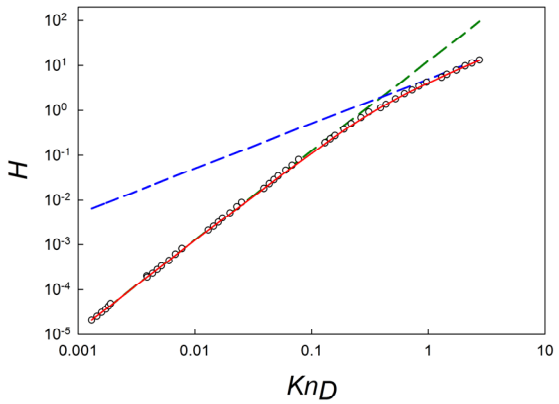

Figure 1. $\mathrm{H}(Kn_D)$ in the continuum limit (green), free molecular limit (blue), from equation (3) (red), and from mean first passage time calculations considering the image potential (open circles).

Spark discharge generators are widely used for a controllable and stable production of high-purity aerosol nanoparticles down to sizes in the range of 1 nm (Schwyn et al. 1988). The mechanism of particle formation is caused by an evaporation/condensation type process based on a capacitive spark discharge between two target electrodes. During spark discharge, material is evaporated from the electrodes, and is immediately quenched in a flow of inert carrier gas. Through coalescence, these clusters grow into bigger primary particles, which are carried away from the discharge zone by the carrier gas.

While little is known about the mechanism of the charging process within the spark discharge, it appears to lead to a much higher charging probability than the Boltzmann-type equilibrium distribution (Tabrizi 2008). Knowledge of the charge distribution would be of great importance, since combining spark generators with mobility classifiers represents a versatile method of producing well-defined nanoparticles. Spark discharge nanoparticle generators usually produce a particle concentration that leads to rapid coagulation, changing the charge distribution.

We report a measurement, which allows derivation of an estimate of the primary particle charge distribution for the size range around 2 nm using Pt as electrode material. In order to calculate the portion of charged primary particles, the total number concentration of particles needs to be measured, and this is the greatest challenge. Due to their small size it is not possible to apply condensation nucleus counters, and charging methods are hardly efficient enough to allow the use of an Aerosol Electrometer (AEM) for the fraction that is initially neutral.

To overcome this limitation, we allowed our primary particles to coagulate in a controlled manner and measured their growth by means of electrical mobility analysis. Particle growth due to coagulation is a function of the particles total number concentration, and the coagulation coefficient, which, in turn, depends on particle size and charge. Coagulation theory (Huang 1990) can then be used to derive the total number concentration of primary particles, if the other parameters are known. With such an approach, due to the dependence of the coagulation coefficient on the charged state of the particles (Maisels 2002), the charged state of primary particles can be outlined.

Measurements of the size distribution of the charged fraction of the generated particles were performed using a High-Flow DMA coupled with an aerosol electrometer (AEM). Primary particles of both polarities were classified in terms of their electrical mobility while preserving their initial charge distribution. In a second run, an agglomeration chamber was placed between the spark generator and the DMA, allowing particles to grow for a very short residence time (ca. 0.6 sec). Shift of mean particle size after agglomeration is the parameter used in the agglomeration model in order to calculate the total concentration of the primary particles.

Results

There is strong evidence for the multiply charged nature of Pt primary particles eroding from the spark discharge. They appear having significantly larger electrical mobility, than the “neutralized” size distribution (fig.1). Calculations showed that higher charged state (mostly 3 charges) defines particle charged state. The portion of triply charged particles was calculated to 0.70% of the total number concentration of primary particles.
