Preface

The European Aerosol Conference is the meeting place in Europe for the international research community working in the field of aerosol science and technology. These conferences are organized under de auspices of the European Aerosol Assembly (EAA) and in 2012 the conference takes place from 2nd to 7th September in Granada, Spain. It is organized by the Spanish Science and Technology Aerosol Association and hosted by the University of Granada, gathering world-class scientists in all fields of aerosol science from fundamentals to applications.

The conference follows the format of previous editions, with oral sessions preceded by a daily plenary lecture in one of the key areas of active aerosol research. Sessions are organized according to the 11 thematic areas of the EAA Working Groups with additional 5 special sessions. The program ensures key sessions dealing with cutting edge activities encouraging the interaction of the community, especially young scientists. Poster sessions are accommodated in the afternoons on Monday, Tuesday and Thursday; with also room for societies and boards meetings requested.

The organizers of the EAC2012 gratefully acknowledge the effort of the EAA Working Groups and the support of the Scientific Committee in the review process, the identification of plenary speakers and setting up of the special sessions. Last but not least, a grateful thank-you to all sponsors and exhibitors for their financial support.

Lucas Alados Arboledas and Francisco José Olmo Reyes
Co-chairs of EAC2012

Committees

Conference Chairman: Lucas Alados-Arboledas
Conference Co-Chairman: Francisco José Olmo Reyes

Organising Committee:

- Inmaculada Foyo Moreno
- Jesús Fernández Gálvez
- Hassan Lyamani
- Francisco Navas Guzmán
- Juan Antonio Bravo Aranda
- Antonio Valenzuela Gutiérrez
- María José Granados Muñoz
- Gloria Titos Vela
- Arturo Quirantes Sierra
- Mª Ángeles Rivas Romera

Technical Program Committee (also responsible for abstracts reviewing):

- Lucas Alados-Arboledas
- Juan Luis Guerrero Rascado
- Rami Alfarra
- Christoph Asbach
- Ari Asmi
- Darrel Baumgardner
- George Biskos
- Andrei Bologa
- David Broday
- Jeroen Buters
- José L. Castillo
- Charles Clement
- Aladar Czitrovszky
- Yannis Drossinos
- Luca Ferrero
- Ian Ford
- Gary Fuller
- Pedro L. García-Ybarra
- Martin Gysel
- Andreas Held
- Regina Hitzenberger
- Helmuth Horvath
- Otto Klemm
- Thomas Kuhlbusch
- Yoshi Iinuma
- Martina Krämer
- François-Xavier Ouf
- Hanns-Rudolf Paur
- Andreas Petzold
- Johannes Schneider
- Manabu Shiraiwa
- Olli Sippula
- Roberta Vecchi
- Elisabetta Vignati
- Birgit Wehner
- Wendelin Stark
- Sabine Wurzler
- Caner Yurteri

The European Aerosol Assembly

The European Aerosol Assembly (EAA) consists of 12 national or regional societies across Europe, though membership of these societies is not limited to European nationals. The major activity of the EAA and its working groups takes place at the European Aerosol Conference, held in three out of every four years.

The Spanish Science and Technology Aerosol Association

The Spanish Science and Technology Aerosol Association (AECTA, Asociación Española de Ciencia y Tecnología de Aerosoles) was born in 2006 during the 7th International Aerosol Conference held in Minnesota (USA) and had its first official meeting in Madrid in 2007. It is a forum of aerosol scientists and technologists in Spain coordinating activities on aerosols sciences as well as holding annual meetings and summer schools within the field of aerosols.

General Information

Venue
The European Aerosol Conference 2012 is held at the Parque de las Ciencias (Sciences Park, www.parqueciencias.com), Av. de la Ciencia s/n. 18006 Granada. The plenary, oral and poster sessions as well as exhibitions take place in the Macroscopio Building, the brand new area of the largest science park in Andalusia. The Parque de las Ciencias is an interactive museum, of more than 70,000 m^2, placed a few minutes of the historical center of Granada with one of the most varied offers of Europe's cultural and scientific leisure.

Transport to the Conference Centre
By taxi
Tele-Radio-Taxi 958 280 654
Radio-Taxi-Genil 958 132 323
Taxis-Granada 958 35 71 36
A typical taxi fare from the Conference Centre to the city centre is 4-6 €.

By bus
Tourist and city bus: 1, 5 directly to the Science Park (Stop: Parque de las Ciencias), 4, 10, 11 y 21 (Stop: Plaza de las Américas), 22 (Stop: Jardín de la Reina).

Train Station: bus 11, 21.

Bus Station: bus 10.

More bus details: http://www.transportesrober.com/transporte/lineas.htm#

By train
National Railways of Spain (RENFE):
http://www.renfe.com/EN/viajeros/index.html

By plane
Granada Airport,
http://www.aena-aeropuertos.es/csee/Satellite/Aeropuerto-Federico-Garcia-Lorca-Granada-Jaen/en/Page/1047397546288/
Málaga Airport,
http://www.aena-aeropuertos.es/csee/Satellite/Aeropuerto-Malaga/en /

On foot
It is about 15 min from the city centre.

Name badges
Upon registration you will receive a delegate badge which should be worn at all conference events including social activities. The double sided badge is designed for maximum visibility.
Please ensure you wear your delegate badge as this will be your entry identification and it will allow you to freely move around the garden of the Parque de las Ciencias.

Lunch, coffee/tea and snacks
Coffee/tea points
Refreshments will be available at coffee/tea points in the Macroscopio Building during the designated morning and afternoon breaks. There is also a restaurant and a cafeteria inside the Science Park.

Lunch boxes
Sandwich lunches will be provided in boxes during the designated lunch breaks. A vegetarian option will be available upon request. This is inclusive in the registration fee.

Cafeterias/Restaurants outside the Science Park
There are a large number of cafeterias and restaurants around the Conference Venue with opening hours from 8am to 11pm. Lunch is normally served from 1:30pm to 3:30pm and dinner from 7:30pm.

Internet
A Wi-Fi internet connection is available throughout the conference buildings.

The conference website www.eac2012.com will have uptaded information about the conference.

The emergency number is 112
Ambulance
Police
Fire department

Banks
Opening hours Monday to Friday from 9:00 to 14:00.

Credit cards
Credit cards are widely accepted. They can be used in stores, restaurants and hotels.

Tipping
In restaurants and taxis, service is included in the price. Tipping is not necessary but customers may leave a tip if they wish.

Smoking
Smoking is prohibited indoors in public places.

Drinking water
Granada tap water is of good quality and can be consumed safely throughout the city. Bottled mineral and spring water is available in shops and restaurants.

Sponsors and Exhibitors

The organisers wish to acknowledge the support of the many exhibitors present at EAC2012. Please visit their stands on the Macrospocio Building and consult their entries at the back of this handbook. The exhibitors are listed below:

Air Monitors Ltd	GRAW Radiosondes	Sunset Laboratory Inc
Alava Ingenieros	Grimm Aerosol Tech.	Tellus-B
Cambustion Ltd	Ingenieros Asesores	Topas GmbH
Certio	IONER - RAMEM S.A.	TSI
Copley Scientific Ltd	Magee Scientific	URG Corporation
Dekati Ltd	Matter Aerosol	
Droplet Measurement	Metrohm AppliKon	
Ecotech Pty Ltd	Palas GmbH

General information
Organizing Committee info@eac2012.com
Technical Programme Committee techprog@eac2012.com

Main presentation sessions
The conference will open at 8:45 on Monday 3rd September and close at 13:30 on Friday 7th September according to the schedule shown later in this handbook.

Exhibition
Exhibitors are located next to the main conference rooms in the Macroscopio Building and will be available during the conference hours from Monday to Friday.

Registration and information desk
The registration and information desk will be open at the entrance of the Macroscopio Building in the Science Park as follows:

Sunday, Sept 2: 18:00 –20:00
Monday, Sept 3: 08:00 –18:00
Tuesday, Sept 4: 08:30 –18:00
Wednesday, Sept 5: 08:30 –13:30
Thursday, Sept 6: 08:30 –18:00
Friday, Sept 7: 08:30 - 13.30

Certificate of attendance
Certificates will be available upon request at the registration and information desk.

Social Programme

Sunday 2nd September
Welcome Reception
Forum Building (5 min walk from the Conference Venue)
Time: 20:00 - 21:00

There will be a free welcome party on Sunday 2th September in the Forum Building, 5 min walk from Parque de las Ciencias. This will be an opportunity to meet colleagues.

Monday 3rd September
Concert
Hospital Real, Cuesta del Hospicio
Time: 20:30 - 21:30

The concert will be held in the Royal Hospital, nowadays the headquarters of the University of Granada for the vice-chancellorship and other university services. It was built during the Catholic Kings´ reign as a place to assist injured persons that were fighting in the war against the Arabs. It is one of the few civil monuments in this capital city. The building is a mixture of different styles: Mudejar, Gothic and Renaissance. We suggest being on time due to the limited capacity of the Hall.

The choir “El Orfeón de Granada” will delight us with its more recent production “De lo divino y de lo humano” that will take us back to the Twentieth Century in a sonorous trip representing a tribute to the popular

and classical music, through songs that have become masterpieces of the contemporary music.

Tuesday 4th September
Granada Mayor's Reception
Palacio de Los Córdova, Cuesta del Chapiz
Time: 20:30 - 21:30

The Palace of Los Córdova holds nowadays the City Historical Archive. It was originally built around 1530 at Placeta de las Descalzas more than 1 km away from its actual location at Cuesta del Chapiz when it was reconstructed in 1960. With the enjoyable view of the Alhambra from its gardens, the Mayor of Granada will welcome EAC2012 participants with a cocktail reception offered by the Conference. Afterwards you will have the opportunity to explore the heart of the Albaycín (UNESCO World Heritage Site) with its rich repository of Moorish vernacular architecture.

Thursday 6th September
Conference Dinner
Rte La Mamunia
Time: Drinks from 20:30, Dinner at 21:00

The conference dinner will be held on Thursday 6th September in La Mamunia Restaurant, Granada. This will be a nice opportunity to meet colleagues in a relaxing and charming atmosphere. There will be a separate fee to attend the dinner. Please book your place on the registration page. There will be bus service available from Parque de las Ciencias (departure at 20:00 from the main entrance).

If you have any special dietary requirements, please ensure you email at eac2012granada@viajeseci.es

Dress Code is smart casual, this means smart trousers and a shirt for men (there is no need for a tie or jacket) and the comparable for women.

Awards

Smoluchowski Prize
The award will be given by GAeF to a young researcher (as a rule under 40 years of age) who has achieved and published significant new results in aerosol science in the preceding 3 years.

Best Poster Prizes

To recognize excellence in poster presentation, the EAA will award a number of Best Poster Prizes at the conference. The criteria for selection will be effective design, clarity of communication and scientific quality.

The Prize Committee will be chaired by Dr. Nonne Prisle.

All presentations accepted for poster presentation are eligible for award, but to be included for consideration, participants must send a pdf-copy of the poster to Dr. Prisle at Nonne.prisle@helsinki.fi by 26th August 2012 at the latest. By sending in a pdf-copy of the poster, you can either nominate yourself or alternatively you can nominate the student/colleague presenting the poster.

Board meetings

- GAeF Board Meeting. Monday 3rd September, 12:50-14:00. Room: Sala Presidencia.
- Elsevier Board Meeting. Monday 3rd September 17:00-19:30. Room: Faraday.
- EAC2015 Organizing Meeting. Monday 3rd September 18:30-19:30. Room: Cine 3.
- Journal of Aerosol Science Board Meeting. Monday 3rd September 17:00-19:30. Room: Gutenberg.
- Ioner Meeting. Wednesday 5th September 14:00-17:00. Room: Cine 3.
- EMEP Meeting. Wednesday 5th September 14:00-16:00. Room: Gutenberg.

Assemblies

- Spanish Aerosol Society Assembly. Monday 3rd September 18:30-19:30. Room: Auditorio.
- GAeF General Assembly. Tuesday 4th September 18:30-19:30. Room: Auditorio.

EAA Working Group meetings

The purpose of these meetings is to discuss general matters within the various topic areas and to help plan future events, particularly the next EAC. All delegates are welcome.

Tuesday 4th September 16:00-17:00. The following groups meet at:

WG 1:	Atmospheric Aerosols: Aerosol Processes and Properties	Auditorio
WG 2:	Atmospheric Aerosols: Specific Aerosols Types	Auditorio
WG 3:	Aerosol Chemistry	Faraday
WG 4:	Combustion Aerosols	Gutenberg
WG 5:	PMx	Cine 3
WG 6:	Particle Lung Interactions	Legado Andalusí
WG 7:	Aerosol-based Nanotechnology	Einstein
WG 8:	Instrumentation	Sagan
WG 9:	Aerosol Modelling	Curie
WG 10:	Fundamentals	Newton
WG 11:	Electrical Effects	Sala Presidencia

Presentation Information

Abstracts
All accepted abstracts are published in the EAC2012 Electronic Abstract Book, included in a USB memory together with your conference bag.

Instructions for oral presentations
Please report to the Oral Presenters' Office in advance to upload your presentation electronically. Morning sessions' presenters must upload their presentations during the previous afternoon and afternoon sessions' presenters must upload their presentations during the current morning.

Due to logistical reasons, personal laptops cannot be used for presentations. Electronic formats allowed are Microsoft PowerPoint, OpenOffice Impress and PDF. A copy of your presentation will be available on the PC installed in the appropriate conference room. Oral presenters are requested to be at least 10 minutes prior to beginning of the session and identify themselves to the corresponding chairs.

The time available for oral presentations is 20 minutes (15 minutes for the talk and 5 minutes for discussion).

Instructions for oral reserve presentations

Oral reserve presentations are poster presentations that will also be offered a slot for oral presentation should a vacancy become available. Presenters should check the status with chairs at the beginning of the corresponding session.

Instructions for poster presentations

Posters are displayed on the Poster Space on the first floor (3a) and ground floor (3b, 3c) of the "Parque de las Ciencias". The poster designation A-code, B-code or C-code indicates session A (Monday), session B (Tuesday) or session C (Thursday). The number of board is listed in the next pages and the location of board is indicated on the poster hall plans in this handbook.

– Poster session A, Monday 3rd September, 16:00 – 18:30.

Posters for this session must be mounted from Monday morning and left on display until Tuesday morning before the Plenary Session.

– Poster Session B, Tuesday 4th September, 17:00 – 18:30.

Posters for this session must be mounted from Tuesday morning coffee break and left on display until Thursday morning before the Plenary Session.

– Poster Session C, Thursday 6th September, 16:00 – 18:30.

Posters for this session must be mounted from Thursday morning coffee break and left on display until Friday morning coffee break.

Presenting authors are kindly asked to be available to present their posters during the poster sessions. Posters should be A0, in portrait orientation (841mm wide x 1189mm high). There will be material for fixing your poster, please do not use your own fixing material.

Late posters

Late posters will be displayed on the Poster Space (3c) on the ground floor of the Science Park, during poster session B on Tuesday 4th September.

Internet

A Wi-Fi internet connection is available throughout the Conference Building. Please select Wi-Fi connection "EAC2012" with Password "Angstroem2012".

Working Groups

WG 1: Atmospheric Aerosols: Aerosol Processes and Properties
WG 2: Atmospheric Aerosols: Specific Aerosols Types
WG 3: Aerosol Chemistry
WG 4: Combustion Aerosols
WG 5: PMx
WG 6: Particle Lung Interactions
WG 7: Aerosol-based Nanotechnology
WG 8: Instrumentation
WG 9: Aerosol Modelling
WG 10: Fundamentals
WG 11: Electrical Effects
Special Sessions

Sessions

WG 1

WG01S1O. Optical Properties
WG01S2O. New Particle Formation
WG01S3O. Remote Sensing of Aerosol Properties
WG01S4O. Physical and chemical properties + Transport 1
WG01S5O. Physical and chemical properties + Transport 2
WG01S6O. Climate effects of aerosols
WG01S7O. Aerosol Cloud Interaction

WG 2

WG02S1O. Biomass Burning and Bioaerosol
WG02S2O. Mineral Dust
WG02S3O. Urban Aerosol in Large Cities (1)
WG02S4O. Marine and Carbonaceous Aerosol
WG02S5O. Urban Aerosol Chemical and Physical Properties (2)

WG 3

WG03S1O. Chemistry of Organic Aerosol: Laboratory Study 1
WG03S2O. Chemistry of Organic Aerosol: Laboratory Study 2
WG03S3O. Characterisation Techniques for Organic Aerosol
WG03S4O. Chemistry of Organic Aerosol: Field Study

WG 4

WG04S1O. Combustion and industrial aerosols
WG04S2O. Engines related emissions

WG 5

WG05S1O. Physical and chemical analysis of PMx
WG05S2O. Carbonaceous aerosol and wood burning contribution to PMx
WG05S3O. PMx source apportionment

WG 6

WG06S1O. Particle toxicity
WG06S2O. Particle lung deposition

WG 7

WG07S1O. Application of engineered nanoparticles
WG07S2O. Fundamentals and measurement of nanoparticles
WG07S3O. Gas phase synthesis of nanoparticles

WG 8

WG08S1O. New Instrumentation I
WG08S2O. New Instrumentation II
WG08S3O. Measurement Methods

WG 9

WG09S1O. Aerosol Modelling: Atmospheric Applications
WG09S2O. Aerosol Modelling: Emission inventories, transport and transformation
WG09S3O. Aerosol Modelling: New particle formation and further topics

WG 10

WG10S1O. Aerosol Nucleation, Condensation and Coagulation
WG10S2O. Aerosol Dynamics

WG 11

WG11S1O. Electrical effects

Special Session

SS01S1O. ACTRIS
SS02S1O. A ground-based integrated study of chemical aerosol-cloud interaction (HCCT2010)
SS03S1O. Source apportionment
SS04S1O. Chemical characterization of combustion aerosols
SS05S1O. Field observations and modeling of special events (Fukushima accident and Eyjafjallajökull ash plume)

Monday 3rd September

08:45-09:00	Opening Ceremony (Auditorio)
09:00-10:00	Plenary 1. **Vincent Castranova** *Characterization of Responses to Carbon Nanotubes and Carbon Nanofibers* Room: Auditorio Chair: J.L. Castillo
10:00-10:30	Coffee-break
10:30-12:50	**Session WG01S1O. Optical Properties** Room: Auditorio Chairs: H. Horvath / J. Andrey

10:30	WG01S1O01	**Profiling of the aerosol hygroscopicity in the planetary boundary layer** B. Rosati, E. Weingartner, P. Zieger, G. Wehrle, U. Baltensperger
10:50	WG01S1O02	**The effect of hygroscopicity on the aerosol extinction** V. Gácser, A. Molnár
11:10	WG01S1O03	**Nephelometric study of fine aerosol fraction in Beijing** M.A. Sviridenkov, A.S. Emilenko, V.M. Kopeikin and Wang Gengchen
11:30	WG01S1O04	**Observed darkening of the aerosol** J.P. Putaud, F. Cavalli, A. Dell'Acqua, C. Gruening, and S. Martuins Dos Santos
11:50	WG01S1O05	**Spectral dependence of aerosol light absorption obtained from several field experiments** S. Mogo, V.E. Cachorro1, A. de Frutos, B. Torres, J.F. López, C. Toledano, A. Berjón and B. Barja
12:10	WG01S1O06	**Measuring the optical properties of single particles and aerosol ensembles using cavity ring down spectroscopy** B.J Mason, R.E.H. Miles, S.-J. King, K. Manfred, J.S.

		Walker, A.E. Carruthers, A.J. Orr-Ewing and J.P. Reid
12:30	WG01S1O07	**Modelling radiative properties of light-absorbing carbon aggregates encapsulated in a sulphate shell** M. Kahnert, T. Nousiainen, H. Lindqvist, and M. Ebert
Reserve paper	WG01S1B00	**Optical properties of SiO2 particles: inversion data from laboratory IR absorption spectra** D. Petitprez, H. Herbin

10:30-12:50 **Session WG02S1O. Biomass Burning and Bioaerosol**
Room: Legado Andalusí
Chairs: J. Schneider / C. Ruzene

10:30	WG02S1O01	**Impact of prescribed burning on urban air quality: a case study** C. He, B. Miljevic, L. Crilley, L. Morawska, F. Salimi, G. A. Ayoko, J. Bartsch, E. Uhde
10:50	WG02S1O02	**Physical and chemical properties of aerosol particles from wild fires in South Africa** V. Vakkari, P. Tiitta, H. Laakso, A. Venter, K. Jaars, M. Josipovic, C. Walsh, P. Dagsson Waldhauserova, G. Mafusire, T. Korhola, M. Paramonov, M. Vana, M. Kulmala, J.P. Beukes, P.G. van Zyl, J.J. Pienaar and L. Laakso
11:10	WG02S1O03	**Impact of wood combustion on the ambient aerosol in Augsburg, Germany: A joint measurement campaign using innovative on-line and off-line mass spectrometric systems for chemical profiling** R.Zimmermann, M.Oster, M. Elsasser, J. Schnelle-Kreis, J. Orasche, G. Abbaszade, M. Crippa, A.S.H. Prévôt, T. Gustafson, J.B.C.Pettersson
11:30	WG02S1O04	**Airborne measurements of biomass burning layers over Central Europe: A case study** F. Dahlkötter, B. Weinzierl, D. Sauer, A. Minikin, M. Gysel, C. Voigt, and A. Ansmann
11:50	WG02S1O05	**Comparison of methods for generating bioaerosols** J. Löndahl, O. Nerbrink, N. Burman, A. Thedeby, A. Massling, T. Santl Temkiv, M. Bohgard
12:10	WG02S1O06	**Seasonal and spatial characteristics of fungal**

		spore tracers in Taiwan G. Engling, S.H. Chen and B.J. Tsuang
12:30	WG02S1O07	**Numerical modelling of pollen concentrations: a comparison to measured concentrations** K. Zink, A. Pauling, B. Clot and M.W. Rotach
Reserve paper	WG02S1B00	**Real-time measurement of continuous thermal-inactivated bioaerosols by aerosol fluorescence sensor with dual UV- and Vis-channels** Jae Hee Jung, Gwi Byoung Hwang, Bo Mi Kwon, Jung Eun Lee, and Gwi Nam Bae

10:30-12:50 **Session WG03S1O. Chemistry of Organic Aerosol: Laboratory Study 1**
Room: Faraday
Chairs: R. Alfarra / Y. Iinuma

10:30	WG03S1O01	**Do Organic Aerosols Shrink?** N.M. Donahue, E. S. Robinson, A. Ahern, E. Trump, and R. Saleh
10:50	WG03S1O02	**Gas phase formation of extremely oxidized α-pinene reaction products and their role in aerosol particle formation** M. Ehn, E. Kleist, H. Junninen, T. Petäjä, G. Lönn, S. Schobesberger, M. Sipilä, M. Dal Maso, R. Tillmann, A. Trimborn, M. Kulmala, D. R. Worsnop, A. Wahner, J. Wildt, Th. F. Mentel
11:10	WG03S1O03	**α-Pinene and β-pinene ozonolysis - Effect of CO on SOA formation and product distribution-** A. Kahnt, Y. Iinuma, A. Mutzel, O. Böge and H. Herrmann
11:30	WG03S1O04	**Is the chemical composition of α-pinene secondary organic aerosol dependent on particulate water content?** L. Pfaffenberger, P. Barmet, R. Wolf, J. G. Slowik, J. Dommen, A. S. H. Prévôt and U. Baltensperger
11:50	WG03S1O05	**Kinetic multi-layer model of gas-particle interactions in aerosols and clouds (KM-GAP): linking condensation, evaporation and reactions of organics, oxidants and water** M. Shiraiwa, C. Pfrang, T. Koop and U. Pöschl
12:10	WG03S1O06	**The effect of humidity on the ozonolysis of**

		unsaturated compounds in aerosol particles and on particle phase M. Kalberer, F.D. Pope, P.J. Gallimore, P. Achakulwisut J. Lee, J. F. Davies, V. Garrascon, S. Fuller, A. Björkegren and D. R. Spring
12:30	WG03S1O07	**Composition, Reactivity, and Energetics of Sulphuric Acid Clusters Containing Ammonia and Amines** B. R. Bzdek, J. W. DePalma, J. Laskin, D. P. Ridge and M. V. Johnston
Reserve paper	WG03S1B00	**Simultaneous study of gas and particulate products formed from isoprene oxidation: laboratory and field measurements** C. Rio, S. Rossignol, S. Fable, L. Chiappini

10:30-12:50 **Session WG06S1O. Particle toxicity**
Room: Cine3
Chairs: W. Hofmann / O. Schmid

10:30	WG06S1O01	**Characterization of an Air-Liquid Interface Cell Exposure system for Cigarette Smoke (ALICE_CS) using fluorescence imaging and a quartz crystal microbalance** M. Shoaib, A. G. Lenz, F. Prade, B. Lentner, M. Schmidmeir, T. Stoeger, O. Eickelberg, O. Schmid
10:50	WG06S1O02	**Analysis of the Dosimetric Properties of a Novel Thermal Precipitator for Cell Exposure to Nanoparticles at Air-Liquid Interface** D. Broßell, S. Plitzko, G. Linsel, N. Azong-Wara, C. Asbach, H. Fissan, A. Schmidt-Ott
11:10	WG06S1O03	**Estimation of biodurability of smectite particles in (synthetic) lung fluids** M.E. Ramos, C. Cappelli, M. Rozalén, S. Fiore and F.J. Huertas
11:30	WG06S1O04	**Toxicity testing of domestic wood combustion aerosols** S. Mülhopt, S. Gauggel, D.R. Dietrich, T. Schröder, B. van der Burg, H.-R. Paur
11:50	WG06S1O05	**An experimental comparison of dust resuspension due to human walking** Yilin Tian, Kyung Sul, Jing Qian and Andrea Ferro
12:10	WG06S1O06	**Identification of plant DNA in air: DNA analysis**

		and relevance for human health I. Müller-Germann, J. Fröhlich-Nowoisky, U. Pöschl,and V. R. Després
12:30	WG06S1O07	**Effective density of particles in an urban environment – measured with a DMA-APM system for lung dose estimations** J. Rissler, P.T. Nilsson, J. Pagels, A. Eriksson, E. Nordin, E. Swietlicki, B. Svenningsson, M. Frosch, E. Ahlberg, C. Wittbom, J. Löndahl, A. Wierzbicka, J.G. Hemmingsen, S. Loft, S. Sjögren
Reserve paper	WG06S1B00	**Effects of different combustion conditions on the toxicological properties of PM1 in adjustable biomass combustion reactor** O. Uski, J. Leskinen, P. Jalava, A. Virén, H. Lamberg, T. Kaivosoja,T. Kettunen, I. Nuutinen, M. Happo, T. Torvela, J. Tissari, O. Sippula, J. Jokiniemi, M.-R. Hirvonen

10:30-12:50 **Session WG08S1O. New Instrumentation I**
Room: Gutenberg
Chairs: O. Bischof / C. Asbach

10:30	WG08S1O01	**LOAC: a new small balloon-borne aerosol counter/sizer with some particle characterization** J.-B. Renard, G. Berthet, F. Dulac, J. Sciare, J. Nicolas, M. Mallet, P. Durand, C. Thaury, S. Salles,J.-L. Mineau, T. Tonnelier and N. Verdier
10:50	WG08S1O02	**Aerosol detection with induced currents** M. Fierz, D.Meier, P.Steigmeier and H. Burtscher
11:10	WG08S1O03	**Remote sensing of atmospheric aerosols with the spectropolarimeter SPEX** J. de Boer, G. van Harten, F. Snik, O. P. Hasekamp, H. Volten, A. Apituley, C. U. Keller, J. H. H. Rietjens, J. M. Smit, D. M. Stam, and P. Stammes
11:30	WG08S1O04	**Evaluation of the Cavity Attenuated Phase Shift (CAPS) Extinction Monitor** A.Petzold, T. Onasch, P. Kebabian, A. Freedman
11:50	WG08S1O05	**Improvement of the nanoparticle charging efficiency by using sheath air flow in a single-wire corona unipolar charger** C.L. Chien, C.J. Tsai, V. Wattanmekhinkul
12:10	WG08S1O06	**An optical set-up for the multi-wavelength**

		characterization of carbonaceous particulate matter D. Massabò, M.C. Bove, E. Cuccia, P. Prati, V. Bernardoni, G. Valli, R. Vecchi
12:30	WG08S1O07	**A new expansion chamber CPC applicable to atmospheric measurements** T. Pinterich, P.M. Winkler, P.E. Wagner and A. Vrtala
Reserve paper	WG08S1B00	**A new device for fast measurements of nanoparticle size distributions** Hans Grimm, Lothar Keck, Markus Pesch, Matthias Richter, Hans-Joachim Schulz

14:00-16:00 **Session WG01S2O. New Particle Formation**
Room: Auditorio
Chairs: T. Petäjä / E. Coz

14:00	WG01S2O01	**The role of marine microcolloids in new particle formation over the Arctic Ocean** M. Karl, E. Coz and C. Leck
14:20	WG01S2O02	**Response of Cloud Condensation Nuclei (> 50 nm) to changes in ion-nucleation** M. B. Enghoff, H. Svensmark, and J. O. P. Pedersen
14:40	WG01S2O03	**Estimating the effect of gas-phase kinetics and nanoparticle dynamics on observed particle formation rate dependencies** M. Dal Maso, H. Korhonen, K. Lehtinen, H. Vehkamäki
15:00	WG01S2O04	**The role of amines in atmospheric nucleation** Almeida-Simões, João, Curtius, Joachim, Kirkby, Jasper
15:20	WG01S2O05	**Atmospheric amine measurements with CI-APi-TOF** T. Jokinen, M. Sipilä, H. Junninen, M. Ehn, G. Lönn, J. Hakala, T. Petäjä, R. L. Mauldin III, M. Kulmala and D.R. Worsnop
15:40	WG01S2O06	**Lewis bases as the unifying concept for ion-induced and neutral H2SO4 nucleation** Theo Kurtén, Ismael K. Ortega, Oona Kupiainen, Tinja Olenius, Ville Loukonen and Hanna Vehkamäki
Reserve paper	WG01S2B00	**Differences between Classes of Nucleation Events during the Summer Period in Thessaloniki, Greece: Kerbside versus urban background measurements** D. Siakavaras, C. Samara, M. Petrakakis, G. Biskos

14:00-16:00 **Session WG02S2O. Mineral Dust**
Room: Legado Andalusí
Chairs: L. Ferrero / J. A. García Orza

14:00	WG02S2O01	**The importance of Nocturnal Low-level Jets for simulating mineral dust emission** S. Fiedler, K. Schepanski, B. Heinold, P. Knippertz and I. Tegen
14:20	WG02S2O02	**Resuspension and wind erosion in semi-arid SE Spain: overview and key results from field campaigns in 2005 – 2012** J.A.G. Orza, M. Cabello, M.A. Barrero, L. Cantón, A. Berasaluce, A. Romero-Díaz, F. Belmonte-Serrato, V. Lidón and J. Martínez
14:40	WG02S2O03	**Long-term observations of mineral dust deposition to the Northeast Atlantic Ocean and hygroscopic properties at the Cape Verde Islands** N. Niedermeier, T. Müller, A. Held, K. Kandler, and A. Wiedensohler
15:00	WG02S2O04	**Elemental Composition of Air Particulate Matter in Cape Verde** M. Almeida-Silva, S. M. Almeida, C.A. Pio, T. Nunes, J. Cardoso
15:20	WG02S2O05	**Optical behaviour of mineralogical composition. A laboratory study** T. Ajtai, Á. Filep, N. Utry, M. Pintér, Z. Bozóki, G. Szabó
15:40	WG02S2O06	**The Amsterdam-Granada Light Scattering Database** O. Muñoz, F. Moreno, D. Guirado, D.D. Dabrowska, H. Volten, J.W. Hovenier
Reserve paper	WG02S2B00	**CLIMARENO 2011 campaign: a multi-instrumental characterization of a Saharan dust intrusion over the Iberian Peninsula by airborne and ground-based instrumentation** J. Andrey, J. Fernández-Gálvez, J.L. Guerrero-Rascado, M. Sorribas-Panero, G. Titos-Vela, A. Corrales-Sierra, M. Gil-Ojeda, V. Cachorro, B. de la Morena F.J. Olmo and L. Alados-Arboledas

14:00-16:00 **Session WG03S2O. Chemistry of Organic Aerosol: Laboratory Study 2**
Room: Faraday
Chairs: M. Kalberer / M. Shiraiwa

14:00	WG03S2O01	**A source of oxygenated organic aerosol and oligomers from primary emitted gases** John Liggio, Shao-Meng Li and Alexander Vlasenko
14:20	WG03S2O02	**Uptake of glyoxal by organic and inorganic seed aerosols: Optical, physical and chemical properties of the product aerosols** M. Trainic, A. A. Riziq, A. Lavi, J. M. Flores and Y. Rudich
14:40	WG03S2O03	**Secondary organic aerosol formation from glyoxal** J.G. Slowik, E.M. Waxman, C.J. Kampf, J. Timkovsky, B. Nozière, A.P. Praplan, L.Pfaffenberger, T. Hoffmann, T. Kuipers, R. Holzinger, J. Dommen, A.S.H. Prévôt, U. Baltensperger, and R. Volkamer
15:00	WG03S2O04	**Evolution of SOA chemical composition during ageing: impact of irradiation, cloud processing and presence of pre-existing seeds** N. Maurin, E.Perraudin, J. F. Doussin, P. Pardon, H. Budzinski
15:20	WG03S2O05	**Size dependence of growth rates: results of experiments in the CLOUD chamber** A. Franchin, S. Schobesberger, T. Nieminen K. Lehtipalo, H.E. Manninen
15:40	WG03S2O06	**Modelling study on the effect of salt formation on the atmospheric nanoparticle growth** T. Yli-Juuti, K. Barsanti, L. Hildebrandt Ruiz, A.-J. Kieloaho, T. Kurtén, U. Makkonen, T. Petäjä, M. Äijälä, M. Kulmala and I. Riipinen
Reserve paper	WG03S2B00	**Primary and Secondary Organic Aerosol from Road Vehicles** S. Platt, I. El Haddad, A.A. Zardini, M. Clairotte, C. Astorga, R. Wolf, J. G. Slowik, B. Temime-roussel,N. Marchand, I. Jezek, L. Drinovec, G. Mocnik, O. Möhler, U. Baltensperger and A.S.H. Prévôt

14:00-16:00 **Session WG06S2O. Particle lung deposition**
Room: Cine 3
Chairs: D. Broday / W. Hofmann

14:00	WG06S2O01	**Determining the regional deposition of tobacco smoke in the human respiratory system** C.J. Dickens, C.M. McGrath, J. Perkins, P. Biggs, R.A. Cabot, J.J. McAughey
14:20	WG06S2O02	**Phase transition of inhaled particles within the human respiratory system** L. Pichelstorfer and W. Hofmann
14:40	WG06S2O03	**Particle deposition under transient high frequency ventilation air flow in a physiologically realistic bifurcation** E. Makris, M. Pilou ,P. Neofytou,S. Tsangaris and C.Housiadas
15:00	WG06S2O04	**Dynamics of exhaled aerosol with mixed composition** D. Katoshevski, D. Parienta, L. Morawska, G.R. Johnson, Z.D. Ristovski, M. Hargreaves, K. Mengersen, S. Corbett, C.Y.H. Chao, Y. Li
15:20	WG06S2O05	**In vivo regional deposition of submicron-sized airborne particles in the baboon respiratory model** J. Pourchez, I. Albuquerque-Silva, M. Durand, J. Avet, D. LePennec, M. De Monte, J. Montharu, M. Cottier, F. Dubois, L. Vecellio
15:40	WG06S2O06	**Not only Asbestos exposure, but also inherited susceptibility, is responsible for the occurrence of mesothelioma in humans** F. Cetta, P. Paladini, C. Ghiribelli, M. Monti, F. Granato, R. Borrelli, V. Guercio, D. Stergiou and G. Gotti
Reserve paper	WG06S2B00	**Personal daily exposure of children to ultrafine particles and black carbon** C. Vargas Trassierra, S. Marini, L. Stabile, A. Russi, F. Fuoco, G. Buonanno

14:00-16:00 **Session WG08S2O. New Instrumentation II**
Room: Gutenberg
Chairs: I. Agranovski / R. Caldow

14:00	WG08S2O01	**Characterization of the Airmodus A20 Condensation Particle Counte** K. Lehtipalo, J. Vanhanen, T. Toivola, J. Mikkilä, T. Petäjä and M. Kulmala

14:20	WG08S2O02	**Broadband Aerosol Extinction Spectrometer, a new instrument for measuring the spectral dependence of aerosols** R.A. Washenfelder, J.M. Flores, C.A. Brock, S.S. Brown and Y. Rudich
14:40	WG08S2O03	**Comprehensive Laboratory Characterization of a New Nano Water-based CPC and Performance Comparison to an Ultrafine CPC** A. Kupc, O.F. Bischof, M. Beeston, T. Tritscher, T. Krinke and P.E. Wagner
15:00	WG08S2O04	**Calibration and performance of a novel particle sensor for automotive application** L. Ntziachristos, S. Amanatidis, A. Rostedt, J. Keskinen, K. Janka, J. Tikkanen
15:20	WG08S2O05	**A novel portable instrument for exposure analysis in nanotechnology workplaces** C. Asbach, H. Kaminski, H. Fissan, T.A.J. Kuhlbusch, N. Azong-Wara, D. Broßell, R. Caldow, J. Scheckman, H.-G. Horn
15:40	WG08S2O06	**Device for Measuring Electrical Mobility Size and Concentration of Nanoparticles** S. Elzey, R. Caldow, J.P. Johnson, M. Grose, S. Morell, D. Jensen
Reserve paper	WG08S2B00	**Effect of particle diffusivity on DMAs with multiple monodisperse-particle outlets: theory validation and design optimization** M.Giamarelou, M. Stolzenburg, D.-R. Chen and G. Biskos

POSTER SESSION A

001	A-WG01S1P01	**Aerosol optical properties over East Asia: An integrating CMAQ-simulated and satellite-retrieved aerosol data using a data assimilation technique** C.H. Song, R.S. Park, K.M. Han and M.E. Park
002	A-WG01S1P02	**Temporal variations of the single scattering albedo in the southwestern Iberian Peninsula (Portugal)** S.N. Pereira, F. Wagner and A.M. Silva
003	A-WG01S1P03	**Retrieval of Single Scattering Albedo values from Brewer spectrophotometer irradiance measurements at Uccle, Belgium** V. De Bock and H. De Backer
004	A-WG01S1P04	**Constraining optical properties and refractive index**

		of soot through combined experimental and modelling studies J. Kim, H. Bauer, T. Dobovicnik, R. Hitzenberger, D. Lottin, D. Ferry and A. Petzold
005	A-WG01S1P05	**Modelling light scattering by mineral particles with small-scale surface roughness** M. Kahnert, T. Nousiainen, M. A. Thomas, and J. Tyynelä
006	A-WG01S1P06	**Physical and optical properties of atmospheric aerosol in Eastern Antarctica** A. Mangold, H. De Backer, V. De Bock, C. Hermans, I. Gorodetskaya and W. Maenhaut
007	A-WG01S1P07	**Aerosol Scattering and Absorption Angström Exponents during desert dust events over Granada** A.Valenzuela, F.J. Olmo, H. Lyamani, M. Antón, A.Quirantes, and L. Alados-Arboledas
008	A-WG01S1P08	**DIAPASON: A better assessment of the impact of Saharan dust on PM measurements** G.P. Gobbi, H. Wille, R. Sozzi, S. Frey, A. Bolignano, F. Costabile, F. Angelini, and F. Barnaba
009	A-WG01S1P09	**Spatial variation of aerosol optical properties around the high-alpine site Jungfraujoch** P. Zieger, E. Kienast, M. Starace, von Bismarck, N. Bukowiecki, U. Baltensperger, F.G. Wienhold, T. Peter, T. Ruhtz, M. Collaud Coen, L. Vuilleumier, O. Maier, E. Emili, C. Popp, and E. Weingartner
010	A-WG01S1P10	**Light scattering by ice-covered carbonaceous aerosol particles** S.S. Vlasenko,E.F. Mikhailov
011	A-WG01S1P11	**First ambient aerosol measurements with a polar nephelometer** M. Paixão, T. Müller and A. Wiedensohler
012	A-WG01S1P12	**Spectral dependence of in-situ aerosol optical properties** F. Costabile, F. Angelini, F. Barnaba and G.P. Gobbi
013	A-WG01S1P13	**Aerosol Characteristics and Radiative Forcing during summer and winter seasons over Pakistan** Khan Alam, Thomas Trautmann, Thomas Blaschke
014	A-WG01S1P14	**Seasonal distinctions and temporal trends in frequency of different types of hygrograms in West Siberia** S.A. Terpugova, T.A. Dokukina, E.P. Yausheva and M.V. Panchenko
015	A-WG01S1P15	**Trends in aerosol optical properties using AERONET surface observations** Aswathy V Nair and S. K. Satheesh

016	A-WG01S1P16	**Optical properties of SiO2 particles : inversion data from laboratory IR absorption spectra** Denis Petitprez, Hervé Herbin
017	A-WG01S1P17	**Climatology of aerosol optical properties with a synergy of remote sensing/altitude in situ measurements.** M.Hervo, K. Sellegri, J-C. Roger
018	A-WG01S1P18	**Combined observations with multi-wavelength Raman lidars and sun photometers on the southern Iberian Peninsula** J. Preißler, J.A. Bravo-Aranda, F. Wagner, M.J. Granados-Muñoz, F. Navas-Guzmán, J.L.Guerrero-Rascado, H. Lyamani, and L. Alados-Arboledas
019	A-WG01S1P19	**Seasonal and regional variation of the vertical optical properties of aerosol from CALIPSO validated with aircraft in situ measurements** A. Cazorla, P.S. Praveen, K.A. Prather and V. Ramanathan
020	A-WG01S1P20	**Optical Characterization of Aerosols at a Rural Site in Southeast England During the Winter ClearfLo IOP** P. Massoli, A. Aiken, K. Gorkowski, S. Herndon, E. Fortner, J. Jayne, J. Franklin, W. Brooks, P. Chhabra, T. Onasch, L. Williams, M. Dubey, D. Worsnop and A. Freedman
021	A-WG01S1P21	**Long term measurements of aerosol optical depth in the UV range in central Poland** J. Jarosławski
022	A-WG01S1P22	**Retrieving aerosol properties over the Mediterranean basin with a climate model** N. Hatzianastassiou, P. Ginoux, V. Ramaswamy
023	A-WG01S1P23	**Day and night columnar aerosol properties at Granada (Spain) using sun and star photometry measurements** D. Perez-Ramirez, H. Lyamani, F.J. Olmo, D.N. Whiteman and L. Alados-Arboledas
024	A-WG01S1P24	**Absorption closure – filter-based absorption instruments compared to extinction-scattering measurements** E. Andrews, P. Massoli, A.G. Hallar, A. Sedlacek, A. Freedman, J. A. Ogren and P. Sheridan
025	A-WG01S1P25	**Continuous measurements of aerosol size distribution at two Siberian stations: new particle formation bursts** M.Yu. Arshinov, B.D. Belan, A.V. Kozlov , P.N. Antokhin, D.K. Davydov and V.G. Arshinova

026	A-WG01S1P26	**Insights into the nucleation by organic compounds involving oxidation products of pinanediol and sulphuric acid** F. Bianchi, S. Schobesberger, S. Ehrhart, H. Junninen, N. M. Donahue, J. Dommen, M. Kajos, S. Schallhart, T. Ruuskanen, M. Kulmala, D. R. Worsnop U. Baltensperger and the CLOUD collaboration
027	A-WG01S1P27	**Differences between Classes of Nucleation Events during the Summer Period in Thessaloniki, Greece: Kerbside versus urban background measurements** D. Siakavaras, C. Samara, M. Petrakakis, G. Biskos
028	A-WG01S1P28	**Source apportionment of ultrafine and fine particles in Huelva industrial city** R. Fernández-Camacho, S. Rodríguez, J. de la Rosa, A.M. Sánchez de la Campa, Y. González-Castanedo
029	A-WG01S1P29	**Basic Statistics of New Particles Formation Events at Kosetice Station** N. Zikova and V. Zdimal
030	A-WG01S1P30	**Investigation of consecutive particle formation events in mixed residential and mining area in South Africa** A. Hirsikko, V.Vakkari, P. Tiitta, V.-M. Kerminen, J. Hatakka, J.P. Beukes, H.E. Manninen, M. Kulmala, D. Mabaso, and L. Laakso
031	A-WG01S1P31	**New particle formation events in Hungarian background air at K-puszta, 2008-2011** Zs. Bécsi, Á. Molnár, K. Imre, T. Nieminen, J. Hakala, T. Petäjä and M. Kulmala
032	A-WG01S1P32	**Continental source for secondary biogenic aerosols in Antarctica** E.-M. Kyrö, A. Virkkula, V.-M. Kerminen, M. Dal Maso, J. Parshintsev, J. Ruiz-Jimenez L. Forsström
033	A-WG01S1P33	**NanoShip: Mapping of new particle formation events over the North Sea** N. Kelbus, A. Massling, M. Fiebig, B. Henzing, M. Glasius, M. Bilde, M. Moerman, G. de Leeuw, M. Dal Maso, and A. Kristensson
034	A-WG01S1P34	**Direct observations of atmospheric sub-2 nm neutral and charged clusters** J. Kontkanen, M. Kulmala, K. Lehtipalo, H.E. Manninen, T. Petäjä, M. Sipilä, H. Junninen, S. Schobesberger, P. Rantala, A. Franchin, T. Jokinen, E. Järvinen, M. Äijälä, J. Kangasluoma, T. Nieminen, J. Hakala, P.P. Aalto, P. Paasonen, J. Mikkilä, J. Vanhanen, J. Aalto, T. Ruuskanen, R.L. Mauldin III, J. Dublissy, J. Bäck, I. Riipinen, M.

		Johnston, J.N. Smith, V.-M. Kerminen and D.R. Worsnop

053	A-WG01S1P53	**The Variation of Aerosol Number Concentrations in Relation with 3D wind components in the Ieodo Ocean Research Station** Sung-Hwa Park, Sang-Min Jang, Dong-In Lee, Woon-Seon Jung and Jong-Hoon Jeong
054	A-WG01S1P54	**Time lag between the tropopause height and 7Be activity concentrations on surface air** A. Ioannidou, A. Vasileiadis and D. Melas
055	A-WG01S1P55	**Aerosol Measurements Evaluating the Effects of the**

		Red Mud Disaster in Hungary A. Nagy, A. Czitrovszky, D. Oszetzky and A. Kerekes
056	A-WG01S1P56	**Correlation between measurement results for three-type portable air purifiers: filter, ionizer and wet ones** Bangwoo Han, Hak-Joon Kim and Yong-Jin Kim
061	A-WG02S1P01	**Drug-resistance and heavy metal tolerance of airborne microbes** O. Nikiforou, A. Kikna, M. Lazaridis, and E. Katsivela
062	A-WG02S1P02	**Investigation of bioaerosols distribution in greenhouse for orchid growth** C.Y. Chuang, S. Yang, M.Y. Chang, C.H. Luo, Y.C. Huang, P.C. Huang and W. Fan.
063	A-WG02S1P03	**Autofluorescence of atmospheric bioaerosols – fluorescent biomolecules, biological standard particles and potential interferences** C. Pöhlker, J. A. Huffman , U. Pöschl
064	A-WG02S1P04	**Fluorescent Biological Aerosol Particle (FBAP) Number Concentrations & Size Distributions Measured by the Waveband Integrated Bioaerosol Sensor (WIBS-4) at Environmental Research Station Schneefernerhaus (UFS)** Emre Toprak and Martin Schnaiter
065	A-WG02S1P05	**Ice Activity of Atmospheric Fungi** Janine Froehlich, Thomas C. J. Hill, Gary D. Franc and Ulrich Poeschl
066	A-WG02S1P06	**Characterization and validation of an easy-to-assemble kit of visible LED lights employed for inactivation of environmental bioaerosols** C.H. Luo and H.K. Chang
067	A-WG02S1P07	**Molecular genetic analysis of biological aerosol particles from African dust storms** Cristina Ruzene-Nespoli, Janine Fröhlich-Nowoisky, T. Nunes, J. Cardoso, S. M. Almeida & Ulrich Pöschl
068	A-WG02S1P08	**Survival of airborne influenza on surfaces** Cordonnier, Florian, Ha,Thi-Lan, Robine, Enric and Gehin, Evelyne
069	A-WG02S1P09	**Internally controlled multiplex bioaerosol detection procedure** E.V. Usachev and I.E. Agranovski
070	A-WG02S1P10	**Could BFFB mode breath aerosol play a role in H5N1 transmission?** L. Morawska, G.R. Johnson and S.C. Bell

071	A-WG02S1P11	**Recent advances in bioaerosol control methods** Byung Uk Lee
072	A-WG02S1P12	**Study on the ventilation and air dispersion in a hospital Intensive Care Unit (ICU) using simulation techniques** J.H. Song, J.Y. Jang, M.Y. Cho, D.S. Park and S.-B. Kwon
073	A-WG02S1P13	**Real-time measurement of continuous thermal-inactivated bioaerosols by aerosol fluorescence sensor with dual UV- and Vis-channels** Jae Hee Jung, Gwi Byoung Hwang, Bo Mi Kwon, Jung Eun Lee, and Gwi Nam Bae
074	A-WG02S1P14	**The numerical pollen dispersion model COSMO-ART: model design and operational use at MeteoSwiss** A.Pauling, K. Zink, H. Vogel and B. Vogel
075	A-WG02S1P15	**Rapid Inactivation of Biological Species in the Air using Atmospheric Pressure Non-thermal Plasma** Yongdong Liang, Yan Wu, Ke Sun, Qi Chen, Fangxia Shen, Jue Zhang, and Maosheng Yao, Tong Zhu, Jing Fang
076	A-WG02S1P16	**Single-particle fluorescence spectroscopy of atmospheric relevant fungal spores and bacteria and potential interferences** S. Saari, M. Putkiranta and J. Keskinen
077	A-WG02S1P17	**Microbial and fungal bioaerosol concentrations in Lithuanian schools** I. Radziuniene, D. Martuzevicius, D. Ciuzas, E. Krugly, and T. Prasauskas
078	A-WG02S1P18	**Airborne bacterial deposition in Sierra Nevada National Park** G. D´Orta, N. Mladenov and I. Reche
079	A-WG02S1P19	**Neutralization of Viable Aerosolized Microorganisms due to Exposure to Combustion of Reactive Materials** S.A. Grinshpun, A. Adhikari, M. Yermakov, T. Reponen, E. Dreizin, M. Schoenitz, and V. Hoffmann
080	A-WG02S1P20	**Carbonaceous compounds emitted from domestic biomass burning** M.A.C. Duarte, A.I. Calvo, L.A.C. Tarelho, T. Nunes, M. Evtyugina, C.A. Alves
081	A-WG02S1P21	**Inventory of emissions from residential wood combustion in Portugal** C. Gonçalves, C. Alves and C. Pio
082	A-WG02S1P22	**Aerosol aging during transport from Thailand to Taiwan**

		C.-T. Lee, M.-T. Chuang, N.-H. Lin, K. Sopajareepom, S.-Y. Chang, Y.-J. Chang
083	A-WG02S1P23	**Summer 2010 forest fires in central Portugal: characterisation of trace gases and aerosol emissions** A.M. Vicente, C.A. Alves, A.I. Calvo, A.P. Fernandes, T. Nunes, A.C. Monteiro, M. Evtyugina, L.A.Tarelho and C.A. Pio
084	A-WG02S1P24	**Contribution to PM2.5 from domestic wood burning in a small community in Sweden** P. Molnár and G. Sallsten
085	A-WG02S1P25	**Characterisation of regional ambient biomass burning organic aerosol mixing ratios** M. D. Jolleys, H. Coe, G. McFiggans, G. Capes, J. D. Allan, J. Crosier, P. I. Williams, G. Allen and J. L. Jimenez
086	A-WG02S1P26	**Large use of wood combustion for domestic heating in France: impacts on the air quality in rural environments** C. Piot, J. Cozic, J.-L. Besombes and J.-L. Jaffrezo
087	A-WG02S1P27	**Burning of Olive Tree Branches: A Major Organic Aerosol Emission Source in the Mediterranean** E. Kostenidou, C. Kaltsonoudis, E. Louvaris, M. Tsiflikiotou, and S.N. Pandis
088	A-WG02S1P28	**Airborne measurements in the lower atmosphere in Finland during Russian wildfires in the summer 2010** K. Leino, R. Väänänen , T. Pohja , P.P. Aalto , T. Petäjä A. Virkkula and M. Kulmala
089	A-WG02S1P29	**Measurement of fluorescence from ambient aerosol particles using WIBS-4 instrument** F. Taketani, Y. Kanaya, W. R. Stanley and P.H. Kaye
090	A-WG02S1P30	**Carbonaceous species and anhydrosugars measurements in coarse and fine aerosols size fractions at an urban area in the Po Valley, Italy** T.M.G. La Torretta, L.A. Stante, A. Malaguti, R. Nuzzi, M. Berico
091	A-WG02S1P31	**Mobile measurements for the detection of wood combustion: a case study in a rural environment** M. Van Poppel, N. Bleux, J. Peters, J. Van den Bossche P. Berghmans
092	A-WG02S1P32	**An exceptional air pollution event in the southwest of Europe** J.A. Adame, M. Sorribas, M.A. Hernández-Ceballos,

		J.P. Bolivar and B.A. De la Morena
093	A-WG02S1P33	**Identification of African dust influence to PM10 concentrations at the Athens air quality monitoring network during 2010** V. Aleksandropoulou and M. Lazaridis
094	A-WG02S1P34	**Identifying desert aerosols episodes in Cáceres (Spain)** M.A. Obregón, A. Serrano and M.L. Cancillo
095	A-WG02S1P35	**Mineralogical composition and origin of airborne particles during dust events in the Eastern Mediterranean** Kopanakis Ilias, Thodoros Glytsos, Despoina Pentari, and Mihalis Lazaridis
096	A-WG02S1P36	**Aerosol deposition in the main African dust transport region: establishing a long-term time series at Sao Vicente, Cape Verde** K. Kandler, L. Mendes Neves, N. Niedermeier, and T. Müller
097	A-WG02S1P37	**Influence of Saharan dust in deposition fluxes of nutrients in Spain** S. Castillo, X. Querol, A. Alastuey, A. Ávila, E. Cuevas, and J. de la Rosa
098	A-WG02S1P38	**Laboratory investigations of contact and immersion freezing of mineral dust using two techniques: vertical wind tunnel and acoustic levitator** K. Diehl, H. Schmithüsen, M. Debertshäuser, S.K. Mitra, and S. Borrmann
099	A-WG02S1P39	**Long-term Chemical Characterization of Aerosol at the CVAO** K. Müller, K. W. Fomba, E. Brüggemann, T. Gnauk, G. Spindler, H. Herrmann
100	A-WG02S1P40	**Effects of desert dust aerosols on surface UV radiation from OMI satellite instrument at Granada (Spain)** M. Antón, A. Valenzuela, R. Román, H. Lyamani, N. Krotkov, A. Arola, F.J. Olmo, L. Alados-Arboledas
101	A-WG02S1P41	**Aerosol sampling and coarse mode aerosol measurement of African mineral dust during Fennec 2011 field campaign** J.K.Brooke, M.Bart, J. Trembath, J.B. McQuaid, B.J.Brooks, P. Rosenberg, T. Malkin and S.Osborne
102	A-WG02S1P42	**Optical properties and radiative impact of intense dust outflows in the Mediterranean basin, based on a synergistic use of satellite,**

		ground-based measurements and modelling A. Gkikas, N. Hatzianastassiou, S. Kazadzis, V. Amiridis, S. Basart, E. Marinou, M. Taylor, J.M. Baldasano
103	A-WG02S1P43	**Combination of AERONET and CALIPSO data for the study of Saharan dust outbreaks over Valencia (Spain)** C.R. Marcos, R. Pedrós, J.L. Gómez-Amo, J.A. Martínez-Lozano, M.P. Utrillas
104	A-WG02S1P44	**Experimental study of hygroscopic properties of mineral dust particles** T.I. Ryshkevich, E.F. Mikhailov and S.S. Vlasenko
105	A-WG02S1P45	**Optical properties of a desert dust cloud after long-range transport using scattering matrix formalism and a polarization Lidar** G. David, B. Thomas, A. Miffre and P. Rairoux
106	A-WG02S1P46	**Desert-dust episodes over a background European environment: relationship between optical and physical properties by in-situ and columnar-integrated techniques** M. Sorribas, J.A. Ogren, F.J. Olmo, R. Fraile, B.A. de la Morena and L. Alados- Arboledas
107	A-WG02S1P47	**Estimation of dust emission amount for spring in East Asia using WRF/Chem** Jung-Yoon Kang and Soon-Chang Yoon
108	A-WG02S1P48	**Carbonaceous and inorganic water soluble species in PM in Cape Verde atmosphere** Teresa Nunes, João Cardoso, Danilo Custódio, Mário Cerqueira, Suzana Marta Almeida, M. Almeida-Silva and Casimiro Pio
109	A-WG02S1P49	**Ground-based measurements of suspended and re-suspended volcanic ash in Iceland after the Grímsvötn eruption in 2011** S. von Löwis, C. Fischer, A. Vogel, K. Weber, R. Reichardt and T. Jóhannsson
110	A-WG02S1P50	**Development of a certified reference material for Asian mineral dust (Gobi Kosa)** M. Nishikawa, I. Matsui, T. Sano, M. Ukachi, K. Nagano, K. Onishi, D.Batdorj, N. Enkhmaa and I.Mori
111	A-WG02S1P51	**Planetary Boundary Layer and Saharan Air Layer top height determination using Ceilometer and Micro Pulse Lidar. Intercomparison for two case studies** Y. Hernández, S. Alonso-Pérez, E. Cuevas, C. Camino, J. de Bustos, A.J. Gomez-Pelaez, R. Ramos,C. Córdoba-Jabonero

		and M. Gil
112	A-WG02S1P52	**An empirical relationship to estimate mineral dust concentration from visibility observations** C. Camino, S. Alonso-Pérez, E. Terradellas, S. Rodríguez, A.J. Gomez-Pelaez, P.M. Romero-Campos, Y.Hernández, S. Basart, J.M.Baldasano, E. Cuevas
113	A-WG02S1P53	**Particulate Matter Deposition Monitoring: Neglected Importance of Titanium?** G. Jereb, G. Dražič and B. Poljšak
114	A-WG02S1P54	**Diurnal variation of particulate concentration by size and micrometeorology in semi-arid rural environments** M. Cabello, J.A.G. Orza, M.A. Barrero, L. Cantón, A.Berasaluce, V. Lidón and J. Martínez
115	A-WG02S1P55	**Mineralogy of Atmospheric Dust in Santiago island, Republic of Cape Verde: preliminary results** F. Rocha, A. Quintela, D. Terroso, C. Costa, J. Cardoso; T. Nunes; C.A. Pio, S. M. Almeida and M.C. Freitas
116	A-WG02S1P56	**Modelling of long-range transport of mineral dust in Cape Verde** O. Tchepel, J. Ferreira, A.P. Fernandes, C. Gama, JM Baldasano, C. Borrego, J. Cardoso, S.M. Almeida, C. Pio
117	A-WG02S1P57	**CLIMARENO 2011 campaign: a multi-instrumental characterization of a Saharan dust intrusion over the Iberian Peninsula by airborne and ground-based instrumentation** J. Andrey, J. Fernández-Gálvez, J.L. Guerrero-Rascado, M. Sorribas-Panero, G. Titos-Vela,A. Corrales-Sierra, M. Gil-Ojeda, V. Cachorro, B. de la Morena F.J. Olmo and L. Alados-Arboledas
118	A-WG02S1P58	**The influence of the Atlas Mountains and the meteorological situation on the impact of African dust outbreaks on the Iberian Peninsula** J.A.G. Orza, M. Cabello
149	A-WG03S1P01	**Computational investigation of vinylhydroperoxide dissociation: there is a barrier** Theo Kurtén, Neil M. Donahue
150	A-WG03S1P02	**Reaction of airborne allergenic protein with different nitrating agents** K. Selzle, C. Ackaert, S. Kofler, G.J. Oostingh and U. Pöschl
151	A-WG03S1P03	**Temperature dependence of water activity in aqueous solutions of alcohols and organic acids** Gouri Ganbavale, Claudia Marcolli, U. K. Krieger, Greta Stratmann, Andreas Zuend, Thomas Peter

152	A-WG03S1P04	**Heterogeneous Uptake of HO2 Radicals onto Submicron Atmospheric Aerosols** P. S. J. Matthews, I. J. George, B. Brooks, A. Goddard, L. K. Whalley, M. T. Baeza-Romero and D. E. Heard
153	A-WG03S1P05	**How do night-time oxidants affect the fate of an organic coated aerosol droplet?** F. Sebastiani, R.A. Campbell, I. Hoare and C. Pfrang
154	A-WG03S1P06	**From free electrons to H2SO4 - assessing the efficiency of ion catalysed SO2 oxidation** N. Bork and H. Vehkamäki
155	A-WG03S1P07	**Simultaneous study of gas and particulate products formed from isoprene oxidation: laboratory and field measurements.** C. Rio, S. Rossignol, S. Fable, L. Chiappini
156	A-WG03S1P08	**Aerosol yields from ozonolysis of α- and β-pinene in simulation chamber experiments with low precursor concentrations** H. Saathoff, K.-H. Naumann, and O. Möhler
157	A-WG03S1P09	**Phase-changes during oxidation of atmospheric aerosols: ozonolysis of levitated droplets containing oleic acid** C. Pfrang, A. M. Squires, M. Rittman, M. Ghosh, K. Rastogi, and A. D. Ward
158	A-WG03S1P10	**Characteristics of polymer blend particles produced by evaporation of binary solution droplets of incompatible polymers** V. Rajagopalan, E. A. Grulke and A. K. Ray
159	A-WG03S1P11	**An Inversion Method for Aerosol Particle Concentrations in the CERN CLOUD Experiment** C. Williamson, D Wimmer, K.Lehtipalo, J. Curtius and the CLOUD collaboration
160	A-WG03S1P12	**Development of an aqueous-phase mechanism for secondary organic aerosol formation** F. Couvidat, K. Sartelet and C. Seigneur
161	A-WG03S1P13	**Capturing of low-level CO2 using AC particles** Y. H. Lim, Y. M. Jo
162	A-WG03S1P14	**SOA Formation from Acid Catalysed Rearrangement Reactions** Y. Iinuma, A. Kahnt, O. Böge and H. Herrmann
163	A-WG03S1P15	**Surface tension and aggregate formation in nanoaerosols containing model HULIS compounds** T. Hede
164	A-WG03S1P16	**Formation and aging of secondary organic aerosol through evaporation of aqueous phase processed**

		isoprene reaction products F. Siekmann, P. Renard, B. Temime-Roussel and A. Monod
165	A-WG03S1P17	**Influence of reaction conditions on the formation of dimers and peroxides originating from the ozonolysis of a-pinene and the OH reaction of nopinone** A.Mutzel, Y. Iinuma, O. Böge, A. Kahnt and H. Herrmann
166	A-WG03S1P18	**Comparison of sesquiterpene oxidation products in secondary organic aerosol from different vegetation zones** A. van Eijck, C. Kampf, T. Hoffmann
167	A-WG03S1P19	**Ozonolysis of ultra fine particles of oleic acid: a detailed study mixing on line gas and condensed phase analyses** Maxence Mendez, Vincent Crenn, Véronique Riffault, Sylvie Gosselin, Nicolas Visez, Denis Petitprez
168	A-WG03S1P20	**Effect of ions on the measurement of sulphuric acid at CLOUD** Rondo, Linda, Kürten, Andreas Ehrhart, Sebastian, Curtius, Joachim and the CLOUD collaboration
169	A-WG03S1P21	**Characterisation of thin films on optically trapped single aerosols using broadband white light Mie spectroscopy** S.H. Jones, M.D King and A.D. Ward
170	A-WG03S1P22	**Study on the effect of CO2 partial pressure on mechanism of sulfation of calcium carbonate sorbent particle** Seongha Jeong, Kang Soo Lee, Sang In Keel, Jin Han Yun, and Sang Soo Kim
171	A-WG03S1P23	**Pressure dependence of sulfuric acid induced SOA formation** P. T. M Carlsson, J. E. Dege, C. Keunecke, B. C. Krüger, J. L. Wolf and T. Zeuch
172	A-WG03S1P24	**Changes in hygroscopicity and cloud-activation of diesel exhaust aerosols upon ageing** C.Wittbom, B. Svenningsson, J.Rissler, A. Eriksson, E. Swietlicki, E. Nordin, P. Nilsson and J. Pagels
173	A-WG03S1P25	**Hygroscopicity and optical properties of secondary organic aerosol formed in CESAM simulation chamber** C. Denjean, P. Formenti, B. Picquet-Varrault, Y. Katrib, E. Pangui, P. Zapf and J.F. Doussin
174	A-WG03S1P26	**Secondary Organic Aerosol formation from isoprene photooxidation**

		L. Brégonzio, J.F. Doussin, E. Pangui, A. Monod, F. Siekmann, B. Temime, M. Camredon, B. Aumont
175	A-WG03S1P27	**AMISOC 2012: Multi-instrument campaign for assessment of trace gas-aerosol interactions** O. Puentedura, M. Gil, J.A. Adame, J. Andrey, C. Córdoba-Jabonero, L. Gómez, T. Hay, M. Navarro, C. Prados-Román, A. Saiz-López, M. Sorribas, D. Toledo and B. de la Morena
176	A-WG03S1P28	**Direct Surface Analysis of Size- and Time- Resolved Organic Aerosol** S.J Fuller, M. Kalberer, Y. Zhao, A.S Wexler
177	A-WG03S1P29	**The Manchester Photochemical Aerosol Chamber: Formation, Transformation and Properties of Secondary Organic Aerosols** M.R Alfarra, A. Buchholz, W. Hesson, J.F. Hamilton, K.P. Wyche, I. White, P. Monks, A. Lewis, and G.B. McFiggans
178	A-WG03S1P30	**Compound specific condensation to secondary organic aerosols providing size dependent information** D. Mogensen, D. Lowe, G. Capes, D. O. Topping, G. B. McFiggans, S. Smolander, M. Kulmala and M. Boy
179	A-WG03S1P31	**Direct observations of surface/bulk partitioning and acid/base speciation in aqueous solutions of the atmospheric surfactant sodium decanoate using synchrotron X-ray photoelectron spectroscopy** N.L. Prisle, N. Ottosson, G. Öhrwall, J. Söderström, M. Dal Maso, and O. Björneholm
180	A-WG03S1P32	**13-Carbon Isotopic Fractionation in Secondary Organic Aerosol Formation** C. Meusinger, U. Dusek, S.M. King, R. Holzinger, M. Bilde, T. Röckmann and M.S. Johnson
181	A-WG03S1P33	**Sizing, Infrared Spectra and Phase Transitions of Neutral Water Clusters** C.C. Pradzynski, R.M. Forck, U. Buck and T. Zeuch
182	A-WG03S1P34	**Growing clusters involving pinanediol oxidation products during nucleation experiments in the CLOUD chamber, observed by APi-TOF ion mass spectrometers** Schobesberger, Siegfried; Franchin, Alessandro; Junninen, Heikki; Bianchi, Federico; Dommen, Josef; Donahue, Neil; Ehrhart, Seba
183	A-WG03S1P36	**Aerosol mass spectrometer study of secondary organic aerosol formed during isoprene and methacrolein reaction chamber experiments -**

		Composition and effect of humidity F. Siekmann, L. Bregonzio, B. Temime-Roussel, S. Ravier, J.F. Doussin andA. Monod
184	A-WG03S1P37	**Pathways from aromatic aldehydes to aerosol in urban atmosphere: a competition between oxidation and photopolymerization** T.A. Maksimova, G.G. Dultseva and S.N. Dubtsov
185	A-WG03S1P38	**Atmospheric Degradation of Oxygenated Volatile Organic Compounds on Mineral Aerosol Surfaces** Cristina Iuga, C. Ignacio Sainz-Díaz, and Annik Vivier-Bunge
186	A-WG03S1P39	**Primary and Secondary Organic Aerosol from Road Vehicles** S. Platt, I. El Haddad, A.A. Zardini, M. Clairotte, C. Astorga, R. Wolf, J. G. Slowik, B. Temime-roussel, N. Marchand, I. Jezek, L. Drinovec, G. Mocnik, O. Möhler, U. Baltensperger and A.S.H. Prévôt
187	A-WG03S1P40	**Optimization of a GC/MS method to analyse products from photo-oxidation of biogenic and anthropogenic mixtures of VOCs** O. Pindado Jimenez, R.Mª Pérez-Pastor, M. García Vivanco, M. Santiago Aladro.
188	A-WG03S1P41	**Development of a new tool to study atmospheric aerosol particles origin** L. Bourcier and B. Geypens
189	A-WG03S1P42	**Aerosol chemical characterization by PMF analysis of single particle ATOFMS spectra** C. Giorio, A. Tapparo, M. Dall'Osto, R.M. Harrison, D.C.S. Beddows and E. Nemitz
190	A-WG03S1P43	**Analysis of surgical aerosols by on-line single particle and high resolution mass spectrometry** K.-P. Hinz, A. Fendt, K.-C. Schäfer, Z. Takats and B. Spengler
191	A-WG03S1P44	**Artefacts Associated with ChemVol® Impactor Sampling of Semivolatile Organic Compounds (SVOCs)** E. Galarneau, M. Patel, G. Poole, J.-P. Charland, and J. Brook
192	A-WG03S1P45	**In-situ methylation thermal extraction GC-MS method for the determination of anhydro-sugars in atmospheric aerosol samples** G. Matuschek, A. Wüst
193	A-WG03S1P46	**Studying Atmospheric Aerosols by Acoustic Levitation: Linking Head Space Solid-Phase Micro-Extraction (HS-SPME) with Gas Chromatography-Mass Spectrometry (GC-MS)**

		S. Almabrok, G. Marston and C. Pfrang
194	A-WG03S1P47	**Calibration of CPCs at low temperatures using the CLOUD chamber** D. Wimmer, F.Kreissl, A. Kürten, J. Curtius, F. Riccobono, A. Kupc, K. Lehtipalo and the CLOUD collaboration
195	A-WG03S1P48	**A method for assigning AMS measured nitrates and sulphates into molecular subgroups.** Äijälä, Mikko, Junninen, Heikki, Ehn, Mikael, Häkkinen, Silja, Hong, Juan, Petäjä, Tuukka, Kulmala, Markku and Worsnop, Douglas
196	A-WG03S1P49	**Simplifying the complex nature of water-soluble organic matter from atmospheric aerosols: new insights from comprehensive two-dimensional liquid chromatography** R.M.B.O Duarte, A.C. Barros and A.C. Duarte
197	A-WG03S1P50	**Characterization of a thermal desorption mass spectrometer for freshly nucleated secondary aerosol particles** S. G. Gonser and A. Held
198	A-WG03S1P51	**Comparison of two Laser Ablation Time-Of-Flight Aerosol Mass Spectrometers** S. R. Zorn, K.-P. Hinz, P. Croteau, B. Spengler, D. R. Worsnop, J. T. Jayne and A. M. Trimborn
199	A-WG03S1P52	**Complexation of transition metal ions by organic and inorganic ligands in size-segregated atmospheric aerosol particles in Melpitz, Germany** S. Scheinhardt, K. Müller, D. van Pinxteren, K. Fomba, A. Grüner, G. Spindler, H. Herrmann
200	A-WG03S1P53	**The organic carbon and total protein concentrations in atmospheric aerosol of Southwestern Siberia boundary atmospheric layer** A.S. Safatov, G.A. Buryak, S.E. Olkin, I.K. Reznikova, V.I. Makarov and S.A. Popova
201	A-WG03S1P54	**PM2.5 and PM10 composition in São Paulo city Atmosphere – Summer and Winter campaigns** P.C. Vasconcellos, B. Oraggio, P.V. Veiga, A. Soreira, E. G. Alves, J.B De Andrade
202	A-WG03S1P55	**Aliphatic and aromatic amines in atmospheric aerosol particles** J. Ruiz-Jimenez, J. Parshintsev, T. Laitinen, K. Hartonen, T. Petäjä, M. Kulmala, M.–L. Riekkola
203	A-WG03S1P56	**Organic composition of fog: transformation between liquid and interstitial phase** S. Schüttauf, J. Matschullat, D. van Pinxteren, Y. Iinuma, H.

		Herrmann
204	A-WG03S1P57	**Secondary particulate matter formation during foggy days** A.Piazzalunga, M.Anzano, V.Bernardoni, P.Fermo, M.Urbani, G.Valli and R.Vecchi
205	A-WG03S1P58	**Fingerprint of shipping emissions on PM10 at Barcelona** J. Pey, N. Pérez, A. Alastuey, X. Querol, J. Cortés
206	A-WG03S1P59	**Characteristics of surface ozone over Qinghai Lake area in Northeast Tibetan Plateau, China** Zhenxing Shen, Xin Wang, Junji Cao, Zhuzi Zhao
207	A-WG03S1P60	**Seasonal and diurnal variations of mono- and di-carbonyls in Xi'an, China** W.T. Dai, S.S.H. Ho, K.F. Ho, W.D. Liu, J.J. Cao, S.C. Lee
208	A-WG03S1P61	**Gas conversion to sulfate and nitrate in fine particulate matter at southern Taiwan** J.H. Tsai, J.H. Lin and L.P. Chang
209	A-WG03S1P62	**Regional contributions of arsenic species in Southwestern Spain** González-Castanedo Y, Sánchez-Rodas D., Sánchez de la Campa A.M., Fernández-Camacho R., de la Rosa J. D
210	A-WG03S1P63	**Water soluble compounds in Arctic aerosols (Ny Alesund, Svalbard)** R. Zangrando, C. Turetta, E. Barbaro, P. Zennaro, N. M. Kehrwald, J. Gabrieli, A. Gambaro, C. Barbante
211	A-WG03S1P64	**Aerosol-fog chemical interactions: a case study in the Po Valley (Northern Italy)** L.Giulianelli, S. Gilardoni, M. Rinaldi, S. Decesari, M. Paglione, C. Carbone, S. Fuzzi and M.C. Facchini
212	A-WG03S1P65	**Sulfur containing Polycyclic Aromatic Hydrocarbons (PASHs): new perspectives of tracers for source apportionment of aerosols** B. Golly, C. Piot, J.L. Jaffrezo, D. Chapuis, J.L. Besombes
213	A-WG03S1P66	**Physical-chemical characterization and origin of atmospheric particulate material in Cordoba City – Spain** E. García-Lorenzo, J.D. de la Rosa, A.M. Sánchez de la Campa, Y. González-Castanedo and R. Fernández-Camacho.
214	A-WG03S1P67	**Chemical composition and microphysical parameters of fog samples in a 27 year long study in the Po Valley (Italy)** Giulianelli, Lara; Rinaldi, Matteo; Carbone, Claudio; Decesari, Stefano; Facchini, Maria Cristina; Fuzzi, Sandro

215	A-WG03S1P68	**Determination of Molecular Composition in Boreal Forest Aerosols (PM1.0), Hyytiala, Finland using Ultra-High Resolution Mass Spectrometry** I. Kourtchev, S. Fuller, J. Aalto, T. Ruuskanen, W. Maenhaut, M. Kulmala, and M. Kalberer
216	A-WG03S1P69	**Nucleation and Aitken mode atmospheric particles in relation to O_3 and NO_X at semirural background in Denmark** Q.T. Nguyen, J.K. Nøjgaard, M. Glasius and L.L. Sørensen
217	A-WG03S1P70	**Preliminary results on the characterisation of organic aerosols in urban schools by Aerosol Mass Spectrometry** L. Crilley, G. A. Ayoko, E.R. Jayaratne, L. Morawska
218	A-WG03S1P71	**Pb isotope of atmospheric aerosols in the Iberian Pyrite Belt, SW Spain** J. de la Rosa, A.M. Sánchez de la Campa, Y. González-Castanedo, J.C. Fernández Caliani, A. Romero, I. González-Díez
219	A-WG03S1P72	**Metals and trace element characterization of weather condition - air quality relationships due to event based measurements of particulate matter** Silvia Leise, Frank Zimmermann, Jörg Matschullat
220	A-WG03S1P73	**Characterization of humic-like substances (HULIS) in size segregated atmospheric aerosol** G. Kiss, N. Törő, A. Hoffer, J. Dautovic, S. Frka, Z. Kozarac, M. Harir, P. Schmitt-Kopplin
221	A-WG03S1P74	**A multi-tracer approach to better understand Secondary Organic Aerosol sources and (trans)formation processes in the Mediterranean region** J. B. Nicolas, J. Sciare, R. Sarda-Estève, N. Mihalopoulos, G. Kouvarakis and F. Dulac
222	A-WG03S1P75	**Size-resolved measurement of the mixing state of soot in the megacity Beijing, China: diurnal cycle, aging and parameterization** Y. F. Cheng, H. Su, D. Rose, S. S. Gunthe, M. Berghof, B. Wehner, P. Achtert, A. Nowak, N. Takegawa, Y. Kondo, M. Shiraiwa, Y. G. Gong, M. Shao, M. Hu, T. Zhu, Y. H. Zhang, A. Wiedensohler, M. O. Andreae, and U. Pöschl
223	A-WG03S1P76	**Impact of urban atmospheric aerosols on cultural heritage objects of Granada, Southern Spain** C. Cardell, M. Urosevic, B. Horemans, V. Kontozova-Deutsch, S. Potgieter-Vermaak, E. Sebastián-Pardo and R. Van-Grieken
225	A-WG06S1P01	**Characterisation of nasal spray drug delivery**

		K.Inthavong, M.C.Fung, W.Yang and J.Y. Tu
226	A-WG06S1P02	**Evolution of droplet size distribution during nebulization of liposomes** T.R. Sosnowski
227	A-WG06S1P03	**Bipolar Charge Analyzer for inhaler particles** J. Kannosto, V. Niemelä, H. Isherwood, J. Yli-Ojanperä, J. Keskinen, R. Hillamo, A. Frey and A. Ukkonen
228	A-WG06S1P04	**Characterizing the Time-Dependant Hygroscopic Response of Aerosols Generated From Commercially Available Nebuliser Formulations** A.E. Haddrell, J.F. Davies, L.A. Dailey, D. Murnane and J.P. Reid
229	A-WG06S1P05	**Using the carbon-nanotube plasma for removal of indoor bioaerosols** S. Yang, C.H. Luo, Y.C. Huang, C.Y. Chuang, H.Z. Chen, P.C. Hung
230	A-WG06S1P07	**Periodical interruption of chronic exposure to PM in metropolitan areas could be of benefits to prevent chronic alterations of respiratory function in humans** G. Schiraldi, F. Cetta, P. Paladini, J. Martellucci, F. Granato, B. Lorenzi, R. Zangari, V. Guercio, E. Bolzacchini, M. Monti, G. Gotti and L.Allegra
231	A-WG06S1P08	**A 4-years follow-up study of traffic related respiratory changes in school children in Milan, Italy** M. Sala, F. Cetta, S. Argirò, P. Ballista, R. Zangari, V. Guercio, E. Bolzacchini, M. Monti and M. Mandelli
232	A-WG06S1P09	**Spirometric and laboratory assessment of the respiratory function as an effect of PM exposure in asymptomatic subjects living in a metropolitan area (Milan, Italy) and in a remote alpine site (Aprica)** L.Allegra, F. Cetta, G. Schiraldi, R. Zangari, V. Guercio, D. Stergiou, C. Ghiribelli, P. Paladini, L. Luzzi, E. Bolzacchini, M. Monti and G. Gotti
233	A-WG06S1P10	**Cryo-imaging as a quantitative pre-clinical method to determine the amount and spatial distribution of drugs in lung tissue: A feasibility study for fluorescent substances** Friedrich Prade, Nikolaos C. Deliolanis, Katie Dextraze, Nirav Barapatre, Vasilis Ntziachristos, Oliver Eickelberg, Otmar Schmid
234	A-WG06S1P11	**Stochastic rat lung dosimetry for radon progeny: A surrogate for the human lung**

		M.Hussain , R. Winker-Heil, and W. Hofmann
235	A-WG06S1P12	**Aerosol infection of chickens by avian influenza virus A/H5N1** Ar.A. Sergeev, O.K. Demina, O.V. Pyankov, O.G. Pyankova, A.P. Agafonov, S.A. Kiselev, I.E. Agranovski, Al.A. Sergeev, A.N. Shikov, L.N. Shishkina, A.S. Safatov and A.N. Sergeev
236	A-WG06S1P13	**A better knowledge of causative pathophysiological mechanisms, in addition to proper markers of effects, as key tools for a deeper insight into health effects of air pollution** F. Cisternino, V. Guercio, M. Monti, F. Granato, B. Lorenzi, J. Martellucci, R. Zangari and F. Cetta
237	A-WG06S1P14	**Aerosolization system for experimental inhalation study of metal oxides nanoparticules** Presumé, M, Attoui, M., Lanone, S.
238	A-WG06S1P15	**Comparison of methods for measurement of surface area for six different nanomaterials** M. Levin, I. K. Koponen, S. Bau, O. Witschger, E. Jankowska, C. Guiot, O. Spalla, K. A. Jensen
239	A-WG06S1P16	**Medical effect from nanoparticlate hypotensive drugs inhaled by male rats** A. A. Onischuk, T. G. Tolstikova, M. V. Khvostov, I. V. Sorokina, A.M. Baklanov, O. V. Borovkova, V. V. Boldyrev, V. M. Fomin
240	A-WG06S1P17	**Aerosol Particles in Different Types of Museum Environment** L. Maškova, J. Smolik, and M. Ohlidalova
241	A-WG06S1P18	**Transport of particulate matter in the indoor environment of the National Library in Prague** J. Smolik[1], L. Maškova
242	A-WG06S1P19	**Temporal evolution of pyrethroid aerosol concentrations after insecticide spray treatment in indoor atmosphere using a High Resolution Aerosol Time-of-Flight Mass Spectrometer (HR-ToF-AMS)** Aude Vesin, Nicolas Marchand, Etienne Quivet, Brice Temime-Roussel, Henri Wortham
243	A-WG06S1P20	**Particulate matter in school classrooms and outdoor air** C. Alves, T. Nunes, J. Silva, M. Duarte, C. Borrego
244	A-WG06S1P21	**Indoor and outdoor ultrafine particle characterisation in primary schools in Barcelona** M. Viana, I. Rivas, J. Sunyer, L. Bouso, M. Álvarez, Sioutas C, A. Alastuey and X. Querol
245	A-WG06S1P22	**Variations of PM concentrations in Lithuanian**

		multifamily buildings: Preliminary results from INSULAtE study Tadas Prasauskas, Dainius Martuzevicius, Edvinas Krugly, Darius Ciuzas, Ulla Haverinen-Shaughnessy, Mari Turunen, Virpi Leivo, Anu Aaltonen and the INSULAtE Project Group
246	A-WG06S1P23	**Personal daily exposure of children to ultrafine particles and black carbon** C. Vargas Trassierra, S. Marini, L. Stabile, A. Russi, F. Fuoco, G. Buonanno
247	A-WG06S1P24	**Assessing workers inhalation exposure and dose during production TiO2 particles** A.J. Koivisto, J. Lyyranen, J. Jokiniemi, T. Tuomi and K. Hämeri
248	A-WG06S1P25	**Semi-volatile partitioning effect on indoor PM: inorganic ions and PAHs.** G. Sangiorgi, M.G. Perrone, L. Ferrero, C. Lo Porto, B. Ferrini, S. Petraccone
249	A-WG06S1P26	**Variation of Wintertime PM2.5 and PM10 in Primary Schools of Kaunas, Lithuania** E. Krugly, T. Prasauskas, L. Kliucininkas, D. Ciuzas, D. Martuzevicius
250	A-WG06S1P27	**Biomass burning source: Indoor - Outdoor comparison** Andriani E., Dambruoso P., de Gennaro G., Demarinis Loiotile A, Di Gilio A., Marzocca A., Mazzone A. , Palmisani J. and Tutino M.
251	A-WG06S1P28	**Comparison of nasal deposition efficiency between Taiwanese and Caucasian adults** Y.M. Sun, C.W. Lee and D.J. Hsu
252	A-WG06S1P29	**Lung deposition of charged aerosol particles – particle characterisation and experimental setup for a human volunteer study** M.D. Wright, M.F. Biddiscombe, J.C. Matthews, S.R. Underwood, D.L. Henshaw, O.S. Usmani and D.E. Shallcross
253	A-WG06S1P30	**Theoretical and experimental investigation of aerosol deposition in realistic human airway model** A. Kerekes, A. Nagy, A. Czitrovszky
254	A-WG06S1P31	**Computational study of aerosol flow in a physiologically realistic bifurcation under the influence of an external magnetic field** M. Pilou, E. Makris, P. Neofytou, S. Tsangaris and C. Housiadas
255	A-WG06S1P32	**Cytotoxicity of organic extracts of particles emitted from a soy-biodiesel fuelled generator**

		J.H. Tsai, S.J. Chen, K.L. Huang, C.C. Lin1 and W.Y. Lin
256	A-WG06S1P33	**Toxicological effects of indoor PM10 in primary schools under different street traffic intensities** T. Moreno, A. Langford, K. BéruBé, T. Jones, W. Gibbons and BREATHE participants
257	A-WG06S1P34	**Layered silicate nanofillers and their influence on the pulmonary surfactant** D. Kondej and T.R. Sosnowski
258	A-WG06S1P35	**The increasing importance of "perinatal susceptibility window" to PM exposure in the pathogenesis of cardiovascular and respiratory diseases occurring later in life** F. Granato, M. Sala, E. Riva, V. Guercio, R. Zangari, B. Lorenzi, J. Martellucci M. Monti, O. Caratozzolo, E. Bolzacchini and F. Cetta
259	A-WG06S1P36	**Cytotoxicity and genotoxicity of emission particles from heavy EURO4 engine operated with conventional and biobased diesel fuels and compressed natural gas.** P.I. Jalava, M.S. Happo, T. Murtonen, P. Yli-Pirilä, P. Hakulinen, P. Aakko-Saksa, J. Mäki-Paakkanen, J. Jokiniemi and M-R. Hirvonen
260	A-WG06S1P37	**Experimental study of aerosol transport in semi-realistic human airway model** J. Jedelsky, F. Lizal, J. Elcner and M. Jicha
261	A-WG06S1P38	**Hygroscopic particle deposition in the human lung – a model comparison** W. Hofmann, R. Winkler-Heil, G.A. Ferron and B. Asgharian
262	A-WG06S1P39	**Effects of different combustion conditions on the toxicological properties of PM1 in adjustable biomass combustion reactor** O. Uski, J. Leskinen, P. Jalava, A. Virén, H. Lamberg, T. Kaivosoja,T. Kettunen, I. Nuutinen, M. Happo, T. Torvela, J. Tissari, O. Sippula, J. Jokiniemi, M.-R. Hirvonen
263	A-WG08S1P01	**Aircraft Engine Soot Emissions and Smoke Number Uncertainties** M.E.J. Stettler and A.M. Boies
264	A-WG08S1P02	**Estimation of uncertainty of elemental concentration in PM 1** G. Valotto, E. Pecorari, G. Rampazzo, F. Visin and D. Zannoni
265	A-WG08S1P03	**Collection efficiency and interstage nanoparticle loss in MOUDI** A. Awasthi, C. N. Liu, B. Gumgamsetty and C.J. Tsai

266	A-WG08S1P04	**On the calibration of the Single Particle Soot Photometer (SP2)** M. Gysel, M. Laborde, P. Mertes, P. Zieger, J. Dommen, and U. Baltensperger
267	A-WG08S1P05	**Using a CPMA-Electrometer System as a Suspended Mass Standard** T.J. Johnson , J.P.R. Symonds, K.St.J Reavell, J.S. Olfert
268	A-WG08S1P06	**First field application of a thermal desorption resonance-enhanced multiphoton-ionisation single particle time-of-flight mass spectrometer for on-line measurements of particle bound polycyclic aromatic hydrocarbons and source identification** M. Oster , G. Dragan, M. Elsasser, J. Schnelle-Kreis and R. Zimmermann
269	A-WG08S1P07	**A Study of the Shape and Fluorescence of SOA using ASPECT combined with AFS** M.V.Ghosh, I. Hoare, S. Almabrok, L. Chen, J.M. Clark, G.Cartwright, G. Marston and C. Pfrang
270	A-WG08S1P08	**Rupture event scanning: a novel procedure based on QCM to measure particle size within the nanometer range** F.N. Dultsev , S.N. Dubtsov
271	A-WG08S1P09	**Counting efficiency of Nano-LDA equipment in 100nm polystyrene particles experiments** P. Jani, L. Vámos, A. Nagy, P. Schlosser
272	A-WG08S1P10	**Field measurements with the dual wavelength optical particle analyzer** A. Nagy A. Czitrovszky, A. Kerekes, W.W. Szymanski, Z. Bozóki, T. Ajtai, Á. Filep
273	A-WG08S1P11	**Atmospheric Aerosol Sampling using All-in-one Balloon System** Kang Ho Ahn, Hong Ku Lee, Eun Hee Ram, Gun Ho Lee
274	A-WG08S1P12	**A new device for fast measurements of nanoparticle size distributions** Hans Grimm, Lothar Keck, Markus Pesch, Matthias Richter, Hans-Joachim Schulz
275	A-WG08S1P13	**Sampling test of particle concentration for single-nozzle impactor with collection trap** C-H Huang , S-W Shen , C-J Wu , C-Y Tai and M. Alonso
276	A-WG08S1P14	**Environmental monitoring of ultrafine particles in NW Europe (Joaquin project)** J. Staelens, G.P.A. Kos, E.P. Weijers, D. de Jonge, E. Frijns, P. Berghmans, C. Matheeussen and E.oekens

277	A-WG08S1P15	**A seven Aethalometer correction algorithm intercomparison** J. Backman, A. Virkkula, A. Hyvärinen, A. Dell'acqua
278	A-WG08S1P16	**Water Soluble Organic Carbon (WSOC) Measurement: A Theoretical Analysis** M. Psichoudaki, S.N. Pandis
279	A-WG08S1P17	**Insights on BC determination on quartz-fibre and PTFE filters: results of two field experiments in Milan (Italy)** R. Vecchi, G. Valli, V. Bernardoni, C. Paganelli, and A. Piazzalunga
280	A-WG08S1P18	**Comparison of methods for measuring black carbon in medium speed diesel engine exhaust** S. Saarikoski, S. Carbone, M. Happonen, A. Rostedt, T. Rönkkö, J. Ristimäki, J. Keskinen and R. Hillamo
281	A-WG08S1P19	**Efficiency of portable counters in measuring particle number and lung deposited surface area concentrations** C. Vargas Trassierra, G. Buonanno, P. De Felice, L. Stabile, F. Cardellini, A. Russi
282	A-WG08S1P20	**Comparison between offline and semi-continuous analyzers for aerosol organic and elemental carbon detection** G. Belz, A. Cinieri, P.R. Dambruoso, B.E. Daresta, G. de Gennaro, A. Giove, G. Miglietta, R.M. Nacci, C. Tortorella
283	A-WG08S1P22	**Investigating aerosol functionalization using HRMS: inputs, advantages, validation in controlled environment and comparison with AMS.** G. Salque-Moreton, D. Voisin, N. Marchand, F. Siekmann, A. Monod, B. Nozières, B. D'Anna, J.-L. Jaffrezo, J.-L. Besombes and R. Thissen
284	A-WG08S1P23	**Determination of site specific correction parameters for Aethalometer using multi-wavelength photoacoustic data.** Á. Filep, T. Ajtai, N. Utry, Z. Bozóki, G. Szabó
285	A-WG08S1P24	**Comparison of new UFP monitor with SMPS system in urban sites, in Athens, Greece** E. Diapouli, S. Vratolis, V. Vasilatou, M. Gini, G. Habilomatis, S. Cheristanidis, A. Chaloulakou, S. Pothos and K. Eleftheriadis
286	A-WG08S1P25	**A dry high altitude astronomical observatory in continental Europe** A. Gardini, E. Pérez and J.A. Quesada
287	A-WG08S1P26	**Batch-to-Batch-Variability of Stöber synthesized**

		SiO2 nanoparticles– Comparison of DLS and SMPS data within Q-NANO S. Mülhopt, M. Hauser, E. Mahon, Reinhard Schneider, H.-R. Paur
288	A-WG08S1P27	**Field experiment with ozone scrubber for monitoring of PAHs** L. Hejkrlík, I. Nikolova, H. Plachá
289	A-WG08S1P28	**Retrieval of sky radiance at three wavelengths using a sky camera** R. Román, M. Antón, A. Cazorla, A. de Miguel, F.J. Olmo, J. Bilbao and L. Alados-Arboledas
290	A-WG08S1P29	**Correlating the extinction-based dustiness to the morphology of particles** S. Bach, E. Schmidt
291	A-WG08S1P30	**Indoor aerosols sampling and analysis using personal aerosol sampler and filters** A. Akachat, H. Rebbah
292	A-WG08S1P31	**Chemical composition of commonly used CPC calibration ions in the sub 2nm range** J. Kangasluoma, J. Mikkilä, K. Lehtipalo, J. Vanhanen, H. Junninen, M. Sipilä, M. Kulmala, T. Petäjä
293	A-WG08S1P32	**Methodology for mapping air pollution in an urban environment: the background issue** M. Van Poppel, J. Peters, N. Bleux
294	A-WG08S1P33	**On the use of Direct Analysis in Real Time/Quad-Time of Flight (DART/Q-TOF) for the analysis of Organic Aerosol** A. Sylvestre, S. Ravier and N. Marchand
295	A-WG08S1P34	**Using a Single Particle Soot Photometer to detect and distinguish different absorbing aerosol types** K. Heimerl, B. Weinzierl, M. Gysel, D. Baumgardner, G. Kok, C. Linke, M. Schnaiter, J. Schwarz, P. Sheridan, R. Subramanian and J. Walker
296	A-WG08S1P35	**Detection efficiency of a TSI Environmental Particle Counter 3783 particle counter: experimental and simulated results** J. Hakala, H.E. Manninen, T. Petäjä and M. Sipilä
297	A-WG08S1P36	**Evaluation of collection efficiency for the Aerodyne Aerosol Chemical Speciation Monitor using long-term ambient air data** M. Maasikmets, F. Canonaco, J.G. Slowik, A.S.H. Prévôt, U. Baltensperger
298	A-WG08S1P37	**An innovative and efficient method for the analysis of levoglucosan in ambient air particulate matter by**

		thermal desorption coupled with GS/MS. E. Grandesso, P. Perez Ballesta, K. Valler, K. Kowalewski, C. A. Belis
299	A-WG08S1P38	**The use of quartz filters as reference material for analysis of PAHs in particulate matter ambient air samples** P. Pérez Ballesta, E. Grandesso, K. Kowalewski, C. A. Belis
300	A-WG08S1P39	**Deposition chamber for in vitro toxicity tests of nanoparticles** N. Jeannet, D. Egli, P. Steigmeier, M. Geiser, M. Fierz, Zs. Juranyi, M. Kalberer, and H. Burtscher
301	A-WG08S1P40	**A new Nano ion-DMPS for measuring the charging state of the sub-3 nm aerosol particles** E. Järvinen, H. E. Manninen, P. P. Aalto, M. Sipilä, K. Lehtipalo, T. Petäjä, V.-M. Kerminen and M. Kulmala
302	A-WG08S1P41	**Developments towards an NO2 denuder for elevated temperatures** J. C. Wolf and R. Niessner
303	A-WG08S1P42	**Development of a portable instrument to determine the fractal dimension from angular light scattering meaurements** Zs. Jurányi, A. Keller and H. Burtscher
304	A-WG08S1P43	**iSPEX: Measure aerosols with your smartphone!** H. Volten representing the iSPEX team
305	A-WG08S1P44	**Near-ground hyperspectral imaging for urban scale remote sensing of aerosols, during nighttime – laboratory and upscaling study** Y. Etzion, D.M. Broday
306	A-WG08S1P45	**New instrument to investigate size-resolved chemical composition of nano-particles** A. Kürten, J. Hoker, C. Fuchs and J. Curtius
307	A-WG08S1P46	**Development of New Particle Size Magnifier Using Cooling Nucleation Tube** T. Yamamoto and M. Adachi
308	A-WG08S1P47	**High Temperature Condensation Particle Counter** K. Rongchai and N. Collings
309	A-WG08S1P48	**Effect of particle diffusivity on DMAs with multiple monodisperse-particle outlets: theory validation and design optimization** M.Giamarelou, M. Stolzenburg, D.-R. Chen and G. Biskos
310	A-WG08S1P49	**Influence of Turbulent Diffusion in an Electrical Mobility Spectrometer** J. Salm, P. Intra, A. Yawootti, N. Tippayawongand, U. Hõrrak

311	A-WG08S1P50	**A Micro-Orifice Volatilization Impactor (MOVI) coupled to an ion trap mass spectrometer with a soft ionization source (APCI-IT/MS) for the analysis of secondary organic aerosols** M. Brueggemann, A. Vogel and T. Hoffmann
312	A-WG08S1P51	**A Novel Compact Aerosol Mass Spectrometer - the ToF-ACSM: Instrument Performance and First Field Deployment** R. Fröhlich, M. J. Cubison, J. G. Slowik, A. S. H. Prévôt, U. Baltensperger, U. Rohner, M. Gonin J. R. Kimmel, D. R. Worsnop and J. T. Jayne
313	A-WG08S1P52	**Novel Polar Nephelometer for the Measurement of the Particle Asymmetry Parameter** Paul L. Kebabian, Timothy B. Onasch, Joda C. Wormhoudt and Andrew Freedman
314	A-WG08S1P53	**Scattering Coefficients and Asymmetry Parameters derived from the Polar Nephelometer Aurora4000** T. Müller, M. Paixão and A. Wiedensohler
315	A-WG08S1P54	**Feasibility study of a Differential Aerodynamic Diameter Analyzer** D. Kiesler and F.E. Kruis
316	A-WG08S1P55	**Experimental comparison of two Very Long DMAs** J. Uin, E. Tamm
317	A-WG08S1P56	**Applying Particle Size Magnifier to nano-particle measurements** J. Mikkilä, K. Lehtipalo, J. Kangasluoma, J. Vanhanen, T. Petäjä and M. Kulmala
318	A-WG08S1P57	**Novel continuous ambient air quality monitoring system that simultaneously reports multiple PM-fractions, number concentration and size distribution** M. Weiss, J. Spielvogel
319	A-WG08S1P58	**Direct probing of aerosol surfaces by synchrotron-radiation-based XPS** J. Werner, Y. Cai, N. L. Prisle, G. Öhrwall, J. Söderström, M. Dal Maso and O. Björneholm
320	A-WG08S1P59	**Liquid sample nanoparticle sizing system** J.E. Farnsworth, K. Erickson, B.L. Osmondson, and R. Caldow
321	A-WG08S1P60	**Approximate relationship between mobility and voltage for Brownian particles in a cylindrical DMA** M. Alonso, F.J. Alguacil and C.H. Huang
322	A-WG08S1P61	**Evaluation of Size Selective PM10 Sampling Inlets in Aerosol Wind Tunnel**

		Sangil Lee, Miae Yu, Hyun Ho Kim
323	A-WG08S1P62	**Enhanced multiple charge inversion algorithm for mobility size spectrometers** S. Pfeifer, T. Müller and A. Wiedensohler
324	A-WG08S1P63	**Thermodynamic characterization of the atmosphere during a Saharan dust intrusion over South Spain with onboard and remote sensing instrumentation: CLIMARENO** N. Seoane-Vieira, J. Andrey-Andrés, M.J. Granados-Muñoz, J. Fernández-Gálvez, R. González-Armengod, J.A. Adame, J. Tabrizi Sirvani, F. Lahoz-Pequerul,O. Serrano, M. Marco-Saurín
325	A-WG08S1P64	**Integrated instrument data and control for CLOUD chamber** J. Almeida, A. Amorim, A. David, P. Pereira, A. Tomé and Cloud Collaboration
326	A-WG08S1P65	**Reducing measurement error of Cloud Droplet Probe with a statistical smoother** S.Mikkonen, H. Portin, M. Komppula, A. Laaksonen and S. Romakkaniemi
327	A-WG08S1P66	**Off-line organic aerosol analyses of filter samples using aerosol mass spectrometry** I. El Haddad, J. Slowik, U. Baltensperger, A.S.H. Prévôt

Tuesday 4th September

08:45-09:45 Plenary 2. **Gelsomina Pappalardo**. *ACTRIS Research Infrastructure for coordinated long-term observation of aerosols, cloud-aerosol Interactions, and trace gases in Europe*
Room: Auditorio
Chair: Urs Baltensperger

09:45-10:30 Coffee-break

10:30-12:50 **Session SS01S1O. ACTRIS**
Room: Auditorio
Chairs: G. Pappalardo / P. Laj

10:30	SS01S1O01	**Long-term trends of aerosol number concentrations at GAW stations** A. Asmi, M. Collaud Coen, E. Andrews, M. Fiebig, A. M. Fjaeraa, P. Laj, J.A. Ogren, P. Sheridan, A. Virkkula, U. Baltensperger and E. Weingartner
10:50	SS01S1O02	**Long-term trend analysis of aerosol optical variables at GAW stations** M. Collaud Coen, E. Andrews, A. Asmi, M. Fiebig, A. M. Fjaeraa, P. Laj, C. Lund Myhre, J. A. Ogren, J.-P. Putaud, P. J. Sheridan, A. Virkkula, A. Wiedensohler, U. Baltensperger, and E. Weingartner
11:10	SS01S1O03	**Soot absorption over Europe combining observations and models** E. Vignati, M. Schulz, F. Cavalli, T. Mueller, A. Virkkula, C. Lund Myhre, A. Wiedesohler and P. Laj
11:30	SS01S1O04	**Merging air ion spectrometer and particle mobility size spectrometer measurements** H.E. Manninen, T. Petäjä, P. Aalto, W. Birmili, M. Kulmala and A. Wiedensohler
11:50	SS01S1O05	**Retrieval of aerosol microphysical properties profiles by combination of Lidar and sun photometer measurements. Application to mineral dust and volcanic aerosols** M.J. Granados-Muñoz, J.A. Bravo-Aranda, F. Navas-Guzmán, J.L. Guerrero-Rascado, H. Lyamani, A. Chaikovsky, J. Wagner, U. Wandinger, F.J.Olmo and L. Alados-Arboledas

12:10	SS01S1O06	**Optical and microphysical characterization of volcanic sulphate particles in the lower troposphere by Raman lidar** F. Navas-Guzmán, D. Müller,J. A. Bravo-Aranda, D. Pérez-Ramírez, F.J. Olmo, J.L. Guerrero-Rascado, U. Wandinger and L. Alados-Arboledas
12:30	SS01S1O07	**ACTRIS Data Centre: An atmospheric data portal** Cathrine Lund Myhre, Aasmund Fahre Vik, Robert Logna, Kjetil Tørseth, Holger Linné, Ewan O'Connor

10:30-12:50 **Session WG02S3O. Urban Aerosol in Large Cities (1)**
Room: Legado Andalusí
Chairs: T. Kuhlbusch / G. Fuller

10:30	WG02S3O01	**SAPUSS Solving Aerosol Problems by using synergistic strategies in Barcelona, Spain** M. Dall'Osto, A. Alastuey, M. A. Pedemonte, B. L. van Drooge, M. Pandolfi, M. C. Minguillon, F. Amato, T. Moreno, J. Pey, C. Reche, M. Cusak, M. Viana, A. Roca, J. Gietl, D. Beddows, Roy M. Harrison, J. Wenger, E. Mc Gillcuddy, J. Sudou, R. Healy, D. Ceburnis, G. Martucci, C. O'Dowd, F. Lucarelli, S. Nava, J. L. Jimenez, F. Gomez Moreno, B. Artinono, A. S. H. Prevot, L. Pfaffenberger, S. Frey, F. Wilsenack, S. Ng, D. Worsnop, D. Casabona Fina, P. Jiménez Guerrero and X. Querol
10:50	WG02S3O02	**Simultaneous Single Particle Mass Spectrometry Measurements at Two Different Urban Sites and Comparison with Quantitative Techniques** Eoin McGillicuddy, Manuel Dall'Osto, Franco Lucarelli, Silvia Nava, Xavier Querol, Roy M. Harrison, Johanna K. Gietl, David C. S. Beddows, Deborah Gross, Robert Healy, John Wenger , John Sodeau
11:10	WG02S3O03	**Hourly elemental concentrations at two different urban locations in Barcelona, Spain** F. Lucarelli, S. Nava, G. Calzolai, M. Chiari, M. Dall'Osto, X. Querol
11:30	WG02S3O04	**Seasonal comparison of comprehensive aerosol measurements in London during ClearfLo** D.E. Young, J.D. Allan, P.I. Williams, M.J. Flynn, D. Liu, J.D. Whitehead, N.H. Robinson, A.S.H. Prevot, S. Visser, M. Furger, M.W. Gallagher, and H.Coe

11:50	WG02S3O05	**A mobile measurement network for ultrafine particulate matter in the city of Zurich** A. Richard, P. Steigmeier, H. Burtscher and M. Fierz
12:10	WG02S3O06	**High-resolution mobile monitoring of traffic emissions in an urban area in Finland** L. Pirjola, T. Lähde, A. Malinen, J.V. Niemi, A. Kousa, T. Rönkkö,P. Karjalainen, J. Keskinen, A. Frey, and R. Hillamo
12:30	WG02S3O07	**Spatial and Seasonal Variations of Black Carbon and NO2 Concentrations in an Urban Environment and correlation with UFP concentrations at selected locations** M. Van Poppel, C. Matheeussen, P. Berghmans
Reserve paper	WG02S3B00	**Spatial distribution of particle number concentrations measured with the AERO-TRAM** B. Vogel, R. Hagemann, R. Rinke, A. Wieser, U. Corsmeier, Ch. Kottmeier

10:30-12:50 **Session WG03S3O. Characterisation Techniques for Organic Aerosol**
Room: Faraday
Chairs: A. Held / J. Schneider

10:30	WG03S3O01	**Single particle mass spectrometry of bacteria – lab measurements as reference for the identification of ambient bioaerosols** B. Sierau, F. Freutel, A. Roth, J. Schneider, C. Oehm, O. Möhler, and A. A. Mensah
10:50	WG03S3O02	**On-line analysis of organic aerosols with an ion-trap aerosol mass spectrometer** S.J. Gallavardin, J. Fachinger, F. Helleis, F. Drewnick, and S. Borrmann
11:10	WG03S3O03	**Organic particle and gas phase measurements with a new MOVI-CI-TOF-MS** C. Mohr, F. Lopez-Hilfiker, J. D. Wargo, R. L. N. Yatavelli, and J. A. Thornton
11:30	WG03S3O04	**Urban organic aerosols composition measured by ultra-high resolution mass spectrometry** A.G. Rincón, A.I. Calvo, M. Dietzel, M. Kalberer
11:50	WG03S3O05	**Unravelling the molecular organic signature of the EC/OC fractions of PM: Coupling of an EC/OC-carbon analyzer to photo-ionization mass**

		spectrometry J.Grabowski, T.Streibel, M.Sklorz, J.Chow, J.Watson and R.Zimmermann
12:10	WG03S3O06	**A long pathlength absorbance photometer for the determination of peroxide content and brown carbon in primary and secondary organic aerosol** J. Dommen, P. Mertes, S.M. Platt, I. El Haddad, L. Pfaffenberger, A.S.H. Prévôt, M. Kalberer, and U. Baltensperger
12:30	WG03S3O07	**Investigation of Free Radicals Formed in the Oxidation of Acoustically Levitated Alpha-Pinene Droplets by Electron Spin Resonance** M.V.Ghosh, P.Ionita, S. Almabrok, G. Marston, and C. Pfrang
Reserve paper	WG03S3B00	**Studying Atmospheric Aerosols by Acoustic Levitation: Linking Head Space Solid-Phase Micro-Extraction (HS-SPME) with Gas Chromatography-Mass Spectrometry (GC-MS)** S. Almabrok, G. Marston and C. Pfrang

10:30-12:50 **Session WG07S1O. Application of engineered nanoparticles**
Room: Cine3
Chairs: S. Pratsinis / A. Nasibulin

10:30	WG07S1O01	**Plasmonic biosensors with composite nanosilver structures** G.A. Sotiriou, C. O. Blattmann and S. E. Pratsinis
10:50	WG07S1O02	**Tailoring Single-walled Carbon Nanotube Diameters in Aerosol Synthesis Method** A. G. Nasibulin Y. Tian, M. Timmermans, A. O. Kaskela, K. Mustonen, T. Susi, I. V. Anoshkin, E. I. Kauppinen
11:10	WG07S1O03	**Aerosol-derived antimony doped-tin oxide nanoparticles and studies on the influence of organic and inorganic shells in nanoparticle assemblies on the overall conductance** S.B. Bubenhofera, C.M. Schumachera, G.A. Sotirioub, R.N. Grassa and W.J. Stark
11:30	WG07S1O04	**Synthesis of well-structured Pt catalysts on spherical SiO2 support by a CVS/CVD process using novel metal-organic precursors** M. Faust, K. Gao, M. Enders, S. Bräse, W. Gerlinger and

		M. Seipenbusch
11:50	WG07S1O05	**Different hybrid and single-phase nanoparticles by aerosol-photopolymerization** E. Akgün, W. Gerlinger, M. Wörner, B. Sachweh, J. Hubbuch
12:10	WG07S1O06	**Continuous, electrostatic controlled synthesis of organic-inorganic composite particles** S. Sigmund, E. Akgün, J. Meyer, M. Wörner, W. Gerlinger and G. Kasper
12:30	WG07S1O07	**Room temperature ultraviolet nanophosphor of geometrical MgO nanoparticles** P.V. Pikhitsa, C.H. Kim, S. Chae, S. Shin, S. Jung and M. Choi
Reserve paper	WG07S1B00	**Electrospray deposition of graphene nanosheets** L. B. Modesto-Lopez, O. V. Bilousov, J. J. Carvajal, F. Díaz and J. Rosell-Llompart

10:30-12:50 **Session WG08S3O. Measurement Methods**
Room: Gutenberg
Chairs: R. Niessner / V. Szymanski

10:30	WG08S3O01	**The use of Nuclear Reaction Analysis technique for the determination of Nitrogen in aerosol samples collected on Teflon filters** I. García Orellana, S. Becagli, G. Calzolai, M. Chiari, J. García López, S. Nava, F. Lucarelli, M. Respaldiza, R. Vecchi
10:50	WG08S3O02	**Laser Vaporizer-AMS for exposure assessment and detection of airborne engineered metal nanoparticles** P.T. Nilsson, A. C. Eriksson, M. E. Messing, C. Isaxon, M. Hedmer, H. Tinnerberg, B. O. Meuller, C. R. Svensson, K. Deppert, M. Bohgard and J. Pagels
11:10	WG08S3O03	**Size and surface area characterization of Carbon nanoparticle aggregates by means of a cascade epiphaniometer** M.I. Gini, K. Eleftheriadis, S. Vratolis, C. Helmis, K. Giannakopoulos, D. Papanastasiou, G.Orfanopoulos E. Raptakis
11:30	WG08S3O04	**TwinPAS – a photoacoustic instrument for the parallel, time-resolved analysis of soot and NO2 in exhaust gas** C. Haisch and R. Niessner

11:50	WG08S3O05	**Investigation of Fast Scanning SMPS Measurements: 16s and Below** K. Erickson, F. Quant, J. Farnsworth and R. Caldow
12:10	WG08S3O06	**New portable device for high time resolved measurements of particle size distributions** H. Grimm, D. Huhn, M. Pesch, M. Richter and F. Schneider
12:30	WG08S3O07	**Experimental aerosols characterization for the evaluation of source term from RDE's (Radiological Dispersion Events)** F.G. Di Lemma, J.Y. Colle, H. Thiele and R.J.M. Konings
Reserve paper	WG08S1B00	**Batch-to-Batch-Variability of Stöber synthesized SiO2 nanoparticles– Comparison of DLS and SMPS data within Q-NANO** S. Mülhopt, M. Hauser, E. Mahon, R. Schneider, H.-R. Paur

14:00-16:00 **Session WG01S3O. Remote Sensing of Aerosol Properties**
Room: Auditorio
Chairs: L. Alados-Arboledas / P. Sheridan

14:00	WG01S3O01	**In situ aerosol measurements for the validation and improvement of CALIPSO lidar extinction retrievals** P. Sheridan, J.A. Ogren, E. Andrews, J.L. Tackett, and D.M. Winker
14:20	WG01S3O02	**CLIMARENO-GRA 2011 campaign: Aerosol optical properties characterization from ground-based instrumentation** J.A.Bravo-Aranda, F. Navas-Guzmán, J. Andrey, M.J. Granados-Muñoz, J.L. Guerrerro-Rascado, M. Gil, H. Lyamani, A. Valenzuela, G. Titos, J. Fernández-Gálvez, F.J. Olmo and L. Alados-Arboledas
14:40	WG01S3O03	**Tropospheric aerosols remote sensing with a sensitive and accurate UV-VIS polarization Lidar** G. David, B. Thomas, A. Miffre and P. Rairoux
15:00	WG01S3O04	**Study on the influence of different error sources on sky radiance measurementsand inversion-derived aerosol products in the frame of AERONET** B. Torres, C. Toledano, A.J. Berjón, O. Dubovik, V. E.

		Cachorro, Y. Bennouna, D. Fuertes,R. González, P. Goloub, T. Podvin, L. Barel, A. M. de Frutos
15:20	WG01S3O05	**Evaluation of aerosol OC / BC estimations derived from AERONET data, using in-situ ground measurements** D. Paraskevopoulou, S. Kazadzis, N. Mihalopoulos, A. Arola, K. Eleftheriadis, C. Theodosi, A. Bougiatioti, E. Diapouli and E. Gerasopoulos
15:40	WG01S3O06	**Retrieving MODIS Aerosol Optical Depth in real time at 500 m resolution: urban-scale evaluation over Hong Kong** M. Bilal, J. E. Nichol, M. P. Bleiweiss, D. Dubois
Reserve paper	WG01S3B00	**Aerosol vertical distribution and its variability over Sweden during nighttime: A view from the CALIOP-CALIPSO and AIRS instruments** M.A. Thomas, A. Devasthale and M. Kahnert

14:00-16:00 **Session WG02S4O. Marine and Carbonaceous Aerosol**
Room: Legado Andalusí
Chairs: D. Baumgardner / A. I. Calvo Gordaliza

14:00	WG02S4O01	**Radiocarbon analysis on organic and elemental carbon in aerosol samples and source apportionment at an urban site in Northern Italy** V. Bernardoni, G. Calzolai, M. Chiari, M. Fedi, F. Lucarelli, S. Nava, A. Piazzalunga, F. Riccobono, F. Taccetti, G. Valli, R. Vecchi
14:20	WG02S4O02	**Results of monitoring campaign from a cruise ship in the Western Mediterranean** M.C. Bove, G. Calzolai, F. Cavalli, M. Chiari, E. Cuccia, J. Hjorth, D. Massabò, A. Piazzalunga, P. Prati, C. Schembari
14:40	WG02S4O03	**Organic Carbon detection in crude oil plant emissions in South Italy** M. Calvello, F. Esposito, G. Pavese, M. Lovallo, L. Mangiamele
15:00	WG02S4O04	**The Seasonal Cycle of Sea Spray Emissions: Long term Eddy Covariance Aerosol Flux measurements from Östergarnsholm, Baltic Sea (57°27`N ,18°59` E)** E. Douglas Nilsson and Monica E. Mårtensson

15:20	WG02S4O05	**Diurnal cycle of fossil and non-fossil carbon using 14C analyses during CalNex** P. Zotter, A.S.H. Prévôt, I. El-Haddad, Y. Zhang, S. Szidat, L. Wacker, X. Zhang, R. Bahreini, P. Hayes, J.B. Gilman, J.A. de Gouw, J.L. Jimenez, R. Weber, U. Baltensperger
15:40	WG02S4O06	**A new sea-salt module implemented within the NMMB/BSC Chemical Transport Model** M. Spada, O. Jorba, C. Pérez, Z.I. Janjic and J.M. Baldasano
Reserve paper	WG02S4B00	**New Findings on Submicron Sea Salt Source Flux** J. Ovadnevaite, D. Ceburnis, H. Berresheim and C. O'Dowd

14:00-16:00 **Session WG03S4O. Chemistry of Organic Aerosol: Field Study**
Room: Faraday
Chairs: J. Dommen / I. Kourtchev

14:00	WG03S4O01	**Observations of monoterpene organosulfates in wintertime aerosols** A.M.K. Hansen, K. Kristensen, F. Cozzi, A. Zare, M.F. Lauridsen and M. Glasius
14:20	WG03S4O02	**Simultaneous study of gas and particulate products formed from limonene oxidation: smog chamber and citrus fruit field measurements** L. Chiappini, S. Rossignol, C. Rio, S. Fable, G. Grignion, J.L. Savelli
14:40	WG03S4O03	**Quantification of nitrocatechols and related aromatic compounds in atmospheric aerosols** Z. Kitanovski, I. Grgić, M. Claeys, R. Vermeylen and W. Maenhaut
15:00	WG03S4O04	**Contribution of Cooking Emissions to Primary and Secondary Organic Aerosol in Urban Atmospheres** I. El Haddad, S.M. Platt, J. Slowik1, C. Mohr, M. Crippa, B. Temime-roussel, A. Detournay, N. Marchand, U. Baltensperger, A. S. H. Prévôt
15:20	WG03S4O05	**Interpretation of Sources and Formation Processes of Sub-micron Aerosols near Denver, Colorado from Tower Measurements during NACHTT 2011** Öztürk, F., Bahreini, R., Wagner, N., Dubé, W., Young, C., Brown, S.S., Brock, C., Ulbrich, I.M, Jimenez, J and Middlebrook, A.M.

15:40	WG03S4O06	**Composition and formation of organic aerosol particles in the Amazon** C. Pöhlker, K. T. Wiedemann, B. Sinha, M. Shiraiwa, S. S. Gunthe, M. Smith, H. Su, P. Artaxo, W. Elbert, M. K. Gilles, A. L. D. Kilcoyne, R. C. Moffet, M. Weigand, S. T. Martin, U. Pöschl, M. O. Andreae
Reserve paper	WG03S4B00	**Characterization of humic-like substances (HULIS) in size segregated atmospheric aerosol** G. Kiss, N. Törő, A. Hoffer, J. Dautovic, S. Frka, Z. Kozarac, M. Harir, P. Schmitt-Kopplin

14:00-16:00 **Session WG05S1O. Physical and chemical analysis of PMx**
Room: Gutenberg
Chairs: W. Maenhaut / A. Alastuey

14:00	WG05S1O01	**Inhalable aerosol chemistry of transboundary particulate intrusions into western Japan** T. Moreno, T. Kojima, X. Querol, A. Alastuey, F. Amato, F. Lucarelli, J. de la Rosa and W. Gibbons
14:20	WG05S1O02	**Size-segregated Characterization of PM10 in German low lands (EMEP site Melpitz) using a five-stage Impactor: A six year study** G. Spindler, A. Grüner, Y. Iinuma, K. Müller, S. Scheinhardt, H. Herrmann
14:40	WG05S1O03	**Ultrafine particles and PM1 measurements in a hot-spot pollution area: size distribution, mass closure and source apportionment** R. Vecchi, V. Bernardoni, A. Bigi, M. Elser Fritsche, P. Fermo, G. Ghermandi, A. Piazzalunga, R. Gonzales Turrion, M. Urbani, G. Valli
15:00	WG05S1O04	**Factors influencing levels and composition of PM in the Barcelona's city subway system** Querol X., Moreno T., Karanasiou A., Reche C., Alastuey A., Viana M., Font O., Gil J., de Miguel E., Capdevila M
15:20	WG05S1O05	**Chemical characterization and source apportionment of oxidized organic aerosol components by advanced spectroscopic techniques in the Po Valley, Italy** M. Paglione, S. Decesari, M. Dall'Osto, R. Hillamo, S. Carbone, S. Saarikoski, R. Harrison, C. O'Dowd, and M.C. Facchini

15:40	WG05S1O06	**Towards an identification of sources of HUmic LIke Substances (HULIS) by statistical analysis** J. Guilhermet, C. Piot, J. Vessaire, C. Baduel, J.-L. Jaffrezo and D. Voisin
Reserve paper	WG05S1B00	**Personal monitoring of ambient particulate matter – online monitoring and offline filter sample analysis** J. Schnelle-Kreis G. Abbaszade, J. Cyrys, J. Gu, M. Pitz, A. Peters, R. Zimmermann

14:00-16:00 **Session WG07S2O. Fundamentals and measurement of nanoparticles**
Room: Cine 3
Chairs: A. Schmidt-Ott / G. Kasper

14:00	WG07S2O01	**Physical defect formation in few layer graphene-like carbon on aerosol-made metal nanoparticles** C.M. Schumacher, R.N. Grass, M. Rossier, E.K. Athanassiou and W.J. Stark
14:20	WG07S2O02	**Measurement of the velocity of nanoparticles in a molecular beam of a particle mass spectrometer** W. Baumann, H. Mätzing, J. Seibold, M. Hauser, H.-R. Paur and H. Seifert
14:40	WG07S2O03	**Scaling-up the production of monodisperse nanoparticles by means of a high-flow rate parallel plate DMA** M. Rouenhoff, E. Hontañón, A. Azabal, E. Ramiro and F. E. Kruis
15:00	WG07S2O04	**Direct Transfer and Stabilization of Aerosol Particles into Liquid Suspensions by Meansof a Wet Electrostatic Precipitator** C. Anderlohr, K. Schaber, W. Gerlinger
15:20	WG07S2O05	**An Aerosol Process for Fabrication of a Carbon NanoTube Membrane with Tuneable Pore Size** M. Valenti, A.C. Zonnevylle, V. Vons, C.W. Hagen, R. van Ommen and A. Schmidt-Ott
15:40	WG07S2O06	**Structural determination of charged nanoparticles in a Polarizable Gas** C. Larriba and C. Hogan
Reserve paper	WG07S2B00	**A MEMS sensor based personal sampler for ultrafine particles** S. Merzsch, H.S. Wasisto, E. Peiner, I. Kirsch and E. Uhde

POSTER SESSION B

001	B-WG01S2P01	**Estimation of the aerosol optical depth in the UV region at Caceres (Spain) by the Angstrom formula** M.A. Obregón, A. Serrano and M.L. Cancillo
002	B-WG01S2P02	**Calculation of aerosol microphysical properties by neural network inversion of ground-based AERONET data** M. Taylor , S. Kazantzis, A. Tsekeri, A. Gkikas and V. Amiridis
003	B-WG01S2P03	**Aerosol fine fraction characterization by integrated in-situ and columnar measurements** M. Calvello, F. Esposito and G. Pavese
004	B-WG01S2P04	**SPEX: Multi-Angle Spectropolarimetry for aerosol and cloud characterization from the ISS** O.P. Hasekamp, M. Smit, J. Rietjens, F. Snik, G. van Harten & the SPEX team
005	B-WG01S2P05	**Intercomparison of lidar aerosol backscatter and in-situ size distribution measurements** A. Held, T. Seith, I.M. Brooks, S.J. Norris and S.D. Mayor
006	B-WG01S2P06	**SEVIRI based aerosol optical depth and type retrieval** S. Nevens, N. Clerbaux, A. Velazquez Blazquez, E. Baudrez, I. Decoster, S. Dewitte, A. Ipe
007	B-WG01S2P07	**Lidar observations of stratospheric aerosol over the Northern Hemisphere from Nabro volcano: MPLNET, EARLINET, CALIPSO, NDACC synergy** P. Sawamura, J.P.Vernier, J. E.Barnes, T.A. Berkoff, E.J. Welton, L.Alados-Arboledas, F. Navas-Guzmán, L.Mona, D. Lange, M.Sicard, S. Godin-Beekmann, G. Payen, Z. Wang and R.M. Hoff
008	B-WG01S2P08	**Detection of the stratospheric volcanic aerosol plume from the Nabro eruption in summer 2011 in the framework of SPALINET** J.L. Guerrero-Rascado, J.A. Bravo-Aranda, F. Wagner, C. Córdoba-Jabonero, F. Molero, D. Lange, M. Granados-Muñoz, J. Preißler, D. Toledo, A.J. Fernández, M. Sicard, F. Navas-Guzmán, Y. Hernández, A.M. Silva, M. Pujadas, A. Comerón, S. Pereira, F. Rocadenbosch, and L. Alados-Arboledas
009	B-WG01S2P09	**CLIMARENO-GRA 2011 campaign: retrieval of vertically-resolved aerosol microphysical properties by lidar at daytime** J.L. Guerrero-Rascado, M. J. Granados-Muñoz, F. Navas-Guzmán, J. A. Bravo-Aranda, F. J. Olmo, J. Andrey, M. Gil,

		A. Chaikovsky, U. Wandinger and L. Alados-Arboledas
010	B-WG01S2P10	**First profiling of aerosol microphysical properties from combination of multiwavelength lidar (EARLINET) and sun-photometric (AERONET) data at Évora (Portugal)** J.L. Guerrero-Rascado, A. M. Silva, M. J. Costa, J. Preißler, S. Pereira, A. Chaikovsky and F. Wagner
011	B-WG01S2P11	**A case study of a strong aerosol load over Heraclion Crete (Greece), detected with ground-based lidar and in situ airborne measurements** P. Kokkalis, G. Tzeremes, A. Papayannis, V. Amiridis, E. Armandillo
012	B-WG01S2P12	**PBL determination from ground based lidar over Herakleion-Crete Greece** P. Kokkalis, G. Tzeremes, A. Papayannis, and E. Armandillo
013	B-WG01S2P13	**Saharan Air Layer (SAL) over Tenerife: Summertime statistic analysis from lidar measurements** C. Córdoba-Jabonero, D. Toledo, J.A. Adame, Y. Hernández, E. Cuevas and M. Gil
014	B-WG01S2P14	**Polar Stratospheric Clouds observations in coastal Antarctica based on Micro Pulse Lidar measurements. I. Depolarization ratio comparison with CALIOP** C. Córdoba-Jabonero, J.L. Guerrero-Rascado, D. Toledo, M. Parrondo, M. Yela, M. Gil and H. Ochoa
015	B-WG01S2P15	**Polar Stratospheric Clouds observations in coastal Antarctica based on Micro Pulse Lidar measurements. II. PSC-type discrimination assessment** D. Toledo, C. Córdoba-Jabonero, J.L. Guerrero-Rascado, M. Parrondo, M. Yela, M. Gil and H. Ochoa
016	B-WG01S2P16	**Multiwavelength Raman lidar observations of aerosols at Gual Pahari, India** E. Giannakaki, T. Mielonen, K. Korhonen, H. Lihavainen, A.-P. Hyvärinen, D. Mülle, H. Baars, R. Engelmann, D. Althausen, T.S. Panwar, R.K. Hooda, V.P. Sharma, K.E.J. Lehtinen, Y. Viisanen and M. Komppula
017	B-WG01S2P17	**Preliminary results from the new portable backscatter aerosol lidar in Turkey** K. R. Allakhverdiev, A. Secgin, M. F. Huseyinoglu and Z. Salaeva
018	B-WG01S2P18	**Aerosol vertical distribution and its variability over Sweden during nighttime: A view from the CALIOP-CALIPSO and AIRS instruments** M.A. Thomas, A. Devasthale and M. Kahnert

019	B-WG01S2P19	**Aerosol variability over Lemesos, Cyprus: Use of ground based data, satellite observations and model simulations.** RE Mamouri, S. Kleanthous, S. Basart, V. Amiridis, Nisantzi, A., D.G Hadjimitsis, A. Agapiou and J.M.Baldasano
020	B-WG01S2P20	**Nine years of aerosol optical depth measurements over north-central Spain from ground (AERONET-RIMA) and their comparison with satellite (MODIS) observations** Y.S. Bennouna, V.E. Cachorro, B. Torres, R. Rodrigo, C. Toledano, A. Berjón and A.M. de Frutos
021	B-WG01S2P21	**A first approach to study the aerosol indirect effect over Madrid by means of multiwavelength Raman lidar** A.J. Fernández, F. Molero and M. Pujadas
022	B-WG01S2P22	**Single scattering albedo and fine mode faction retrieved with AATSR satellite instrument** E. Rodríguez, P. Kolmonen, A-M Sundström, L. Sogacheva, T. Virtanen, G. de Leeuw
023	B-WG01S2P23	**Optical and Microphysical properties from Raman lidar and depolarization data** F. Navas-Guzman, L. Osterloh, C. Böckmann, M.J. Granados-Muñoz, and L. Alados Arboledas
024	B-WG01S2P24	**Towards a remote sensing tool for aerosol hygroscopicity studies combining lidar and passive microwave radiometry** F. Navas-Guzmán, J. Bravo-Aranda, M.J. Granados-Muñoz, J.L. Guerrero-Rascado, J. Fernández-Gálvez, A.J. Fernández and L. Alados-Arboledas
025	B-WG01S2P25	**A first estimation of aerosol radiative forcing at Málaga (Spain) through the direct method** I. Foyo-Moreno, Alados, I. H. Lyamani, Olmo, F.J. and L. Alados-Arboledas
026	B-WG01S2P26	**Cloud screening and quality control algorithms for star photometry.** D. Pérez-Ramírez, H. Lyamani, F.J. Olmo, D.N. Whiteman, F. Navas-Guzmán and L. Alados-Arboledas
027	B-WG01S2P27	**Mixing height from passive remote sensing at high temporal resolution** J.Fernández-Gálvez, M.J. Granados-Muñoz, F.J. Olmo and L. Alados-Arboledas
028	B-WG01S2P28	**EARLINET and the international ChArMEx and PEGASOS measurement campaigns in summer 2012** L. Mona, M. Sicard, A. Amodeo, A. Apituley, L.Alados-

		Arboledas, D. Balis, C. Böckmann, A. Chaikovsky, A. Comeron, G. D'Amico, F. De Tomasi, V. Freudenthaler, A. Giunta, I. Grigorov, M. Haeffelin, M. Iarlori, H. Linnè, M. McAuliffe, F. Molero, V. Mitev, D. Nicolae, N.Papagiannopoulos, A. Papayannis, M.R. Perrone, A. Pietruczuk, M. Pujadas, J.-P. Putaud, V. Rizi, F. Rocadenbosch, V. Simeonov, N. Spinelli, K. Stebel, T. Trickl, U. Wandinger, X. Wang, F. Wagner, M. Wiegner and G. Pappalardo
029	B-WG01S2P29	**Climatology of aerosol optical properties over a tropical –urban location in western India** G. R. Aher and G. V. Pawar
030	B-WG01S2P30	**Calibration and intercomparison results in the Spanish network on environmental DMAs** F. J. Gómez-Moreno, B. Artíñano, V. Juncal Bello, M. Piñeiro Iglesias, P. López Mahía, N. Pérez, J. Pey, A. Alastuey, B. A. de la Morena, M. I. García, S. Rodríguez, M. Sorribas, G. Titos, H. Lyamani and L. Alados-Arboledas
031	B-WG01S2P31	**Influence of the thermophoresis on aerosol deposition on warm urban surfaces** P. Roupsard, D. Maro, A. Coppalle, H. Branger, O. Connan, D. Hébert and B. Letellier
032	B-WG01S2P32	**Long Term Trends in Arctic Aerosol Composition at Kevo, Finland** P.K. Hopke, J.R. Laing, L. Hussain, V.A. Dutkiewicz, J. Paatero, and Y. Viisinen
033	B-WG01S2P33	**Hygroscopicity of organic/inorganic internally mixed particles by infrared spectroscopy** Lorena Miñambres, Estíbaliz Méndez, María N. Sánchez, Fernando Castaño and Francisco J. Basterretxea
034	B-WG01S2P34	**General assessment of the main factors governing the particle concentrations in urban and regional background environments** J.F. Nicolás, J. Crespo, E. Yubero, N. Galindo, J. Moltó and E. Mantilla.
035	B-WG01S2P35	**Non-volatile aerosol in the Arctic Winter Stratosphere and its role for PSC formation.** R. Weigel, M. Ebert, K. Kandler, S. Molleker, W. Frey, M. Klingebiel, C. M. Volk, G. Günther, H. Schlager, F. Cairo, S. Kaykin, S. Borrmann
036	B-WG01S2P36	**Chemical Characterization of Impactor Samples from seven Sites in Germany** K. Müller, G. Spindler, T. Gnauk, Y. Iinuma, H. Herrmann
037	B-WG01S2P37	**Physicochemical Properties of Ultrafine Aerosol**

		Particles in the North Aegean during the AEGEAN_GAME Field Campaign E. Triantafyllou, M.Giamarelou, S. Bezantakos, K. Barmpounis, E. Bossioli, Ch. Theodosi, M. Tombrou, N. Mihalopoulos, K. Eleftheriadis, G. Biskos
038	B-WG01S2P38	**Physico-chemical characterization of HULIS from different environments** T.B. Kristensen, L. Du, Q.T. Nguyen, H.G. Kjærgaard, C.B. Koch, J.K. Nøjgaard, A.G. Hallar, D.H. Lowenthal, B. Nekat, D. van Pinxteren, M. Glasius and M. Bilde
039	B-WG01S2P39	**Photophoresis of soot aerosols in the atmospheric radiation field** L.B. Kochneva and S.A. Beresnev
040	B-WG01S2P40	**Chemistry of Size Separated Aerosols over the Indian Arctic Station, Himadri** M.P. Raju, S. M. Sonbawne, P.D. Safai, P.S.P. Rao and P.C.S. Devara
041	B-WG01S2P41	**Two years of measurements of atmospheric aerosols at a remote mountain site in NE Spain** A. Ripoll, M.C. Minguillón, J. Pey, X. Querol, A. Alastuey
042	B-WG01S2P42	**Investigating physicochemical properties of marine aerosol over the Atlantic Ocean** S. Huang, L. Poulain , Z. Wu, F. Höpner, H. Herrmann, A. Wiedensohler
043	B-WG01S2P43	**Evaluation of aerosols properties using ground based instruments in Magurele, Romania** J. Vasilescu, L. Marmureanu, A. Nemuc and L. Belegante
044	B-WG01S2P44	**Size-segregated inorganic aerosol compounds during different meteorological scenarios** M. A. Revuelta, F. J. Gómez-Moreno, L. Núñez, M. Pujadas, B. Artíñano
045	B-WG01S2P45	**Ionization of the atmosphere induced by cosmic rays: Full model and practical applications** I.G. Usoskin
046	B-WG01S2P46	**Long term observations of aerosol light absorption and particle volatility properties in the lower tropical free troposphere** T. Hamburger, R. Krejci, M. Matisans, J. Ström, P. Tunved, G. Hoschild, J. Gross, S. Calderon and P. Hoffmann
047	B-WG01S2P47	**Aerosol long-term volatility measurements in a boreal forest environment** S.A.K. Häkkinen, M. Äijälä, K. Lehtipalo, H. Junninen, J. Backman, A. Virkkula, T. Nieminen, M. Vestenius, H. Hakola, M. Ehn, D. R., Worsnop, M. Kulmala, T. Petäjä and I. Riipinen

048	B-WG01S2P48	**Aerosol water soluble organic matter: Characterization of surface active substances by electrochemical method** Z. Kozarac, B. Ćosović, S. Frka, J. Dautović, G. Kiss, A. Hoffer
049	B-WG01S2P49	**Hygroscopic Properties of Ultrafine Aerosol Particles over the Aegean Sea** S. Bezantakos, K. Barmpounis, E. Bossioli, M. Tombrou, N. Mihalopoulos, K. Eleftheriadis, J. D. Allan, H. Coe A. Bacak, G. Biskos
050	B-WG01S2P50	**Hygroscopic Properties of Fine and Ultrafine Aerosol Particles over an Urban Background Site in Athens, Greece** S. Bezantakos, S. Vratolis, L. Diapouli, K. Eleftheriadis, G. Biskos
051	B-WG01S2P51	**Determination of the parameters of the critical nucleus that is formed on the seed particles during heterogeneous nucleation** S.V. Valiulin, V.V. Karasev, S.V. Vosel, A.A. Onischuk, A.M. Baklanov, S. di Stasio
052	B-WG01S2P52	**A Tandem DMA study on selected sugars and sugar alcohols** N.Zannoni, J.Hong, A.A. Zardini, K.Lieke, M. Bilde
053	B-WG01S2P53	**Vertical Profiles of Aerosol Properties and Black Carbon in the Arctic during spring and summer 2011: relationship with nucleation events and ship plumes** L. Ferrero, D. Cappelletti, B. Moroni, V. Vitale, R. Udisti, G. Sangiorgi, M.G. Perrone, M. Busetto, C. Lanconelli, M. Mazzola, A. Lupi, S. Becagli, R. Traversi, D. Frosini, M. Maturilli, R. Neuber, C. Ritter, J. Graeser, M. Fierz, G. Mocnik and E. Bolzacchini
054	B-WG01S2P54	**Influence of adsorbed organic films on ice particle growth under conditions relevant to the upper troposphere** X. Kong, E.S. Thomson, P. Papagiannakopoulos, N. Markovic and J.B.C. Pettersson
055	B-WG01S2P55	**Continuous multiple-year atmospheric nitrate record from East Antarctic plateau** R. Traversi, S. Becagli, D. Frosini, M. Severi, M. Mazzola, C. Lanconelli, V. Vitale and R. Udisti
056	B-WG01S2P56	**Volume-based k-interaction model, hygroscopicity parameters and solute interaction coefficients** E. Mikhailov, S. Vlasenko, D. Rose and U.Pöschl
057	B-WG01S2P57	**Aerosol optical properties at Santiago Island, Cape**

		Verde M. Cerqueira, C. Pio, P. Fialho, J. Cardoso, T. Nunes and S. M. Almeida
058	B-WG01S2P58	**Mass scattering efficiency and chemical composition of different aerosol types at a coastal area of the Gulf of Cadiz (SW Spain)** J.F. López, V.E Cachorro, Y. González-Castanedo, J.D. de la Rosa and A.M. de Frutos
059	B-WG01S2P59	**Long-term atmospheric aerosol deposition in Southern Portugal: first results on chemical and morphological characterization of particles by VP-SEM+EDS** F. Wagner, N. Schiavon, K. Kandler, L. Tobias and J.Mirão
060	B-WG01S2P60	**Arctic aerosol sampled at Ny Ålesund: results from size-segregated samples** G. Calzolai, S. Becagli, C. Ghedini, F. Rugi, D. Frosini, S. Nava, M. Chiari, F. Lucarelli, R. Traversi and R. Udisti
061	B-WG01S2P61	**Carbonaceous aerosol characterization in Piacenza (Italy)** M. Calvello, F. Esposito, G. Pavese, G, Lonati, S. Ozgen and G. Ripamonti
062	B-WG01S2P63	**Saharan vs. local influence on atmospheric aerosol deposition in the southern Iberian Peninsula: significance for N and P inputs** R. Morales-Baquero, C. Pérez-Martínez
063	B-WG01S2P64	**Observations of aerosol of different origin by Siberian - Far Eastern lidar network and photophoresis** A.A. Cheremisin, V.N. Marichev, V.V. Bychkov, B.M. Shevtsov, P.V. Novikov, I.S. Shnipov
064	B-WG01S2P65	**Direct observations and model simulations of long-range transported aerosols over Northeast Asia inferred from ground, airborne and satellite measurements** M.G. Cayetano, Y.J. Kim, J.S. Jung, K.Y. Lee, K.C. Kim, R. S. Park, C.H. Song, M. Koike and Y. Kondo
065	B-WG01S2P66	**Analysis of particle size distribution on urban and rural sites with connection to meteorological conditions** B. Kotlík, J. Keder, L. Černikovský
066	B-WG01S2P67	**Temperature influence on the natural aerosol budget over boreal forests** L. Liao, H. Junninen, M. Kulmala and M. D. Maso
067	B-WG01S2P68	**Large particle climatology in Finland – Estimating**

		the effect of aerosols in extinction of infrared radiation N. Kivekäs, T. Mielonen, H. Portin, T. Kaurila, I. Rajakallio, K.E.J. Lehtinen and H. Lihavainen
068	B-WG01S2P69	**Comparison of new particle formation events and an analysis of aerosol dynamics between three sites in northern Scandinavia** R. Väänänen, T. Nieminen, M. Dal Maso, A. Virkkula, B. Svenningsson, N. Kivekäs, T. Holst, A. Arneth, V-M. Kerminen, M. Kulmala
069	B-WG01S2P70	**The Impact of Meteorological Conditions on PM air pollution in Tartu, Estonia** E.-S. Kerner, M. Eller
070	B-WG01S2P71	**Aerosol investigations with light aircraft during the Grímsvötn eruption and during Etna volcanic activities in the year 2011** Weber, K., Reichardt, R., Elíasson, J., Vogel, A., Fischer, C., Moser, H.M. , Palsson, A., Palsson, T, Sturm, K
071	B-WG02S2P01	**Indoor and Outdoor Particle Concentrations and Elemental and Organic Carbon at 17 Primary Schools** L. Morawska, M. Mazaheri, F. Salimi, R. Laiman, L. Crilley, G. Ayoko
072	B-WG02S2P02	**Carbonaceous aerosols in Barcelona during the SAPUSS campaign** A. Karanasiou, M. Dall'Osto, M. Viana, A. Alastuey, X. Querol
073	B-WG02S2P03	**Carbonaceous content of PM_{10} and $PM_{2.5}$ in urban-traffic and urban background sites within the Thessaloniki Major Area (TMA), northern Greece** C. Samara, D. Voutsa, A. Kouras, Th. Maggos
074	B-WG02S2P04	**Characteristics of fine carbonaceous aerosol at a coastal rural site in the Central Mediterranean as given by OCEC online measurements** Antonella Malaguti, Mihaela Mircea, Teresa M.G. La Torretta, Chiara Telloli, Massimo Berico
075	B-WG02S2P05	**Black carbon optical properties measured in Pasadena, Los Angeles during CalNex** J.W. Taylor, J.D. Allan, M.J. Flynn, D. Liu, P. L. Hayes, J.L. Jimenez, B. Lefer and H. Coe
076	B-WG02S2P06	**FTIR-ATR spectroscopy of water-soluble organic matter from atmospheric aerosols** S.M.S. Freire, R.M.B.O Duarte and A.C. Duarte
077	B-WG02S2P07	**Seasonal and diurnal observations of black carbon**

		and trace gases in the north suburb of Nanjing influenced by industiral areas L.L Tang, X.Z Zhang, D.T. Liu, J. Allan, Hugh Coe
078	B-WG02S2P08	**Organic, elemental and water-soluble organic carbon in size segregated aerosols in the Eastern Mediterranean** A. Bougiatioti, P. Zarmpas, E. Koulouri, M. Antoniou, C. Theodosi, G. Kouvarakis, S. Saarikoski, T. Mäkelä, R. Hillamo and N. Mihalopoulos
079	B-WG02S2P09	**A yearly cycle of radiocarbon in organic and elemental carbon at a rural site in the Netherlands** U. Dusek, M. Monaco, S. Szidat, H. A. J. Meijer, J. van der Plicht, T. Röckmann
080	B-WG02S2P10	**Characterisation of trace metals in airborne carbonaceous aerosols by single-particle EDX - Scanning Electron Microscopy** A. Pietrodangelo, S. Pareti and C. Perrino
081	B-WG02S2P11	**δ13C values of TC, EC+CC and OC in size segregated aerosol particles** A. Garbaras, R. Bariseviciute, K. Kvietkus, R. Skipityte, I. Garbariene, A. Masalaite and V. Remeikis
082	B-WG02S2P12	**Comparison of PM1 Organic and Elemental carbon between an urban and a regional background station** E. Yubero, J.F. Nicolás, Crespo J, M. Chiari, S. Nava, G. Calzolai, F. Lucarelli
083	B-WG02S2P13	**Organic matter and non-refractory aerosol over the remote Pacific: oceanic and combustion sources** L. M. Shank, S. Howell, A. D. Clarke, S. Freitag, V. Brekhovskikh, V. Kapustin, C. McNaughton, T. Campos, R. Wood
084	B-WG02S2P14	**Organic export from the ocean to the atmosphere - first investigations** M. V. Pinxteren, C. Müller, Y. Iinuma, C. Stolle and H. Herrmann
085	B-WG02S2P15	**Investigating primary marine aerosol properties: CCN activity of sea salt and mixed inorganic-organic particles** S.M. King, A.C. Butcher, T. Rosenoern, E. Coz, K. I. Lieke, G. de Leeuw, E. D. Nilsson, M. Bilde
086	B-WG02S2P16	**Aerosol particle distribution in the Baltic Sea marine boundary layer with the enlarged continental outflows and ship exhaust emissions** K. Plauškaitė, N. Špirkauskaitė, S. Kecorius, T. Petelski, T. Zielinski, and V. Ulevicius

087	B-WG02S2P17	**Sub-Antarctic marine aerosol: Significant contributions from biogenic sources** J. Schmale, J. Schneider, E. Nemitz, S.Y. Tang, U. Dragosits, T.D. Blackall, P.N. Trathan, G. Phillips and C.F. Braban
088	B-WG02S2P18	**Amino acids in Arctic aerosols** A. Gambaro, E. Scalabrin, R. Zangrando, E. Barbaro and C. Barbante
089	B-WG02S2P19	**Oceanic energy dissipation and the relationship to laboratory generated SSA** A.C. Butcher, S.M. King, E.D. Nilsson, and M. Bilde
090	B-WG02S2P20	**Shipboard characterization of a wet scrubber system: Influence on particle number concentration, particle size distribution and chemical composition** A.G. Hemmersam, M.K. Lykkegaard, K. Fuglsang, T. Rosenoern, J.B. Markussen, J.P. Hansen, K.I. Lieke and M. Bilde
091	B-WG02S2P21	**New Findings on Submicron Sea Salt Source Flux** J. Ovadnevaite, D. Ceburnis, H. Berresheim and C. O'Dowd
092	B-WG02S2P22	**The composition of Sea Spray Aerosol (SSA) produced from coastal Baltic seawaters** K. Plauskaite, V. Ulevicius, J. Ovadnevaite, M. Rinaldi, M.C. Facchini, C. O'Dowd and D. Ceburnis
093	B-WG02S2P23	**Laboratory based studies of primary sea-spray generation in plankton-enriched sea-water** D. Ceburnis, J. Ovadnevaite, M. Zacharias, J. Bialek, S. Connan, M. Rinaldi, C. Monahan, M.C. Facchini, H. Berresheim, D.B. Stengel and C. O'Dowd
094	B-WG02S2P24	**Characterization of PM1 sampled in the "Marco Polo" airport area (Tessera-Venice)** G. Valotto, D. Bassano, E. Pecorari, E. Rampado, G. Rampazzo, S. Sollecito, F. Visin and D. Zannoni
095	B-WG02S2P25	**Monitoring of ultrafine particles at an urban environment in southern Europe** G. Titos, H. Lyamani, M. Sorribas, I. Foyo-Moreno and L. Alados-Arboledas.
096	B-WG02S2P26	**Short term control efficiencies of dust suppressants to reduce fugitive dust** Sehyun Han, Yoonho Seo and Yongwon Jung
097	B-WG02S2P27	**Source apportionment of PM-bound PAHs, *n*-alkanes and inorganic ions in an urban environment in southeastern Spain** J. Gil-Moltó, N. Galindo, M. Varea and C. Chofre
098	B-WG02S2P28	**An original device for the measure of aerosol**

		deposition. Results of a one year survey period on the Pin Sec catchment in Nantes, France Stéphane Percot, Véronique Ruban, Pierre Roupsard, Denis Maro and Maurice Millet
099	B-WG02S2P29	**Evidence of regional-scale biomass burning contributions to urban aerosols in the Western Mediterranean** M. Viana, C- Reche, F. Amato, A. Alastuey, T. Moreno, F. Lucarelli, S. Nava, M. Rico, J. Gracia and X. Querol
100	B-WG02S2P30	**The effect of size, location, occupancy and microclimatic factors on air quality of university lecture rooms** M. Braniš and K. Stupková
101	B-WG02S2P31	**Impact of port activities on urban air quality at a Mediterranean coastal city** N. Pérez, J. Pey, C. Reche, X. Querol, A. Alastuey and J. Cortés
102	B-WG02S2P32	**Comparative study of ultrafine aerosol within a city** I. Salma, T. Borsós, Z. Németh, P. Aalto and M. Kulmala
103	B-WG02S2P33	**Black carbon mixing state in Paris megacity** M. Laborde, M. Gysel, T. Tritscher, M. Crippa, Zs. Jurányi, P.F. DeCarlo, A. Prévot, U. Baltensperger
104	B-WG02S2P34	**Seasonal variations of saccharides in PM2.5 aerosols in urban area** K. Křůmal, N. Kubátková, P. Mikuška and Z. Večeřa
105	B-WG02S2P35	**Source apportionment of the organic aerosol fraction by comparing positive matrix factorization, EC-tracer-method and 14C-analysis** Wagener, Sandra, Langner, Marcel, Perron, Nolwenn, Hansen, Ute, Moriske, Heinz-J, and Endlicher, Wilfried
106	B-WG02S2P36	**Chemical and optical characterization of aged fossil fuel aerosol** L. Marmureanu, J. Vasilescu, A. Nemuc, D. Nicolae and L. Belegante
107	B-WG02S2P37	**Influence of Meteorological Variables on Particle Number Concentration in Madrid** E. Alonso-Blanco, A. Hidalgo, F.J. Gómez-Moreno, and B. Artiñano
108	B-WG02S2P38	**Characterization of Particulate-phase High Molecular Weight Mono-carbonyls and Dicarbonyls in Urban Atmosphere of Xi'an, China** Kin-Fai Ho, Wen-Ting Dai, Steven Sai Hang Ho, Jun-Ji Cao
109	B-WG02S2P39	**Spatial patterns of high-resolution AOD and PM over Israel**

		Sorek-Hamer M., Broday D.M, and Levy R.C
110	B-WG02S2P40	**Real time characterization of ambient aerosol at Prague suburban site during wintertime** P. Vodička, O. Makeš, J. Ondráček and J. Schwarz
111	B-WG02S2P41	**Levels and chemical composition in airborne particulate matter (PM10) of eastern Andalusia (SE Spain)** A.M. Sánchez de la Campa, R. Fernández-Camacho, Y. González-Castanedo and J.D. de la Rosa
112	B-WG02S2P42	**PM level in Seoul metropolitan subway cabin indoor during the rush hour** S.-B. Kwon, J.B. Kim, J.H. Song, Y. Cho, D.S. Park, W. Jeong and C.H. Shin
113	B-WG02S2P43	**School Children's Personal Exposure to Ultrafine Particles in Urban Environments** M. Mazaheri, M. Mokhtar, R. Jayaratne and L. Morawska
114	B-WG02S2P44	**Distribution characteristics and trends of PM2.5 and PM1 -bound polycyclic aromatic hydrocarbons (PAHs) over an urban Mediterranean area** St. Pateraki, D.N. Asimakopoulos, Th. Maggos, and Ch.Vasilakos
115	B-WG02S2P45	**Particle number size distribution characteristics in the urban background in Helsinki** B. Mølgaard, H. Hannuniemi, G. Ripamonti, T. Wegner, S. Weber, L. Järvi, T. Vesala, K. Hämeri, T. Hussein
116	B-WG02S2P46	**Ionic composition of PM_{10} and $PM_{2.5}$ in urban-traffic and urban background sites within the Thessaloniki Major Area (TMA), northern Greece** E. Gounari, D. Lazarou, E. Manoli, D. Voutsa, C. Samara
117	B-WG02S2P47	**Particle size distribution of *n*-Alkanes and PAHs in urban and industrial areas of Algiers, Algeria** R. Ladji, S. Khedidji, A. Lemou, L. Rabhi and N. Yassaa
118	B-WG02S2P48	**The air pollutants emitted from biomass burning in North Korea to the air quality in Seoul, South Korea** In Sun Kim, Yong Pyo Kim, Ji Yi Lee, Lan Jin
119	B-WG02S2P49	**Analysis of PM10 concentrations in the urban area of Volos, Greece** G.T. Proias, S. Katartzis, P.T. Nastos, A.G. Paliatsos
120	B-WG02S2P50	**Preliminary results of first intensive observation program campaign of "Supersite" Project in Emilia-Romagna region (Italy)** S. Ferrari, I. Ricciardelli, C. Maccone, A. Trentini, F. Scotto, C. Sartini, D. Bacco, S. Gilardoni, M.C. Facchini and V. Poluzzi

121	B-WG02S2P51	**Bias caused by adsorbed water in standard gravimetric PM10 measurements** K. Imre, A. Gelencsér, A. Molnár and V. Dézsi
122	B-WG02S2P52	**Chemical characterization of fine particulate matter collected in Budapest** T. Szigeti, V.G. Mihucz, M. Óvári and Gy. Záray
123	B-WG02S2P53	**Spatial distribution of particle number concentrations measured with the AERO-TRAM** B. Vogel, R. Hagemann, R. Rinke, A. Wieser, U. Corsmeier, Ch. Kottmeier
124	B-WG02S2P54	**Short-term variation in near-highway air pollutant gradients** P. Berghmans, E. Frijns, M. Van Poppel
125	B-WG02S2P55	**Effect of the shutdown of a coal-fired power plant on urban mercury species** Yungang Wang, Philip K. Hopke, Jiaoyan Huang and Thomas M. Holsen
126	B-WG02S2P56	**^{7}Be and ^{210}Pb in both bulk deposition and atmospheric aerosols from Southwest Spain** R.L. Lozano, E.G. San Miguel and J.P. Bolívar
127	B-WG02S2P57	**The effect of winter salting on PM10 concentrations in the Rhine-Ruhr area** D. Gladtke, A. Olschewski, Th. Retny and P. Risthaus
128	B-WG02S2P58	**Composition and Source Identification of Ambient Single Particles on Haulbowline Island, Cork Harbour** J. Arndt, R.M. Healy, D. Healy, L. Hacker, J.R. Sodeau and J.C. Wenger
129	B-WG02S2P59	**Characterization of aerosols released from agricultural operations in the Po Valley** Antonella Malaguti, Chiara Telloli, Massimo Berico, Carmela Vaccaro, Mihaela Mircea
130	B-WG02S2P60	**Atmospheric fluxes of radionuclides at Málaga (Spain)** C. Dueñas, M.C. Fernández, S. Cañete, E. Gordo and M. Pérez
131	B-WG02S2P61	**The importance of forest fires and dust on aerosol over Portugal's background** J.V. Monjardino, A.C. Carvalho, L. Mendes and F. Ferreira
132	B-WG02S2P62	**Primary and secondary marine aerosol at Station Concordia (East Antarctica). Seasonal pattern and implications for atmospheric transport from a multi-year continuous data-set** R. Udisti, S. Becagli, M. Busetto, M. Chiari, U. Dayan, D.

		Frosini, C. Lanconelli, F. Lucarelli, S. Nava, C. Scarchilli, M. Severi, R. Traversi, V. Vitale
133	B-WG02S2P63	**Aerosol and gas concentrations at the Finnish Antarctic station Aboa in Queen Maud Land and comparisons with the Norwegian station Troll** A.Virkkula, S.Begagli, X.Chi, W.Maenhaut, M.Fiebig, H.Hellén, H.Hakola, E.Asmi, S. Häkkinen, J.Backman, T.Vihma, T.Valkonen, S.Kirkwood and M.Kulmala
134	B-WG02S2P64	***In situ* aerosol measurements at Dome C, Antarctica, in 2007 - 2011** A.Virkkula, E. Järvinen, T.Nieminen, R.Väänänen, H. Manninen, P.P. Aalto, E. Asmi, J.Backman, M. Busetto, C. Lanconelli, R. Schioppo, A. Lupi, V. Vitale, R. Hillamo and M.Kulmala
149	B-WG07S1P01	**Advanced gas-phase synthesis of LTO nanocomposites for Li-ion battery applications** T. Karhunen, A. Lähde, J. Leskinen, T. Torvela, E. Pohjalainen, M. Karppinen, O. Waser, R. Büchel, U. Tapper, J. Jokiniemi
150	B-WG07S1P02	**Flame-spray pyrolysis of copper-based p-type semiconducting oxide nanoparticles and their application in printable electronics** D. Kilian, B. Meyer, M.P.M. Jank, M. Voigt, S. Polster, L. Frey and W. Peukert
151	B-WG07S1P03	**Aerosol-derived antimony doped-tin oxide nanoparticles and studies on the influence of organic and inorganic shells in nanoparticle assemblies on the overall conductance** S.B. Bubenhofer, C.M. Schumacher, G.A. Sotiriou, R.N. Grass and W.J. Stark
152	B-WG07S1P04	**Size controlled flame synthesis of CuO nanoparticles for Li-ion batteries** O. Waser, A. Güntner, M. Heß, P. Novák and S.E. Pratsinis
153	B-WG07S1P05	**IrRuO particles for hydrogen generation** J. Forsman, U. Tapper, A. Auvinen, A. Pasanen, M. Johansson, T. Karhunen, J. Jokiniemi, P. Kauranen
154	B-WG07S1P06	**Multimineral supplementation with nano-CaO as carrier matrix** J.T.N. Knijnenburg, F.M. Hilty, M.B. Zimmermann and S.E. Pratsinis
155	B-WG07S1P07	**Flexible superparamagnetic-plasmonic nanocomposite films with flame-made fillers** Georgios A. Sotiriou, Christoph Blattmann and Sotiris E. Pratsinis
156	B-WG07S1P08	**Electrospray deposition of graphene nanosheets**

		L. B. Modesto-Lopez, O. V. Bilousov, J. J. Carvajal, F. Díaz and J. Rosell-Llompart
157	B-WG07S1P09	**A MEMS sensor based personal sampler for ultrafine particles** S. Merzsch, H.S. Wasisto, E. Peiner, I. Kirsch and E. Uhde
158	B-WG07S1P10	**Detecting the Morphology of SiO2 Aerosols using the Universal NanoParticle Analyzer (UNPA)** R. Wernet, A. Gutsche, B. Sachweh, G. Kasper, M. Seipenbusch
159	B-WG07S1P11	**Mass-Mobility Characterization of Flame-made ZrO2 Aerosols: the Primary Particle Diameter** M.L. Eggersdorfer, A.J. Gröhn, C.M. Sorensen, P.H. McMurry and S.E. Pratsinis
160	B-WG07S1P12	**Determination of soot size distributions from spectra extinction measurements: a feasibility study** C. Caumont-Prim, J. Yon, A. Coppalle and K.F. Ren
161	B-WG07S1P13	**Conductivity for Soot Sensing: Possibilities and Limitations** B. Grob, J. Schmid, N. P. Ivleva and R. Niessner
162	B-WG07S1P14	**Concentrations of particles emitted during spraying of product with silver nanoparticles** Jankowska E. and Łukaszewska J.
163	B-WG07S1P15	**Continuous tandem DMA determination of the mass and charge distribution ofelectrosprayed nanometer polystyrene particles** M. Attoui, J. Fernandez-García, J. Cuevas, G. Vidal and J. Fernandez de la Mora
164	B-WG07S1P16	**A carbon nanotubes suspension study by vortex shaker : Sampling and mass analysis** A. Ustache, D. Bernard, O. Le Bihan, E. Peyret, O. Aguerre-Chariol
165	B-WG07S1P17	**Influences on nanoparticle size distributions generated by the spark principle** J. Spielvogel, R. Joachim, M. Schmidt
166	B-WG07S1P18	**Nanoparticle emission measurement during polymer extrusion experiments** Yu-Ying Kuo, Jelena Buha, Haijun Zhang, Andreas Gerecke, Giuseppino Fortunato and Jing Wang
167	B-WG07S1P19	**Dissociation rates of Fe2+, Fe2-, and Fe2** M. Noppel
168	B-WG07S1P20	**Surface concentration of particles emitted during burning of foams with nano-objects** Jankowska E., Sobiech P., Łukaszewska J. and Zatorski W.

169	B-WG07S1P21	**Real-time measurement of airborne nanoparticles released to a windtunnel and filtration test** I.M. Kammenou, J. Wang
170	B-WG07S1P22	**Structure deformation of Ag nanoparticle clusters induced by deposition onto carbon nanotubes** T. Shinohara, N. Nishida, H. Tanaka
171	B-WG07S1P23	**Reactant depletion in chemical reactions inside nanoscale particles** V.V. Levdansky, J. Smolik, V. Zdimal and P. Moravec
172	B-WG07S1P24	**Monitoring a CVD process for the synthesis of nanostructured particles by means of low-pressure impaction** F.Weis, M. Seipenbusch and G. Kasper
173	B-WG07S1P25	**Electro-hydrodynamic atomization of solutions with strongly electrolytic behaviour – governing parameters and applications** A. Maißer, M.B. Attoui, A.M. Ganan-Calvo and W.W. Szymanski
174	B-WG07S1P26	**The effect of charge on ultrafine particle deposition: an experimental pilot study** L.L. Guo, L.Morawska, G.Johnson, R. Jayaratne and W.Hofmann
175	B-WG07S1P27	**A new method for characterizing bounce and charge transfer properties of nanoparticles** H. Kuuluvainen, A. Arffman, E. Saukko, A. Virtanen and J. Keskinen
176	B-WG07S1P28	**Influence of flow conditions and process parameters on the production rate and characteristics of nanoparticles produced by spark discharging** M. Wagner, M. Wild, F. Weis and M. Seipenbusch
177	B-WG07S1P29	**Variability of nanoparticles number concentration during summer in a humid region** V. Juncal-Bello, S. Iglesias-Samitier, M. Piñeiro-Iglesias, P. López-Mahía, S. Muniategui and D. Prada
178	B-WG07S1P30	**Characterization of different CNT using a thermo-optical elemental carbon / organic carbon analyzer in view of workplace aerosol measurements** A.C. John, M. Renker and T.A.J. Kuhlbusch
179	B-WG07S1P31	**(Quasi) Real-time detection of catalytically active nanoparticles in presence of a background aerosol** N. Neubauer, M. Seipenbusch and G. Kasper
180	B-WG07S1P32	**Release of carbon nanotubes from an epoxy-based nanocomposite during an abrasion process**

		L. Schlagenhauf, B.T.T. Chu, J. Buha, F. Nüesch and J. Wang
181	B-WG07S1P33	**Enabled Aerosol-based Methods for Assessing the Toxicity of Engineered Nanoparticles** A. Kourmouli, P. Kavarnoy, K. Barmpounis, O.I. Kalantzi, G. Biskos
182	B-WG07S1P34	**Nanoparticle Balancing from Release to Dose** H. Fissan, B. Stahlmecke, C. Asbach, T.A.J. Kuhlbusch
183	B-WG07S1P35	**Cytotoxicity of nanosilver with different sizes: Effect of Ag+ ion release** A.Pratsinis, P. Hervella, S. E. Pratsinis, J-C. Leroux and G. A. Sotiriou
184	B-WG07S1P36	**Investigations on nanoparticle release from artificially weathered coatings and composites that experience different treatment processes** D. Göhler, A. Nogowski, P. Fiala and M. Stintz
185	B-WG07S1P37	**Assessment of exposure to airborne nanomaterials using a pragmatic, tiered approach** C. Asbach, D. Dahmann, M. Voetz, B. Stahlmecke, H. Kaminski, Thomas A.J. Kuhlbusch, U. Götz, S. Engel, S. Plitzko
186	B-WG07S1P38	**Aerosol particle emissions from sanding coated plates: effect of the sanding paper and filtering method to the human exposure** I.K. koponen, M. Levin and K.A. Jensen
187	B-WG07S1P39	**Expossure and Risk Assessment during Production of Nanoparticles by Plasma Synthesis** Jelena Buha, Drew Thompson, Marc Leparoux, Christian Jäggi, David Y.H. Pui and Jing Wang
188	B-WG07S1P40	**Analysis of aerosol solid nanoparticles produced during soldering using metal alloys** Virginia Gómez, Silvia Irusta, Francisco Balas and Jesús Santamaría
189	B-WG07S1P41	**Particle characterisation from reducing Cl-process producing Cu and Cu-CNT like nanoparticles - safety issues to consider for scale-up** J. Lyyränen, J. Hokkinen, U. Backman, A. Auvinen, J. Jokiniemi
190	B-WG07S1P42	**Particle characterisation during melting of nanoparticle containing coated and uncoated window glass** J. Lyyränen, J. Hokkinen, U. Backman, A. Auvinen, J. Jokiniemi and A. Kurz
191	B-WG07S1P43	**Atmospheric new particle formation in the Central European boundary layer: A long-term study using**

		Neutral Cluster Air Ion Spectrometer (NAIS) data J. Größ, W. Birmili, A. Hamed, A. Sonntag, A. Wiedensohler, G. Spindler, . E. Maninnen, M. ulmala, U. Hõrrak, C. Plass-Dülmer
192	B-WG07S1P44	**Nanostructured catalytic layers for fuel cell electrodes prepared by electrospray** S. Martin, B. Martinez-Vazquez, P.L. Garcia-Ybarra and J.L. Castillo
193	B-WG07S1P45	**Control of phase composition of LiFePO4 prepared with spray pyrolysis** A. Lähde, T. Karhunen, T. Torvela and J. Jokiniemi
194	B-WG07S1P46	**Two-component aerosol nanoparticle coating for paperboard on roll-to-roll process** J. Haapanen, M. Aromaa, H. Teisala, M. Tuominen, M. Stepien, J.J. Saarinen, Toivakka, J. Kuusipalo and J.M. Mäkelä
195	B-WG07S1P47	**Plasmonic properties of size-selected spherical silver nanoparticles** J. Harra, J. Mäkitalo, R. Siikanen, M. Virkki, G. Genty, T. Kobayashi, M. Kauranen and J.M. Mäkelä
196	B-WG07S1P48	**Synthesis of germanium nanoparticles in an aerosol reactor** C. Mehringer, R. Körmer, B. Butz, E. Spiecker and W. Peukert
197	B-WG07S1P49	**Gas-Phase Synthesis of Metal-Decorated Titanium Dioxide Nanoparticles** N. Alam and A.M. Boies
198	B-WG07S1P50	**Spark Generated Intermetallic Mg-Ti Nanoparticles for Hydrogen Storage** R. J. Canales-Perez, T. V.Pfeiffer, A. Anastasopol, J. Middelkoop, S.W.H. Eijt, and A. Schmidt-Ott
199	B-WG07S1P51	**Generation of sub 10 nm self charged particles with a spark generator in positive andnegative mode** Michel ATTOUI
200	B-WG07S1P53	**Morphology dependency of electrospray-generated polymer particles and coatings on ambient humidity** E. Bodnár, P. Kiselev, J. Grifoll and J. Rosell-Llompart
201	B-WG07S1P54	**Formation of rutile nanoparticles from the condensed disperse phase at a surface of high-temperature particles of the titanium** N.Kh. Kopyt, K.I. Semenov, N..N. Kopyt and A.K. Semenov
202	B-WG07S1P55	**Obtaining of nanoparticles near moving heated metal particle** K.I. Semenov, N.Kh. Kopyt, A.K. Semenov and N..N. Kopyt

203	B-WG07S1P56	**Investigation of the particle formation mechanism in flame spray pyrolysis of silica nanoparticles based on optical techniques** D. Kilian, M.Voigt, S. Engel, Y.Gao, A. F. Kögler, T.Seeger, A. Leipertz and W. Peukert
204	B-WG07S1P57	**Formation of advanced SiC and carbon structures with controlled annealing ofpreceramic silicon-carbon nanoparticles** A. Lähde, M. Miettinen, J. Hokkinen ,T. Karhunen, T. Torvela, U. Tapper and J. Jokiniemi
205	B-WG07S1P58	**In situ observation of sintering behavior of Pt particles supported on silica nanoparticles** Kun Gao, Philipp Müller, Matthias Faust, Reinhard Schneider and Martin Seipenbusch
206	B-WG07S1P59	**Synthesis of copper nanoparticles formed on carbon nanotubes by photochemical process** N. Nishida, A. Miyashita, and H. Tanaka
207	B-WG07S1P60	**Aerosol synthesis of building blocks for layered catalyst structures for Fischer–Tropsch reaction** Lintao Zeng and Alfred P. Weber
208	B-WG07S1P61	**The Spark Generator as a Simple Source of sub-Nanometer Atomic Clusters** M.D. Barankin, K.Barmpounis, G. Biskos, T. Bosboom, A. Maisser, T.V. Pfeiffer, A. Schmidt-Ott
225	B-SS01S1P01	**The analysis of size-segregated cloud condensation nuclei counter (CCNC) data from SMEAR II and its implications for aerosol-cloud relations** M. Paramonov, T. Petäjä, P.P. Aalto, M. Dal Maso, N. Prisle, V.-M. Kerminen and M. Kulmala
226	B-SS01S1P02	**Results of elemental and organic carbon (EC-OC) regular measurements within EUSAAR and ACTRIS projects 2009-2011 at the Košetice Observatory** M.Vana, J. Čech, A.Holubová Šmejkalová, E. Chalupníčková and J.Schwarz
227	B-SS01S1P03	**Particle formation and growth in the boundary layer over boreal forest** L. Zhou, M. Boy, H. Vuollekoski, C. Watcharapaskorn, D. Mogensen, S. Smolander, A. Sogachev and Markku Kulmala
228	B-SS01S1P04	**Aerosol particle number concentration studies based on Fourier and wavelet analysis** S. Byčenkienė, S. Kecorius, K. Plauškaitė, J. Andriejauskienė and V. Ulevicius
229	B-SS01S1P05	**A Mediterranean Atmospheric Network for in-situ**

		aerosol measurements: Motivation and Objectives J. Sciare, A. di Sarra, R. Ellul, E. Gerasopoulos, H.C. Hansson, S. Kleanthous, N. Mihalopoulos, J. Pey, A. Alastuey and N. Yassaa
230	B-SS01S1P06	**OVOC – precursors for SOA: measurements within ACTRIS-WP4** J. Englert, C. Plass-Dülmer, E. Tensing, K. Michl and A. Werner
231	B-SS01S1P07	**The "Dual-Spot" Aethalometer: Improved measurement of Aerosol Black Carbon with real-time loading compensation** L. Drinovec, G. Močnik, P. Zotter, A.S.H. Prévôt, C. Ruckstuhl, A.D.A. Hansen
232	B-SS01S1P08	**New particle formation in the western Mediterranean regional background** M. Cusack, A. Alastuey, X. Querol, N. Pérez, A. Wiedensohler
233	B-SS01S1P09	**A Finnish remote-sensing network for monitoring aerosol, clouds, and the boundary layer** A. Hirsikko, E.J. O´Connor, M. Komppula, M. Bauer-Pfundstein, A. Poikonen, M. Kurri, E. Giannakaki, T. Karppinen, H. Lihavainen, A. Laaksonen, Kari E.J. Lehtinen and Y. Viisanen
234	B-SS01S1P10	**Long-term observation of time-resolved submicron aerosol chemical composition in the region of Paris (France)** J-E. Petit, R. Sarda-Estève, J. Sciare, O. Favez
235	B-SS01S1P11	**Characterize aerosol properties observed over Lemesos, Cyprus using passive and active remote sensing instruments** A. Nisantzi, RE Mamouri, P. Kokkalis and D. G. Hatzimitsis
236	B-SS01S1P12	**The AERONET-Europe calibration facility: access within the ACTRIS project** P. Goloub, V.E. Cachorro, E. Cuevas, L. Blarel, A. Berjón, C. Toledano, T. Podvin, A. Lapionak, C. Guirado, R. Ramos, R. González, D. Fuertes
237	B-SS01S1P13	**Data interoperability solutions for the Finnish SMEAR station network** M. Dal Maso, P. Kolari, H. Junninen, P.P. Aalto, P. Keronen, P. Järveläinen, S. Sorvari and M. Kulmala
238	B-SS02S1P01	**Using sulfur isotope analyses to understand in-cloud sulfate formation during HCCT 2010** E. Harris, B. Sinha, P. Hoppe, J. Schneider, D. van Pinxteren, W. Fomba, T. Gnauk, B. Fahlbusch, S. Mertes, T. Lee, S. Foley, S. Borrmann and H. Herrmann

239	B-SS02S1P02	**Inorganic cloud chemistry and its relation to the valley sites particle chemistry during HCCT** K. Müller, G. Spindler, D. T. Lee, J. Collett Jr., van Pinxteren, H. Herrmann
240	B-SS02S1P03	**Evaluation of PM10 and trace gas measurements with the MARGA during the HCCT 2010 campaign** B. Fahlbusch, G. Spindler, L. Poulain, A. Grüner, M. Wallasch and H. Herrmann
241	B-SS02S1P04	**HOx measurements at the upwind site during HCCT** D. Amedro, C. Schoemaecker, C. Fittschen and Jean-François Pauwels
242	B-SS02S1P05	**Characterisation of biological and biomass burning monosaccharides during Hill Cap Cloud Thuringia 2010 (HCCT 2010) campaign** Y. Iinuma and H. Herrmann
243	B-SS02S1P06	**Trace metal characterization during HCCT2010** K. Wadinga Fomba, K. Müller, T. Lee, J. Collett Jr., H. Herrmann
244	B-SS02S1P07	**Cloud influence on local aerosol chemical composition during the Hill Cap Cloud Thuringia 2010** L. Poulain, Z.J. Wu, A. Tilgner, D. van Pinxteren, B. D' Anna, C. George, J. Schneider, A. Wiedensohler and H. Herrmann
245	B-SS02S1P08	**Particle hygroscopicity during atmospheric new particle formation events: Implications for the chemical species contributing to particle growth** Z.J. Wu, W. Birmili, L. Poulain, M. Merkel, B. Fahlbusch, D. van Pinxteren, H. Herrmann, A. Wiedensohler
246	B-SS02S1P09	**The effect of cloud processing on the chemical composition and mixing state of accumulation mode aerosol: A combined SEM-NanoSIMS study during HCCT 2010** B. Sinha, E. Harris, P. Hoppe, S. Mertes, T. Gnauk, J. Schneider, D. van Pinxteren and H. Herrmann
247	B-SS02S1P10	**Physico-chemical analysis of cloud drop residues and interstitial particles sampled inside clouds within the Hill Cap Cloud Thuringia (HCCT) Experiment 2010** S. Mertes, J. Schneider, R. Otto, K. Diekmann, W. Birmili, D. van Pinxteren, A. Roth, Frank Stratmann, and H. Herrmann
248	B-SS02S1P11	**Meteorological characterisation of the HCCT-2010 hill cap cloud experiments: Synoptic and local meteorological conditions, tracer experiments and**

		flow connectivity A. Tilgner, L. Schöne, P. Bräuer, D. van Pinxteren, H. Deneke, W. Birmili, R. Otto, M. Merkel, K. Weinhold, A. Wiedensohler, G. Spindler, and H. Herrmann
249	B-SS02S1P12	**Cloud chemistry during HCCT-2010: Mono- and dicarboxylic acids** Dominik van Pinxteren, Monique Teich, Stephan Mertes, Taehyoung Lee, Jeff Collett, Hartmut Herrmann
250	B-SS02S1P13	**Cloud chemistry during HCCT-2010: Water soluble organic carbon** Dominik van Pinxteren, Stephan Mertes, Johannes Schneider, Stephan Borrmann, Taehyoung Lee, Jeff Collett, Hartmut Herrmann
251	B-SS03S1P01	**Concentrations of organic and trace element PM species and derivation of freeway-based emission rates in Los Angeles** J. Liacos, W. Kam, R.J. Delfino, J.J. Schauer and C. Sioutas
252	B-SS03S1P02	**The impact of harbour activities on the air quality of the city of Genoa: source apportionment and simulation by dispersion models** P. Brotto, M.C. Bove, F. Cassola, E. Cuccia, D. Massabò, A. Mazzino, A. Piazzalunga and P. Prati
253	B-SS03S1P03	**Assessment of vehicular profiles vis-à-vis real-world traffic emissions** Pallavi Pant and Roy M. Harrison
254	B-SS03S1P04	**PMF vs CMB for source apportionment of PM: advantages, limitations, complementarity of the two models explored by applications at different types of environments** C. Piot, M.F.D. Gianini, J. Cozic, L. Polo, J.-L. Besombes, J.-L. Jaffrezo and C. Hueglin
255	B-SS03S1P05	**Concentrations and source contributions of particulate organic matter before and after implementation of a low emission zone** R.M. Qadir, G. Abbaszade, J. Schnelle-Kreis and R. Zimmermann
256	B-SS03S1P06	**Source apportionment of fine aerosol in Athens by positive matrix factorization and Unmix analysis** A. Karanasiou, M. Scoullos, K. Eleftheriadis
257	B-SS03S1P07	**Wintertime aerosol source apportionment in the metropolitan area of Paris by Chemical Mass Balance** E. Abidi, A. Monod, J. Cozic, J.L. Jaffrezo, M. Crippa, J. Slowik, U. Baltensperger, A.S.H. Prévôt and N. Marchand

258	B-SS03S1P08	**Source Apportionment of Particles in London Paddington Station** U. Chong, J.J. Swanson and A.M. Boies
259	B-SS03S1P09	**Chemical mass balance modelling for the source estimation of high PM2.5 concentrations in Milan, Northern Italy** Perrone M.G., Larsen B.R., Ferrero L., Sangiorgi G., De Gennaro G., Udisti R., Zangrando R., Gambaro A. and Bolzacchini E.
260	B-SS03S1P10	**Impacts of industrial and harbor activities on fine particles over Marseille** D. Salameh, A. Detournay, H. Wortham, J.L. Jaffrezo, J. Cozic, A. Armengaud, D. Piga, J. Dron, P. Chamaret, M. Parra, M. Deveze and N. Marchand
261	B-SS03S1P11	**Absorption Ångström exponent, and its correlation with other aerosol variables such as number size distribution, gas phase- and trace elements of the atmosphere. A field study** T. Ajtai, Á. Filep, N. Utry, M. Pintér, Z. Bozóki, G. Szabó
262	B-SS03S1P12	**Source apportionment of indoor and outdoor PM2.5 in an apartment situated in central Athens, Greece** D.E. Saraga, M. Seleventi, C.G. Helmis, Ch. Vasilakos and Th. Maggos
263	B-SS03S1P13	**Source apportionment of PM during 2008-2010 at Station Nord, North East Greenland** J.K. Nøjgaard, H. Skov, L.L. Sørensen, B.J. Jensen, A.G. Grube, A. Massling, M. Glasius and Q.T. Nguyen
264	B-SS03S1P14	**Structural properties of mineral dust from vehicle resuspension** E. Coz, C. Barrios, C. Martín, A. Domínguez and B. Artíñano
265	B-SS04S1P01	**Thermo-chemical properties of fleet ship emitted aerosols: relation to composition and structure** H. Bladt, J. Schmid, E. Kireeva, O. B. Popovicheva, J. Moldanová, N. P. Ivleva and R. Niessner
266	B-SS04S1P02	**Detailed chemical characterization of ultrafine particles from vehicle exhaust** F. Donaz, L. Polo, C. Piot, J. Cozic, B. Golly, N. Marchand, J.L. Besombes and J.L. Jaffrezo
267	B-SS05S1P01	**The field experiments on the HTO washout from the atmosphere** A.V. Golubev, S.V. Mavrin, V.N. Golubeva, A.V. Stengach, Yu.S. Balashov, V.P. Kovalenko, I.I. Solomatin
268	B-SS05S1P02	**Long-range transport of radionuclides released**

		from Fukushima accident into the Iberian Peninsula M.A. Hernández-Ceballos, R.L.Lozano, E.G. San Miguel and J.P. Bolívar
269	B-SS05S1P03	**Atmospheric radioactivity in the High Arctic following the Fukushima nuclear accident** J. Paatero, J. Vira, J. Hatakka, K. Holmén, A.-P. Hyvärinen and Y. Viisanen
270	B-SS05S1P04	**Airborne fission products from the Fukushima accident in the air over Milano, Italy** A. Ioannidou, E. Giannakaki, S.Manenti, L.Gini and F. Groppi
271	B-SS05S1P05	**Modification of cloud properties by the Eyjafjallajökull eruption** H Vogel, M. Bangert, B. Vogel, A. Wintzen, D. Barahona, A. Nenes, and J. Förstner
272	B-LP01S1P01	**Comparison of three particle number concentration standards for CPC calibration in the particle size range from 10 nm up to 10 µm** Jaakko Yli-Ojanperä, Hiromu Sakurai, Kenjiro Iida, Jyrki M. Mäkelä, Kensei Ehara and Jorma Keskinen
273	B-LP01S1P02	**Large-scale modelling of polycyclic aromatic hydrocarbons and polychlorinated dibenzodioxins in open fire aerosols: On the contribution of biomass burning to POPs in air in Africa** G. Lammel, A. Heil and I. Stemmler
274	B-LP01S1P03	**Gas-particle partitioning and air-sea exchange of polycyclic aromatic hydrocarbons and polychlorinated biphenyls in the central and eastern Mediterranean** Marie D. Mulder, Jana Klánová, Petr Kukučka, Jan Kuta, Gerhard Lammel, Roman Prokeš
275	B-LP01S1P04	**Biothreat and distant detection of bioaerosol** P.Grzybowski and T.Ciach
276	B-LP01S1P05	**Mechanistic insights into the formation of 2-methyltetrols from the photooxidation of isoprene under low-NO x conditions** W. Wang, Y. Iinuma, A. Kahnt, O. Ryabtsova, A. Mutzel, R. Vermeylen, P. Van der Veken, W. Maenhaut, H. Herrmann and M. Claeys
277	B-LP01S1P06	**A non-invasive method to sample exhaled endogenous particles from the respiratory tract** Susanna Lohman, Ann-Charlotte Almstrand, Anna Bredberg, Per Larsson, Ekaterina Mirogrodskaya, Evert Ljungström and Anna-Carin Olin

278	B-LP01S1P07	**Field-Performance of a new time-resolved sampler for the collection of dry aerosol particles** A. Eiguren-Fernandez, G.S. Lewis, S.R. Spielman and S.V. Hering
279	B-LP01S1P08	**High Resolution Ion Mobility Spectrometer (HRIMS): a new instrument for aerosol nucleation studies** E. Montoya, S. López-Vidal, P. Dohányosová, E. Ramiro
280	B-LP01S1P09	**Pre-industrial atmospheric elemental carbon concentrations** Tanveer Ahmed, Akhtar Shareef, Abdul Bari, Liaquat Husain
281	B-LP01S1P10	**Nanoparticle synthesis from manganese(II) acetylacetonate** P. Moravec, J. Smolík, S. Bakardjieva and V.V. Levdansky
282	B-LP01S1P11	**Formation of secondary organic aerosol: OH initiated oxidation of dodecane in the presence of NOx** A. Gratien, M. Camredon, Y. Mohamed Yassin, B. Aumont, and J.F. Doussin
283	B-LP01S1P12	**Some considerations about Langley method on the retrieval of spectral irradiance at the TOA and of the total atmospheric optical depth** M. Melgão, M.J. Costa and A.M. Silva
284	B-LP01S1P13	**Reduction of combustion alkali aerosols by addition of kaolin to pelletized biomass fuels** C. Boman, J. Fagerström, G. Gårdbro, E. Steinvall and D. Boström
285	B-LP01S1P14	**Morphology-Controllable of Porous Hyaluronic Acid Prepared using A Spray-drying Method** Asep Bayu Dani Nandiyanto, Takashi Ogi, and Kikuo Okuyama
286	B-LP01S1P15	**Prague Aerosol Supersite, Suchdol (PASS, urban background)** V. Ždímal, J. Ondráček, N. Zíková, P. Vodička, O. Makeš, D. Řimnáčová, L. Štefancová, J. Šilhavý, J. Smolík and J. Schwarz
287	B-LP01S1P16	**Synthesis and Characterization of Pt/WO 3 Nanoparticles Photocatalyst Prepared by Flame Spray Pyrolysis** Takashi Ogi, Asep Bayu Dani Nandiyanto, Agus Purwanto, Kikuo Okuyama
288	B-LP01S1P17	**TiO 2 Thin Film Morphologies Controlled by Aerosol Flame Deposition Process**

		Jinrui Ding and Kyo-Seon Kim
289	B-LP01S1P18	**Chemical Composition and Hygroscopic Properties of Ultrafine Aerosol Particles in the Atmosphere over an Urban Background Site in Patras, Greece** S. Bezantakos, E. Konstenidou, A. Bougiatioti, K. Eleftheriadis, N. Mihalopoulos, A. Nenes, S. Pandis, G. Biskos
290	B-LP01S1P19	**Size resolved penetration of commercial filter materials** J. Ondráček, N. Zíková and V. Ždímal
291	B-LP01S1P20	**Comparison of Chemical Characteristics of Diesel Particulates from a Euro 0, Japanese and US Engines** T.H. Gan, P. Hield, P.J. Hanhela, M. Leist, W. Mazurek and R. Gillett
292	B-LP01S1P21	**Droplet formation via a 1.7 MHz ultrasonic droplet generator** K. Zhong, G. Peabody, A. Marshall, H. Glicksman, and S. Ehrman
293	B-LP01S1P22	**Spatial distribution of the air quality in Portugal (rural, urban, and archipelagos)** A.M.J. Cruz, S.M. Sarmento, A.V. Silva, T. Verburg, S. Almeida, C. Alves, M.C. Freitas, H. Th. Wolterbeek
294	B-LP01S1P23	**Liquid Filter Evaluation using the New TSI Nanoparticle Nebulizer** T.Y. Ling, A. Zerrath and D.Y.H. Pui
295	B-LP01S1P24	**An update on ChArMEx (the Chemistry-Aerosol Mediterranean Experiment) activities and plans for aerosol studies in the Mediterranean region** F. Dulac and an international ChArMEx Team
296	B-LP01S1P25	**TiO 2 thin film structures prepared by controlling the particle formation and deposition in PCVD system** Hoang Hai Nguyen and Kyo-Seon Kim
297	B-LP01S1P26	**Polarized Imaging Nephelometer for Field and Aircraft Measurements of Aerosol Phase Function** G. Dolgos, J.V. Martins
298	B-LP01S1P27	**Water diffusion in glassy aerosol investigated using a new Raman isotope tracer method** H.C. Price, B.J. Murray, J. Mattsson and L.G. Benning
299	B-LP01S1P28	**Exploring the use of satellite-derived whitecap data to improve sea-spray emission estimatesM.F.M.A.** Albert, M.D. Anguelova, G. de Leeuw, A.M.M. Manders, and M. Schaap

Wednesday 5th September

08:45-09:45 Plenary 3. **Ulrike Lohmann**
Aerosols, clouds and climate
Room: Auditorio
Chair: Sabine Wurzler

09:45-10:00 Smoluchowski Award

10:00-10:30 Coffee-break

10:30-12:50 **Session WG01S4O. Physical and chemical properties + Transport 1**
Room: Auditorio
Chairs: A. Petzold / D. Topping

10:30	WG01S4O01	**Fluorescence lifetime imaging of aerosol viscosity and phase** F.D. Pope, N.A. Hosny, C. Fitzgerald, M.Kalberer, and M.K. Kuimova
10:50	WG01S4O02	**Phase state and humidity-induced phase transition studies of SOA particles from biogenic and anthropogenic precursors** E. Saukko,A.T. Lambe, , P. Massoli, T. Koop, J.P. Wright, D.R. Croasdale, D.A. Pedernera, T.B. Onasch, A. Laaksonen,P. Davidovits, D.R. Worsnop and A. Virtanen
11:10	WG01S4O03	**Overview of ClearfLo Detling Site: Study of Aerosol Sources and Processing at a Rural Site Southeast of London** L. R. Williams, S. Herndon, J. Jayne, A. Freedman, B. Brooks, J. Franklin, P. Massoli, E. Fortner, P. Chhabra, M. Zahniser, H. Stark, T. Onasch, D. R. Worsnop, F. Lopez-Hilfiker, C. Mohr, J. Thornton, N. L. Ng, L. Xu, M. Kollman, W. B. Knighton, M. Dubey, A. Aiken, K. Gorkowski, T. Martin and R. Coulter
11:30	WG01S4O04	**Aircraft measurements of gases and particles during CAREBeijing-2008 in surrounded Beijing areas** W.J. Zhang, Z.P Bai, T. Zhu, W. Yang, B.H. Yin
11:50	WG01S4O05	**Single particle characterization using a high resolution time-of-flight aerosol mass spectrometer: Atmospheric observation in Nagoya, Japan**

		T. Mihara and M. Mochida
12:10	WG01S4O06	**Long term measurements of chemical composition of ambient ions** H. Junninen, M. Ehn, S. Schobesberger, G. Lönn, T. Petäjä, D. R Worsnop and M. Kulmala
12:30	WG01S4O07	**Using a new unified model to revisit the relationship between aerosol size and composition** D. Topping, A. Buchholz and M. McFiggans
Reserve paper	WG01S4B00	**Non-volatile aerosol in the Arctic Winter Stratosphere and its role for PSC formation** R. Weigel, M. Ebert, K. Kandler, S. Molleker, W. Frey, M. Klingebiel, C. M. Volk, G. Günther, H. Schlager, F. Cairo, S. Kaykin, S. Borrmann

10:30-12:50 **Session WG02S5O. Urban Aerosol Chemical and Physical Properties (2)**
Room: Legado Andalusí
Chairs: T. Kuhlbusch / G. Fuller

10:30	WG02S5O01	**Summer ammonia measurements in a densely populated Mediterranean city** M. Pandolfi , F. Amato, C. Reche, A. Alastuey, R. P. Otjes, M.J. Blom and X. Querol
10:50	WG02S5O02	**Seasonal variations of black carbon and number size distribution in Paris (France)** J. Sciare,T. Petäjä, J. Hakala, K. Lehtipalo, E. Herrmann, R. Sarda-Estève, J.B. Nicolas, N. Bonnaire and P.P. Aalto
11:10	WG02S5O03	**Effects of the Low Emission Zone on Black Carbon and Ultrafine Particles in Leipzig** A. Wiedensohler, W. Birmili, F. Rasch, K. Weinhold, M. Merkel, A. Sonntag, G. Löschau, A. Hausmann
11:30	WG02S5O04	**Wintertime urban background measurements of PM1, particle lung-deposited surface area, black carbon and particle number concentrations** U. Quass, H. Kaminski, T. A .J. Kuhlbusch B. Bergmans, D. Muck, F. Lenartz
11:50	WG02S5O05	**Soot externally mixed with Asian dust particles in the submicron rangein the marine atmosphere** K.I. Lieke, D. Zhang, K. Kandler, S. Weinbruch, and M. Bilde
12:10	WG02S5O06	**Sources and processes affecting coarse aerosols**

		at street canyon and urban locations in London, UK D. C Green and, G. W Fuller
12:30	WG02S5O07	**Highly time and size-resolved trace elemental composition of aerosols during CalNex-LA 2010** S. Visser, M. Furger, U. Flechsig, K. Appel, A. S. H. Prevot, U. Baltensperger
Reserve paper	WG02S5B00	**Comparative study of ultrafine aerosol within a city** I. Salma, T. Borsós, Z. Németh, P. Aalto and M. Kulmala

10:30-12:50 **Session SS02S1O. A ground-based integrated study of chemical aerosol-cloud interaction (HCCT2010)**
Room: Faraday
Chairs: Y. Inuma / D. Heard

10:30	SS02S1O01	**Hill Cap Cloud Thuringia 2010 (HCCT-2010): Overview and highlight results** D. van Pinxteren, W. Birmili, B. Fahlbusch, W. Fomba, T. Gnauk, Y. Iinuma, S. Mertes, K. Dieckmann, M. Merkel, C. Müller, K. Müller, L. Poulain, G. Spindler, M. Schäfer, F. Stratmann, A. Tilgner, L. Schöne, P. Bräuer, K. Weinhold, A. Wiedensohler, W. Zhijun, S. Borrmann, E. Harris, A. Roth, J. Schneider, B. Sinha, I. George, D. Heard, L. Whalley, B. D'Anna, C. George, M. Müller, W. Haunold, A. Engel, A. Wéber, D. Amedro, C. Fittschen, C. Schoemaecker, J. Collett, T. Lee, and H. Herrmann
10:50	SS02S1O02	**Influence of Cloud Processing on CCN Activation Behavior in the Thuringian Forest, Germany** K. Dieckmann, M. Schäfer, P. Zedler, H. Wex, S. Henning, H. Herrmann, D. van Pinxteren, W. Birmili, M. Merkel, Z. Wu, A. Wiedensohler, Th. Mentel, and S. Stratmann
11:10	SS02S1O03	**Relating particle hygroscopicity to chemical composition during HCCT-2010 field campaign** Z.J. Wu, L. Poulain, W. Birmili, M. Merkel, K. Dieckmann, M. Schäfer, D. van Pinxteren, S. Stratmann, H. Herrmann, A. Wiedensholer
11:30	SS02S1O04	**Cloud residual analysis using two types of aerosol mass spectrometers within the Hill Cap Cloud Thuringia (HCCT) Experiment 2010** J. Schneider, A. Roth, S. Mertes, D. van Pinxteren, H. Herrmann, and S. Borrmann

11:50	SS02S1O05	**Composition analysis of cloud residual and aerosol particles by single particle massspectrometry during the Hill Cap Cloud Thuringia Experiment 2010** A. Roth, S. Mertes, D. van Pinxteren, T. Klimach, J. Schneider and S. Borrmann
12:10	SS02S1O06	**The impact of clouds on radical concentrations: Observations of OH and HO2 during HCCT-2010** L.K. Whalley, I.J. George, D. Stone and D.E. Heard
12:30	SS02S1O07	**SPACCIM model studies on the multiphase chemistry occurring in orographic hill cap clouds during the HCCT-2010 field campaign** A. Tilgner, P. Bräuer, R. Wolke and H. Herrmann
Reserve paper	SS02S1B00	**Cloud influence on local aerosol chemical composition during the Hill Cap Cloud Thuringia 2010** L. Poulain , Z.J. Wu , A. Tilgner , D. van Pinxteren , B. D' Anna , C. George , J. Schneider , A. Wiedensohler and H. Herrmann

10:30-12:50 **Session WG07S3O. Gas phase synthesis of nanoparticles**
Room: Cine 3
Chairs: E. Kruis / J. Jokiniemi

10:30	WG07S3O01	**Aerosol synthesis of ZnO tetrapods for flexible and transparent UV sensors** Albert G. Nasibulin, Simas Rackauskas, Kimmo Mustonen, Terhi Järvinen, Marco Mattila, Olga Klimova, Hua Jiang, Oleg Tolochko, Harri Lipsanen, Esko I. Kauppinen
10:50	WG07S3O02	**Synthesis of germanium-silicon hybrid particles in an aerosol reactor** C. Mehringer, R. Körmer, B. Butz, E. Spiecker and W. Peukert
11:10	WG07S3O03	**Thermostability of flame synthesized core-shell TiO2/SiO2 nanoparticles and its photocatalytic activity** Qi, Fei, Moiseev, Anna, Deubener, Joachim, Weber, Alfred P
11:30	WG07S3O04	**Synthesis of aluminium nanoparticles with the aid of a customized atmospheric plasma**

		E. Daskalos, H. Mandilas, G. Karagiannakis and A. G. Konstandopoulos
11:50	WG07S3O05	**Synthesis of Magnesium Hydride by Spark Discharge in Argon/Hydrogen Mixtures** T.V. Pfeiffer, A. Anastasopol, S.W.H. Eijt, and A. Schmidt-Ott
12:10	WG07S3O06	**WO3-based thin films produced by Electrostatic Spray Deposition** J. Gaury, E. M. Kelder, G. Biskos
12:30	WG07S3O07	**Core-shell nanomagnets** Forsman, Johann, A. Ari, Tapper, Unto, Koskela, Pirjo, van Dijken Sebastiaan, J. Jorma
Reserve paper	WG07S3B00	**Nanostructured catalytic layers for fuel cell electrodes prepared by electrospray** S. Martin, B. Martinez-Vazquez, P.L. Garcia-Ybarra and J.L. Castillo

10:30-12:50 **Session WG09S1O. Aerosol Modelling: Atmospheric Applications**
Room: Gutenberg
Chairs: A. Asmi / B. Vogel

10:30	WG09S1O01	**Regional modelling of the tropospheric multiphase system using COSMO-MUSCAT: 2D-sensitivity-studies** R. Schrödner, A. Tilgner and R. Wolke
10:50	WG09S1O02	**Simulating the impact of controlled sea salt emissions on cloud optical properties in the Southeast Pacific** K. Lundgren, T. Schad, M. Bangert, B. Vogel, A. Ferrone, and H. Vogel
11:10	WG09S1O03	**Atmospheric boundary layer height estimation by different methods: Application to lidar measurements** D. Toledo, C. Córdoba-Jabonero, E. Cuevas and M. Gil
11:30	WG09S1O04	**The impact of the NAO on aerosol concentration levels in Europe** P. Jiménez-Guerrero, S. Jerez, J.P. Montávez and R.M. Trigo
11:50	WG09S1O05	**CCN formation from biogenic VOCs studied with the global climate model ECHAM5-HAM** R. Makkonen, A. Asmi, V.-M. Kerminen, M. Boy, A. Arneth, A. Guenther and M. Kulmala

12:10	WG09S1O06	**Solar radiation management with high speed civil aircrafts and sulfur-enhanced fuel** A. Laakso, H. Kokkola, A-I. Partanen, A. Laaksonen, K.E.J. Lehtinen and H. Korhonen
12:30	WG09S1O07	**Modelling of particle number size distribution over Europe with chemistry transport model LOTOS-EUROS** A. Manders, A. Visschedijk, H. D. van der Gon, B. Henzing, M. Schaap
Reserve paper	WG09S1B00	**Secondary organic aerosol formation during summer 2010 over Central Europe** B. Langmann, K. Sellegri and E. Freney

Thursday 6th September

08:45-09:45 Plenary 4. **Barbara Turpin**
Secondary organic aerosol formation through aqueous chemistry: atmospheric evidence, chemistry, partitionning and prediction
Room: Auditorio
Chair: Cristina Gutiérrez-Cañas

09:45-10:30 Coffee-break

10:30-12:50 **Session Physical and chemical properties + Transport 2**
Room: Auditorio
Chairs: A. Held / P. Zieger

10:30	WG01S5O01	**Summer Campaign on Aerosol Optics, Microphysics, Chemistry and Mineralogy in Portugal – Overview** F. Wagner, K. Kandler, N. Schiavon, L. Tobias, S. Pereira, J. Preißler, A. Candeias and J. Mirão
10:50	WG01S5O02	**Climatology of aerosol optical properties in Amazonia** P. Artaxo, L.V. Rizzo, E. Swietlicki, A. Arana, E. T. Sena, A. Wiedensohler
11:10	WG01S5O03	**Influence of water uptake on the aerosol light scattering at the regional continental site Melpitz, Germany** P. Zieger, R. Fierz-Schmidhauser, L. Poulain, W. Birmili, T. Müller, M. Nan, A. Wiedensohler, E. Weingartner, and U. Baltensperger
11:30	WG01S5O04	**Black carbon hygroscopic properties influenced by coating content and chemical compositions** D. Liu, J. Allan, B. Bandy, H. Coe, Zoe Fleming, Michael Flynn, G. McFiggans, J. Whitehead and D. Young
11:50	WG01S5O05	**Hygroscopicities, ethanol affinities and composition of nanoparticles in CLOUD** H. Keskinen, G. Tsagkogeorgas, J. Duplissy, F. Bianchi, J. Joutsensaari, P. Miettinen, J. Slowik, M. K. Kajos, S.

		Schobesberger, S. Schallhart, T.Ruuskanen, H. Wex, F. Stratmann, D. Worsnop, M. Kulmala, A. Virtanen , and A. Laaksonen
12:10	WG01S5O06	**Hygroscopicity and cloud forming properties of Arctic aerosol during one year** S. Silvergren, U. Wideqvist , J. Ström, and B. Svenningsson
12:30	WG01S5O07	**Particles measured in a low speed ship engine: Cloud condensation nuclei and mixing state on the nano scale** K. I. Lieke, T. Rosenørn, A. C. Butcher, S. M. King, T. G. Frederiksen, K. Fuglsang, J. B. Pedersen, D. Larsson and M. Bilde
Reserve paper	WG01S5B00	**Long Term Trends in Arctic Aerosol Composition at Kevo, Finland** P.K. Hopke, J.R. Laing, L. Hussain, V.A. Dutkiewicz, J. Paatero, and Y. Viisinen

10:30-12:50 **Session WG05S2O. Carbonaceous aerosol and wood burning contribution to PMx**
Room: Legado Andalusí
Chairs: C. Pio / T. Moreno

10:30	WG05S2O01	**Levels of carbonaceous aerosols in remote, rural, urban and industrial sites of Spain** Querol X., Alastuey A., Viana M., Moreno T., Reche C., Minguillón M.C., Ripoll A., Pandolfi M., Amato F., Pérez N., Pey J., Cusack M., Vázquez R., de la Rosa J., Sánchez de la Campa A., Rodriguez S, Pío C., Alados-Arboledas L., Titos G., Atíñano B., Salvador P., García Dos Santos S., Fernández Patier R
10:50	WG05S2O02	**Long term monitoring of black carbon at eight measurement sites in Switzerland** H. Herich, C. Hueglin, A. Fischer and B. Buchmann
11:10	WG05S2O03	**Cartography and long term trends (1998-2011) of polycyclic aromatic hydrocarbons in France** A. Albinet, M. Beauchamp, G. Harel, L. Malherbe and E. Leoz
11:30	WG05S2O04	**On the contribution from wood burning to the PM10 aerosol in Flanders, Belgium** W. Maenhaut, R. Vermeylen, M. Claeys, J. Vercauteren, C. Matheeussen and E. Roekens
11:50	WG05S2O05	**Contribution of wood burning to the exceedance**

		of PM10 limit values in residential areas of the Rhine-Ruhr conurbation (Germany) U. Pfeffer, L. Breuer and D. Gladtke
12:10	WG05S2O06	**A UK-wide assessment of black carbon and PM from wood burning** Gary W. Fuller, David C Green and David Butterfield
12:30	WG05S2O07	**Insight into the primary and secondary organic fraction of the organic aerosols in and around Barcelona** B.L. van Drooge, M. Alier, R. Tauler, J.O. Grimalt

10:30-12:50 **Session WG04S1O. Combustion and industrial aerosols**
Room: Faraday
Chairs: A. Keller / C. Gutiérrez-Cañas

10:30	WG04S1O01	**Effects of Zn on the physicochemical and toxicological properties of PM1 in pellet combustion** T. Kaivosoja, O. Uski, H. Lamberg, J. Leskinen, A. Virén, T. Torvela, J. Tissari, O. Sippula, S. Paukkunen, M.-R. Hirvonen, J. Jokiniemi
10:50	WG04S1O02	**Comparison of particle concentrations measured direct from hot flue gas and diluted sample gas from wood combustion** J. Tissani, H. Lamberg, O. Sippula, J. Jokiniemi
11:10	WG04S1O03	**Continuous flow reactor for a defined measurement of the SOA formation potential of wood burning emissions** A. Keller, H. Burtscher
11:30	WG04S1O04	**A two component optical absorption model for interpretation of different combustion conditions** T. Dobovicnik, H. Bauer, H. Puxbaum, A. Petzold, A. Ibrahim, R. Hitzenberger, G. Mocnik
11:50	WG04S1O05	**Heavy metals contained in the Particulate Matter emitted from Foundries** J.J. Rodríguez-Maroto, J.L. Dorronsoro-Arenal, D. Sanz-Rivera, E. Rojas-García, M. Fernández-Díaz, P. Galán-Valera and E. Conde Vilda
12:10	WG04S1O06	**Coagulation of Combustion-Formed Nanoparticles in Medium Temperature Regime** M. Sirignano, and A. D'Anna

12:30	WG04S1O07	**Nucleation and growth of welding fumes on the vicinity of the welder: Implications on health effects assessment and protection strategy** Marroquin ML, C. Gutierrez-Canas, Egizabal, Aragon G., Mugica I., Casas N., Flor B. and Larrion M.
Reserve paper	WG04S1B00	**Results and experience of long-term study of reduction of fine particle emissions from wood combustion boiler by a compact electrostatic precipitator** A. Bologa, H.-R. Paur and K. Woletz

10:30-12:50 **Session WG10S1O. Aerosol Nucleation, Condensation and Coagulation**
Room: Cine 3
Chairs: J.L. Castillo / A.G. Konstandopoulos

10:30	WG10S1O01	**Novel Features of (Re-) Crystallization and Particle Population Dynamics In Compressed Gas-Expanded Liquid** D. E. Rosner
10:50	WG10S1O02	**New insight into organic driven particle formation and growth during the CLOUD experiment** F. Riccobono, E. Weingartner, U. Baltensperger and the CLOUD collaboration
11:10	WG10S1O03	**Saturation fluctuations and rain initiation** Charles Clement
11:30	WG10S1O04	**Thermophoretic coating with molybdenum oxide nanoparticles** L, Boskovic and I. E. Agranovski
11:50	WG10S1O05	**Studies on thermal diffusion and Dufour effect in condensation of a trace gas and a near-pure vapor: water droplets on Earth and CO2 ice crystals on Mars** C. Listowski, A. Määttänen, I. Riipinen, F. Montmessin, F. Lefèvre
12:10	WG10S1O06	**Design of well-mixed aerosol chambers for stable aerosol generation** J.T.N. Knijnenburg, M.L. Eggersdorfer and S.E. Pratsinis
12:30	WG10S1O07	**Nucleation and droplet growth measured by a pulse-expansion wave tube** M.A.L.J Fransen, J. Hrubý and D.M.J. Smeulders
Reserve	WG10S1B00	**3D study of fractal combustion aerosols using**

paper		**Electron Tomography** D. Lottin, D. Ferry, D. Delhaye, F.-X. Ouf and J. Yon

10:30-12:50 **Session WG09S2O. Aerosol Modelling: Emission inventories, transport and transformation**
Room: Gutenberg
Chairs: S. Wurzler / P. Makar

10:30	WG09S2O01	**A 40-year retrospective high-resolution European radon flux inventory including climatological variability** I. López-Coto, J.L. Mas and J.P. Bolivar
10:50	WG09S2O02	**Modelling Contribution of Biogenic VOCs to New Particle Formation in the Julich Plant Atmosphere Chamber** L. Liao, M. Boy, D. Mogensen, T. F. Mentel, E. Kleist, A. K.-Scharr, R. Tillman, H. Vuollekoski, M. Kulmala and M. D. Maso
11:10	WG09S2O03	**Development of emission inventories of recreational boats** V. Agranovski
11:30	WG09S2O04	**The Role of Compensating Errors in Reaction-Transport Models of Atmospheric Aerosol** P.A. Makar, R. Nissen, A. Teakles, J. Zhang, Q. Zheng, M.D. Moran, H.Yau
11:50	WG09S2O05	**Application of Process Analysis in the CAMx model for evaluating physical and chemical processes affecting PM in Switzerland** G. Ciarelli, S. Aksoyoglu, J. Keller, D.C. Oderbolz, A.S.H. Prévôt
12:10	WG09S2O06	**Modeling aerosol chemical properties: impact on cloud and precipitation formation** C. Barbet, L. Deguillaume and N. Chaumerliac
12:30	WG09S2O07	**Effect of precursor emissions on PM2.5 concentrations over Europe** E. Tagaris, R.E.P. Sotiropoulou, N. Gounaris and S. Andronopoulos

14:00-16:00 **Session WG01S6O. Climate effects of aerosols**
Room: Auditorio
Chairs: M. Krämer / J.P. Díaz

14:00	WG01S6O01	**Model results of cirrus cloud modifications in a climate engineering framework** H. Muri, J.E. Kristjánsson, T. Storelvmo, D. L. Mitchell and M.A. Pfeffer
14:20	WG01S6O02	**The influence of aerosols on the European heat-wave of 2003: a study with the regional model system COSMO-ART** A. Ferrone, H. Vogel, and C. Kottmeier, B. Vogel
14:40	WG01S6O03	**Are indirect forcing estimates sensitive to cloud formation parameterizations, emission scenarios and meteorological fields?** R.E.P. Sotiropoulou, E. Tagaris,N. Meskhidze, J. Kouatchou, L. Oreopoulos, J.M. Rodriguez and A. Nenes
15:00	WG01S6O04	**Airborne measurements of elevated aerosol layers over Central Europe** B. Weinzierl, F. Dahlkötter, D. Sauer, K. Heimerl, A. Minikin, A. Petzold, C. Voigt, H. Flentje, F. Schnell, V. Freudenthaler, M. Wiegner, and A. Ansmann
15:20	WG01S6O05	**The importance of wood burning as a source of absorbing aerosols in the European Arctic** K.E. Yttri, C. Lund Myhre, A. Stohl, C. Dye, D. Hirdman, J. Ström
15:40	WG01S6O06	**Horizontal Meter Scale Variability of Elemental Carbon in Surface Snow** J. Svensson, J. Ström, M. Hansson and H. Lihavainen

14:00-16:00 **Session WG05S3O. PMx source apportionment**
Room: Legado Andalusí
Chairs: R. Vecchi / F. Amato

14:00	WG05S3O01	**Tracer-based source-apportionment from the EUCAARI project and comparison with the EMEP model** D. Simpson, C. Alves, R. Bergström, S. Decesari, J. Genberg, S. Gilardoni, G. Kiss, E. Swietlicki and E. Vignati
14:20	WG05S3O02	**Intercomparison of source apportionment approaches within the EU-MED APICE project** A. Detournay, D. Salameh, J.L. Jaffrezo, J. Cozic, J.Pey, N.

		Perez, X. Querol, P. Prati, M.C. Bove, E. Cuccia, D. Massabo, J. Bartzis, D. Saraga, E. Tolis, K. Filiou, A. Latella, F. Liguori, S. Patti, A. Armengaud, D. Piga and N. Marchand
14:40	WG05S3O03	**European Intercomparison for Receptor Models: Preliminary Results** F. Karagulian, C.A. Belis, F. Amato, D.C.S. Beddows, V. Bernardoni, S. Carbone, D. Cesari, E. Cuccia, D. Contini, O. Favez, I. El Haddad, R.M. Harrison, T. Kammermeier, M.Karl, F. Lucarelli, S.Nava, J. K. Nøjgaard, M. Pandolfi, M.G. Perrone, J.E. Petit, A. Pietrodangelo, P. Prati, A.S.H. Prevot, U. Quass, X. Querol, D. Saraga, J. Sciare, A. Sfetsos, G. Valli, R. Vecchi, M. Vestenius, J.J. Schauer, J.R. Turner, P. Paatero, P.K. Hopke
15:00	WG05S3O04	**Identification of continental and marine aerosol sources in Paris using high resolution aerosol mass spectrometry** M. Crippa, D. Peter F., S. Jay G., El Haddad Imad, M. Claudia, H. Maarten F., C. Roberto, M. Nicolas, B. Urs, P. Andre. S. H.
15:20	WG05S3O05	**PMF source apportionment of PM10 and PM2.5 daily and hourly aerosol data in Tuscany (Italy)** Lucarelli, F., Becagli, S., Calzolai, G., Chiari, M., Giannoni, M., Martellini, T., Rugi, F., Nava, S., Traversi, R. & Udisti, R.
15:40	WG05S3O06	**Source apportionment of indoor, outdoor and personal PM2.5 exposure of pregnant women** M.C. Minguillón, M. Triguero-Mas, A. Schembari, A. de Nazelle, P. Dadvand, F. Figueras, J.A. Salvado, J.O. Grimalt, M. Nieuwenhuijsen, X. Querol
Reserve paper	WG05S3B00	**Comparison of receptor models using synthetic organic aerosol mass spectra** H. Hagino, and T. Morikawa

14:00-16:00 **Session WG04S2O. Engines related emissions**
Room: Faraday
Chairs: A. Petzold / M. Vojtisek-Lom

14:00	WG04S2O01	**Particulate matter emissions from a winter operation of a modern on-road diesel engine powered by heated rapeseed oil.** M. Vojtisek-Lom, M. Pechout, M. Mazač

14:20	WG04S2O02	**Role of exhaust after-treatment devices in diesel exhaust nanoparticle formation processes** T. Rönkkö, J. Heikkilä, T. Lähde, L. Pirjola, F. Arnold, H. Schlager, D. Rothe and J. Keskinen
14:40	WG04S2O03	**The influence of oxygenated organic aerosols (OOA) and its volatile organic content on the oxidative potential of diesel particulate mater** S. Stevanovic, B. Miljevic, N.C. Surawski, P.Vaattovaara, R. J. Brown, Z.D. Ristovski
15:00	WG04S2O04	**Size-resolved particle emission factors for individual ships** Å.M. Jonsson, J. Westerlund and M. Hallquist
15:20	WG04S2O05	**Towards an identification of aircraft soot among urban background: focus on nanoparticles emitted by CFM56 turbofan engines** D. Lottin, D. Ferry, J.-M. Gay and D. Delhaye
15:40	WG04S2O06	**Evolution of Jet Engine Exhaust Aerosol in an Aging Plume** D.E. Hagen, P. Lobo, J. Keehn, M. Trueblood, and P.D. Whitefield
Reserve paper	WG04S2B00	**Exhaust emissions and particle hygroscopicity with a diesel engine run with HVO fuel-oxygenate blend** M. Happonen, J. Heikkilä, P. Aakko-Saksa, T. Murtonen, K. Lehto, A. Rostedt, T. Sarjovaara, M. Larmi, J. Keskinen, A. Virtanen

14:00-16:00 **Session WG10S2O. Aerosol Dynamics**
Room: Cine 3
Chairs: P.L. García-Ybarra / C. Clement

14:00	WG10S2O01	**The mobility radius of small fractal aggregates in the slip-flow regime** A.D. Melas, A.G. Konstandopoulos and Y. Drossinos
14:20	WG10S2O02	**Study of thermophoretic velocity of soot particles with a new device: the radial flow thermophoretic analyser** E. Brugière, F. Gensdarmes, F.-X. Ouf , J. Yon and A. Coppalle
14:40	WG10S2O03	**Forces on a porous particle in an oscillating flow** P. Vainshtein and M. Shapiro

15:00	WG10S2O04	**Stick and rebound of single nanoparticles and nanoparticle agglomerates** S. Rennecke and A.P. Weber
15:20	WG10S2O05	**The Friction Factor and Collision Kernel for Aggregates in the Mass and Momentum Transition Regimes** C. J. Hogan Jr, C. Zhang, T. Thajudeen, R. Gopalakrishnan, C. Larriba, T. Schwartzentruber
15:40	WG10S2O06	**Separation of gas-borne nanoparticles in bubble columns** D. Koch, A.P. Weber
Reserve paper	WG10S2B00	**Modeling of the behavior of droplets deposited on the smooth and rough fiber surfaces** J.M. Gac and L. Gradoń

14:00-16:00 **Session WG09S3O. Aerosol Modelling: New particle formation and further topics**
Room: Gutenberg
Chairs: S. Wurzler / A. Asmi

14:00	WG09S3O01	**Nucleation rate parametrization in the CLOUD experiment over all tropospheric conditions** Almeida-Simões, J., C. Joachim, K. Jasper, C., Ken, D. Eimear, and the CLOUD collaboration
14:20	WG09S3O02	**Modelling of ion-induced binary nucleation in the CERN CLOUD experiment** S. Ehrhart, L. Ickes, J. Kazil, K. D. Froyd, E. R. Lovejoy, J. Curtius and the CLOUD collaboration
14:40	WG09S3O03	**Atmospheric new particle formation mystery unveiled?** I.K. Ortega, O. Kupiainen, T. Olenius, M. McGrath.T. Kurtén, P. Pasonen, M. Kulmala and H. Vehkamäki
15:00	WG09S3O04	**Simulating the contribution of primary emissions and secondary formation to aerosol number concentrations in Europe** C. Fountoukis, I. Riipinen, D. Patoulias, H. D. van der Gon, P.E. Charalampidis, C. Pilinis, and S.N. Pandis
15:20	WG09S3O05	**Modeling Reactive Aerosols in Oxidizing Atmospheres: Severe Accidents in Sodium Fast Reactors** M. García, L.E. Herranz

15:40	WG09S3O06	**The global distribution of aerosol model uncertainty** L.A. Lee, K.S. Carslaw, K.J. Pringle
Reserve paper	WG09S3B00	**Determining the particle diameter growth rate from the fraction of charged particles** J. Leppä, S. Gagné, L. Laakso, K. E. J. Lehtinen, M. Kulmala and V.-M. Kerminen

POSTER SESSION C

001	C-WG01S3P01	**Biomass burning event in Spain: aerosol size distribution, aerosol optical properties and associated radiative forcing** E. Alonso-Blanco, V. Pont, A. Castro, A.I. Calvo, M. Mallet, R. Fraile
002	C-WG01S3P02	**Estimate of direct radiative forcing by aerosols over East Asia with the assimilated aerosol optical properties** C.H. Song, R.S. Park, C.E. Chung, J.H. Lee, and J. Kim
003	C-WG01S3P03	**9-year analysis of the aerosol radiative forcing over a Mediterranean urban coastal site** A.R. Esteve, V. Estellés, M.P. Utrillas and J.A. Martínez-Lozano
004	C-WG01S3P04	**6 years of continuous aerosol size distribution measurements from the foothills of Central Himalayas** A.-P. Hyvärinen, R.K. Hooda, M. Komppula, K. Neitola, E. Asmi, V.P. Sharma, T.S. Panwar, and H. Lihavainen
005	C-WG01S3P05	**Description of the Soot on Snow experiment (SoS 2012) at Jokioinen, Finland** N. Kivekäs, D. Brus, A. Hyvärinen, O. Järvinen, J. Svensson, A. Aarva, O. Meinander, A. Heikkilä and A. Virkkula
006	C-WG01S3P06	**Influence of kappa-Köhler theory based water uptake scheme on a global climate/aerosol model** D. O'Donnell
007	C-WG01S3P07	**Aerosol and cloud SW radiative forcing in the south of Portugal** V. Salgueiro, M.J. Costa, A.M. Silva and D. Bortoli
008	C-WG01S3P08	**Investigating aerosol – radiation feedbacks in high-emission areas using WRF/Chem model** A.Balzarini, G.Pirovano, G.M. Riva

009	C-WG01S3P09	**The Soot on Snow experiment 1 (SoS 2011): Soot from burning organics** A. Virkkula, O. Järvinen, H. Lihavainen, A. Hyvärinen, J. Svensson, T. Mäkelä, N.Kivekäs, R. Väänänen, J. Backman, A. Heikkilä, A. Aarva, E.-M. Kyrö, and G. Leeuw
010	C-WG01S3P10	**A4: Arctic Absorbing Aerosols and Albedo of Snow (2012-2015)** O. Meinander, A. Aarva, L. Backman, A. Heikkilä, P. Kolmonen, A. Kontu, E. Kyrö, H. Lihavainen, N. Kivekäs, J. Pulliainen, P. Räisänen, M. Sofiev, A. Virkkula and G. de Leeuw
011	C-WG01S3P11	**Experimental study of the surface shortwave aerosol forcing efficiency** J.L. Anastasio, I. Foyo-Moreno , A. Valenzuela, M. Antón, F.J. Olmo and L. Alados-Arboledas
012	C-WG01S3P12	**Aircraft Measurements of Aerosol, Cloud Droplet and CCN Distribution Characteristic over Northern China** Duan Ying, Yin Yu, Duan Jing
013	C-WG01S3P13	**A note of caution concerning particle evaporation during measurements of their Cloud Condensation Nucleus potential** H. Wex, P. Herenz, J. Voigtländer and F. Stratmann
014	C-WG01S3P14	**Indirect aerosol effects from Chemistry Transport model coupled to a Regional Climate model** M.A. Thomas, M. Kahnert, H. Kokkola, C. Andersson, R. Bergström, C. Bennet, L. Robertson, U. Hansson, C. Jones and U. Willen
015	C-WG01S3P15	**Mass spectrometric analysis of cloud residuals in tropical trade wind cumuli at Pico Este, Puerto Rico, during PRADACS 2011** J. Schneider, A. Roth, J. Schmale, S. Mertes, L. Schenk, O. L. Mayol-Bracero, C. J. Valle, F. Zurcher, and S. Borrmann
016	C-WG01S3P16	**New cloud chamber experiments on the crystallization and heterogeneous ice nucleation ability of sodium chloride dihydrate particles** R. Wagner, O. Möhler, H. Saathoff and M. Schnaiter
017	C-WG01S3P17	**Experimental and modelled characterization of diffuse spectral UV irradiance under cloudy conditions: impact of aerosol properties** D. Mateos, A. di Sarra, J. Bilbao, M. Cacciani, G. Casasanta, D. Meloni, G. Pace, and A. de Miguel
018	C-WG01S3P18	**Overview of Puijo Cloud Experiments (PuCE 2010 & 2011)** Portin, Harri, Leskinen, Ari, Brus, David, Neitola, Kimmo,

		Hyvärinen, Antti-Pekka, Kortelainen, Aki, Hao, Liqing, Miettinen, Pasi, Jaatinen, Antti, Lihavainen, Heikki, Romakkaniemi, Sami, Laaksonen, Ari, Lehtinen, Kari E.J. and Komppula, Mika
019	C-WG01S3P19	**Experimental study in situ conditions of below-cloud scavenging of aerosol particles** G. Depuydt, O. Masson, J.L. Brenguier, P. Boissery
020	C-WG01S3P20	**Identifying cloud processed aerosol particles with light depolarization** D. Baumgardner, R. Newton, O.L. Mayol-Bracero, C.J. Valle-Diaz, F. Zurcher, S. Mertes
021	C-WG01S3P21	**Inhibition of Heterogeneous Ice Nucleation of Mineral Dust Particles Exposed to Ozone** Z.A. Kanji, A. Welti, C. Chou and O. Stetzer
022	C-WG01S3P22	**Aerosol activation behaviour in liquid-phase clouds at the Jungfraujoch: A comparison of in-situ measurements and box modelling data** E. Hammer, N. Bukowiecki, M. Gysel, C. R. Hoyle, Z. Jurányi, M. Leuenberger, U. Baltensperger and E. Weingartner
023	C-WG01S3P23	**Cloud condensation nuclei (CCN) properties of mixed organic-sulphate particles** Å.K. Watne, R. K. Pathak, A. Eriksson, C. Wittbom, Th. F. Mentel, J. Pagels, B. Sveningsson, E. Swietlicki and M. Hallquist
024	C-WG01S3P24	**Mixed-phase clouds observations at Pallas subarctic background site** D. Brus, K. Neitola, J. Svensson and H. Lihavainen
025	C-WG01S3P25	**First measurements of marine stratocumulus microphysical parameters at a subtropical Atlantic station (Friolera Peak Lab, FPL, 28.6ºN, 16.2ºW)** J.P. Díaz, F.J. Expósito, J.C. Pérez and A. González
026	C-WG01S3P26	**Combustion Particles as Ice Nuclei in an Urban Environment: Evidence From Single-Particle Mass Spectrometry** J.C. Corbin, P. J. G. Rehbein, G. J. Evans and J.P.D. Abbatt
027	C-WG01S3P27	**A Case Study of Cloud Events by High Resolution Aerosol Mass Spectrometer in a Semi-urban Aerosol-cloud Interaction Observation Station** L.Q. Hao, A. Kortelainen, A. Jaatinen, P. Miettinen, S. Romakkaniemi, H. Portin, M. Komppula, A. Leskinen, A. Virtanen, J.N. Smith, D.R. Worsnop and A. Laaksonen
028	C-WG01S3P28	**A new ice selective inlet for the characterization of the atmospheric ice phase** P. Kupiszewski, P. Vochezer, M. Schnaiter, E. Weingartner

029	C-WG01S3P29	**Cloud resolving model simulations of geoengineering of marine stratocumulus cloud by sea salt injections** Z. Maalick, H. Korhonen, H. Kokkola, A. Laaksonen and S. Romakkaniemi
030	C-WG01S3P30	**Size distribution and chemical composition of ice nuclei at a rural site in Germany** M. Ebert, T. Hermann, H. Bingemer, H. Klein, J. Curtius, and S. Weinbruch
031	C-WG01S3P31	**The regime dependency of the susceptibility of convective mixed-phase clouds and precipitation** Di Chang, Hang Su, Philipp Reutter, Jörg Trentmann, Meinrat O. Andreae, and Ulrich Pöschl
032	C-WG01S3P32	**Measuring tropical maritime cumulus cloud particle residual composition and ice nuclei concentration during the ICE-T field campaign** A. Cazorla, K.J. Suski, G.R McMeeking, P.J. DeMott, S.G. Lasher-Trapp, C.H. Twohy and K.A. Prather
033	C-WG01S3P33	**Hygroscopic and CCN properties of submicron atmospheric aerosol in a boreal forest environment during the summer of 2010** J. Hong, M. Paramonov and T. Petäjä
034	C-WG01S3P34	**Ultra-fine aerosol particles above Amazon rainforest** M. Matisans, L. Rizzo, R. Krejci, P. Artaxo, P. Tunved, I. Riipinen, T. Hamburger, E. Swietlicki
035	C-WG01S3P35	**Impacts of Emission Controls and Perturbations on an Intense Convective Precipitation Event during the 2008 Beijing Olympic Games** Y. F. Cheng, C. Wei, P. Marrupu, P. Saide, S. Kulkarni, M. Lin, Q. Zhang, D. G. Streets, H. Su, A. Wiedensohler, G. R. Carmichael
036	C-WG01S3P36	**Relationships between aerosols, cloud condensation nuclei and cloud droplets on a background subarctic site** T. Anttila, D. Brus, A.-H. Hyvärinen, A. Jaatinen, N. Kivekäs, S. Romakkaniemi, H. Lihavainen
037	C-WG04S1P01	**Fate of volatile and non-volatile elements from biomass burned in stoves and boilers** Torben Seidel & Hans Ruppert
038	C-WG04S1P02	**Control of trace pollutants in fuidised bed biomass-residues co-combustion fly-ash.** D. Sanz, J. J. Rodríguez, J. L. Dorronsoro, E. Rojas, R. Ramos, R. Escalada, M. E. Borjabad, M. A. Martínez, M. P. Sanz, A. De La Torre, P. Galán , A. Bahillo, C. Gutierrez-Cañas, G. Aragón and S. Astarloa

039	C-WG04S1P03	**Aerosol mass spectrometer measurements on wood combustion experiments** A. Kortelainen, J. Joutsensaari, A. Jaatinen, P. Miettinen, L. Hao, D. R. Worsnop, J. Jokiniemi and A. Laaksonen
040	C-WG04S1P04	**Effect of improved combustion technology on emissions in hybrid masonry heater from combustion of pellets and wood logs** A. Virén, H. Lamberg, T. Kaivosoja, O. Sippula, J. Tissari, J. Jokiniemi
041	C-WG04S1P05	**Effective density of particles emitted from different biomass combustion conditions** J. Leskinen, A. Virén, H. Lamberg, T. Kaivosoja, T. Kettunen, I. Nuutinen, T. Torvela, O. Sippula, J. Tissari, J. Jokiniemi
042	C-WG04S1P06	**Zinc enrichment in ultrafine particles formed in biomass combustion** T. Torvela, T. Kaivosoja, O. Sippula, A. Virén, J. Leskinen, T. Kettunen, I. Nuutinen, H. Lamberg, J. Tissari, J. Jokiniemi
043	C-WG04S1P07	**Particle formation during combustion of solid recovered fuels in a grate system** W. Baumann, H. Mätzing, H.-J. Gehrmann, M. Hauser, P. Nowak, H.-R. Paur and H. Seifert
044	C-WG04S1P08	**Particulate emissions from the co-combustion of forest biomass waste and sewage sludge in a bubbling fluidised bed** A.I. Calvo, L.A.C. Tarelho, E.R. Teixeira, T. Nunes, C. Alves, M. Duarte, E. Coz, A. Castro, B. Artiñano, R. Fraile
045	C-WG04S1P09	**Ignition and combustion of coal dusts with different fuel mass concentrations** S.G. Orlovskaya, V.V. Kalinchak and O.N. Zuy
046	C-WG04S1P10	**Reduction of particulate matters emitted from a diesel-generator fuelled by waste-edible-oil biodiesel with acetone and isopropyl alcohol addition** J.H. Tsai, S.J. Chen, K.L. Huang, C.C. Lin and W.Y. Lin
047	C-WG04S1P11	**Study of paraffin droplets evaporation and burning** S.G. Orlovskaya, M.S. Shkoropado, F.F. Karimova
048	C-WG04S1P12	**Testing performance of fume hood in chemical laboratory** T. Jankowski
049	C-WG04S1P13	**Anthropogenic influence in bulk deposition fluxes in an urban-industrial area in the southwest of Spain** S. Castillo, J. de la Rosa, Y. González-Castanedo, A. Sánchez de la Campa, R. Fernández and X. Querol

050	C-WG04S1P14	**Number size distribution of welding fumes** M. Manigrasso, C. Fanizza, P. Carrai, and P. Avino
051	C-WG04S1P15	**Clogging of industrial High Efficiency Particulate Air (HEPA) filters in case of fire: extension of an empirical model to realistic fire conditions** F.-X. Ouf, V.-M. Mocho, S. Pontreau and Z. Wang
052	C-WG04S1P16	**Elemental and morphological characterization of combustion by-products released from coal-fired thermal power plants in India** Rakesh Kumar and Sudesh Yadav
053	C-WG04S1P17	**Characterisation of particle number, nitrogen oxides and ozone concentrations in an urban background area located near a municipal waste incinerator** A.Donateo, D.Contini, F.Belosi, F. Prodi, F.M. Grasso
054	C-WG04S1P18	**Analysis of Soot deposit for post fire investigation: comparison between full scale experiment and theoretical approach** A. Bellivier, M. Vigreux, F.X. Ouf and H. Bazin
055	C-WG04S1P19	**Electrical Properties of Carbonaceous Particles Collected from Laminar Premixed Flames** G. De Falco, M. Commodo, V. Pagliarulo, G.P. Pepe P. Minutolo, A. D'Anna
056	C-WG04S1P20	**Towards a discrimination between particle emission from wood/biomass combustion and road traffic by Raman microspectroscopy** N.P. Ivleva, C. W. Müller, I. Kögel-Knabner and R. Niessner
057	C-WG04S1P21	**Field scale evaluation of ultrafine particles emissions from stationary combustion and industrial sources** S.Cernuschi, G. Lonati, M. Giugliano, S. Ozgen, G. Ripamonti
058	C-WG04S1P22	**Characterization of aerosols produced by a commercial combustion aerosol generator MiniCAST^{TM} 5201: EC/TC, size distribution, morphology and optical properties** F.-X. Ouf, E. Brugière, D. Ferry, S. Pontreau and J. Yon
059	C-WG04S1P23	**Selective catalytic NH_3 using rare-earth oxides of gasified biomasses fuels. Part 1. Materials structural characterization** Chang-Mao Hung, Shui-Jen Chen, Wei-Bang Lin and Wen-Liang Lai
060	C-WG04S1P24	**Selective catalytic NH_3 using rare-earth oxides of gasified biomasses fuels. Part 2. Catalytic activity and mechanism study** C.-M. Hung, S.-J. Chen, W.-B. Lin and W.-L. Lai

061	C-WG04S1P25	**Selective catalytic NH_3 using rare-earth oxides of gasified biomasses fuels. Part 3. Reaction kinetic behavior study** Chang-Mao Hung, Shui-Jen Chen, Wei-Bang Lin and Wen-Liang Lai
062	C-WG04S1P26	**Results and experience of long-term study of reduction of fine particle emissions from wood combustion boiler by a compact electrostatic precipitator** A. Bologa, H.-R. Paur and K. Woletz
063	C-WG04S1P27	**Comparison of Methods for On-Line Measurement of Diesel Particulate Matter** Z. Liu, J. Swanson, D.B. Kittelson and D.Y.H. Pui
064	C-WG04S1P28	**Laboratory investigation of PAH transformation during NO2-based DPF regeneration** J. C. Wolf and R. Niessner
065	C-WG04S1P29	**Comparison of genotoxicity of exhaust from a diesel, biodiesel and rapeseed oil powered engine – pilot study** J. Topinka, A. Milcova, J. Schmuczerova, M. Mazac, M. Pechout, M. Vojtisek-Lom
066	C-WG04S1P30	**Experimental Investigations of Sensitivity of Lichens to Diesel Exhaust under Lab Conditions** U. Langmann, P. Madl, W. Hofmann, G. Brunauer, R. Türk
067	C-WG04S1P31	**Nanoparticle emissions from ships calling the port of Gothenburg** J. Westerlund, M. Hallquist and Å.M. Jonsson
068	C-WG04S1P32	**Detailed chemical characterization of PM and COV, and source apportionment near a French highway** L. Polo, C. Piot, A. Charron, J. Cozic, B. Temime-Roussel, N. Marchand, J.L. Besombes and J.L. Jaffrezo
069	C-WG04S1P33	**Time-resolved NO_2 analysis in the presence of soot** J. C. Wolf, K. Thaler, R. Niessner, and C. Haisch
070	C-WG04S1P34	**Particle size and number distribution of particles emitted by a modern diesel engine using mineral diesel and Biodiesel from Soybean** C. C. Barrios S, A. Domínguez-Sáez, C. Martín Jiménez
071	C-WG04S1P35	**Measuring black carbon emission factors of cars in real driving conditions** I. Ježek, G. Močnik
072	C-WG04S1P36	**2D study of the size and morphological properties of soot emitted by an aircraft advanced combustion chamber** D. Delhaye, D. Lottin, D. Ferry, J.-M. Gay and X. Vancassel

073	C-WG04S1P37	**Exhaust emissions and particle hygroscopicity with a diesel engine run with HVO fuel-oxygenate blend** M. Happonen, J. Heikkilä, P. Aakko-Saksa, T. Murtonen, K. Lehto, A. Rostedt, T. Sarjovaara, M. Larmi, J. Keskinen, A. Virtanen
074	C-WG04S1P38	**Effective Density and Fractal–like Dimension of Diesel Soot Aggregates as a Function of Mobility Diameter** P. Baltzopoulou, E. Papaioannou, M. Kostoglou, A.G. Konstandopoulos
075	C-WG05S1P01	**PM10 is responsible for a greater IL-6 secretion after "in vitro" incubation with synoviocytes from patients with Rheumatoid Arthritis than in those with osteoarthrosis** V. Guercio, F. Cetta, F. Laghi Pasini, E. Selvi, E. Balistreri I. Santi, M. Monti , L. Cantarini, E. Bolzacchini and M. Galeazzi
076	C-WG05S1P02	**Damage to newborns, in terms of risks for diseases occurring even decades after exposure to PM, as a crucial item in the global effects of air pollution to a given population** B. Lorenzi, F. Cetta, V. Guercio, P. Paladini, F. Granato, R. Zangari, M. Monti , M. Giovannini, E. D'Auria, M. Mandelli and M. Sala
077	C-WG05S1P03	**A plea for greater caution before extending "in vitro" assessment of PM to risk assessment in humans** J. Martellucci, F Cetta ,V. Guercio, D. Stergiou, B. Lorenzi , M. Monti and E. Bolzacchini
078	C-WG05S1P04	**Source-specific mutagenicity and carcinogenicity of PM2.5-bound polycyclic aromatic hydrocarbons in a large city of North-eastern Italy** M. Masiol, S. Squizzato, A. Hofer, F. Benetello, G. Rampazzo, B. Pavoni
079	C-WG05S1P05	**Quantitative and qualitative relationship between AOD obtained by AERONET and PM2.5 from in situ measurements in Brazilian Amazonia over several years** M. Paixão, D. Mourao, A. Correia, S. Hacon, P. Artaxo
080	C-WG05S1P06	**Statistics of PM10 concentrations in Mazovia, central Poland (2007 – 2011)** A. Pietruczuk, J. Jarosławski and I. Pawlak
081	C-WG05S1P07	**Anions, Cations, Total Carbon and Water Soluble Organic Carbon in PM2.5 and PM1 samples**

		monitored near a waste incinerator plant in the Po Valley (Bologna) M. Rossi, L. Pasti, L. Tositti, S. Zappoli, E. Brattich, S. Parmeggiani, M. Stracquadanio
082	C-WG05S1P08	**Water-soluble fraction Metals in PM2.5 and PM1 samples collected near a waste incinerator plant in the Po Valley (Bologna)** M. Rossi, L. Pasti, M. Remelli, A. Pagnoni and E. Sarti
083	C-WG05S1P09	**Polycyclic Aromatic Hydrocarbons and Nitro-Derivatives PAHs in PM2.5 and PM1 samples collected near a waste incinerator plant in the Po Valley (Bologna)** M. Rossi, L. Pasti, I. Scaroni and P. Casali
084	C-WG05S1P10	**PM2.5 and PM1 aerosol monitoring near a waste incineration plant located next to Bologna, in the Po Valley: the MONITER Project Campaign** M. Rossi, G. Bonafè, F. Scotto, A. Trentini, L. Pasti
085	C-WG05S1P11	**Concentrations of PMx, NO2 and NH3 in the metropolitan area of Barcelona: APICE long monitoring campaign** J. Pey, N. Pérez, A. Alastuey, X. Querol, J. Cortés
086	C-WG05S1P12	**Searching the relationship between PM10 and MODIS aerosol optical depth at Granada (Spain): urban location and background EMEP station** A.I. Calvo, J.L. Guerrero-Rascado, L. Alados-Arboledas, F.J. Olmo
087	C-WG05S1P13	**Origin of PM2.5 and Secondary Inorganic Aerosol (SIA) and relationship with gaseous pollutants in the Venice area** S. Squizzato, M. Masiol, E. Innocente, E. Pecorari, G. Rampazzo, B. Pavoni
088	C-WG05S1P14	**Analysis of the episodes of high PM10 concentrations from January to April and October to November 2011 in Central and Western Europe with focus on North-Rhine Westphalia** S. Wurzler, H. Hebbinghaus, P. Bruckmann, A. Baltruschat, U. Romberg, J. Friesel, U. Pfeffer, W. Straub, J.Geiger
089	C-WG05S1P15	**Health relevant organic compounds on particulate matter (PM2.5) at two urban sites in Munich: Critical data evaluation** J. Lintelmann, K. Fischer, R. Zimmermann
090	C-WG05S1P16	**Variations of PM-10 and its relationship with BE-7 measurements using a high-volume air sampler at Málaga**

		C. Dueñas, M.C. Fernández, E. Gordo, S. Cañete and M. Pérez
091	C-WG05S1P17	**EDXRF analysis of elemental composition of PM2.5 particles sampled in Taif, Saudi Arabia** A. A. Shaltout, D. R. Almallway, Z. F. Shehadeh, J. Boman
092	C-WG05S1P18	**Time-resolved Measurements of Atmospheric Particulate Matter** M. Amodio, E. Andriani, P. R. Dambruoso, G. de Gennaro, A. Di Gilio
093	C-WG05S1P19	**The changes in chemical composition of fine PM between 1994 and 2010 at rural background site Košetice, Czech Republic** J. Schwarz, V. Havránek, R.Krejčí, P. Tunved, E. Swietlicki, and. V. Ždímal
094	C-WG05S1P20	**Temporal and spatial variability of the total particle number concentration in the Venice area** Pigozzo, A., De Bortoli, A., Patti, S., Manodori, L.
095	C-WG05S1P21	**Takeoff – but what was left behind? In an African perspective** M. J. Gatari, J. Boman, V. Kivaya, D. Maina and A. Wagner
096	C-WG05S1P22	**Air Quality Monitoring Strategies for Urban Areas – A Data Base on New Monitoring Technologies, New Metrics and Proxies** T.A.J. Kuhlbusch, M. Viana, A. Borowiak, E.P. Weijers, K. Torseth, X, Querol, P. Quincey, R. Gehrig, C. Hüglin, K. Katsouyanni and U. Quass
097	C-WG05S1P23	**Magnetic properties of PM10x collected at rural site during heating and non-heating seasons** E. Petrovsky, B. Kotlik, A. Kapicka, R. Zboril and M. Roxer
098	C-WG05S1P24	**Comparison of different operational parameters for thermal-optical EC/OC measurements of filter samples from Flanders, Belgium** W. Maenhaut, M. Claeys, J. Vercauteren and E. Roekens
099	C-WG05S1P25	**Road traffic impact on size-segregated atmospheric aerosols loading at Madrid** F. Mirante, C. Alves, C. Pio, M. Fernandez, M.A. Revuelta and B. Artiñano
100	C-WG05S1P26	**Preliminary research on the ammonium content of particulate matter from indoor air of pig housing systems** T. Ulens, N. Van Ransbeeck, H. Van Langenhove and P. Demeyer
101	C-WG05S1P27	**Seasonal variations of ions and metals in urban PM1 aerosol**

		P. Mikuška, K. Křůmal, M. Vojtěšek, N. Kubátková and Z. Večeřa
102	C-WG05S1P28	**Comparison of online measurements with an Aethalometer and an HR-ToF-AMS and offline chemical analysis data for the characterization of PM2.5 aerosols** V. Crenn, V. Riffault, I. Fronval and D. Petitprez
103	C-WG05S1P29	**Spatial and seasonal distribution of dicarboxylic acids and sugars in the surroundings of a municipal waste incinerator near Bologna, Italy** M.C. Pietrogrande, D. Bacco, M. Rossi
104	C-WG05S1P30	**GC-MS method for the simultaneous analysis of water-soluble organic compounds in PM: response surface methodology for optimizing solvent extraction.** M.C. Pietrogrande, D. Bacco, S. Chiereghin
105	C-WG05S1P31	**Total and water-soluble fraction trace element analysis of PM2.5 samples from the city of Patras, Greece** M. Manousakas, H. Papaefthymiou, K. Eleftheriadis
106	C-WG05S1P32	**Recent changes in PM10 levels and associated ions in an industrial environment in Spain** E. Yubero, N. Galindo, J.F. Nicolás, D. Martínez, M. Santacatalina, and A. Carratalá
107	C-WG05S1P33	**Particle source characterisation of a cement plant with automated scanning electron microscopy** M.F. Meier, T. Zünd and B. Grobety
108	C-WG05S1P34	**Indoor Air Quality in Gymnasiums** C.A. Ramos, S. M. Almeida, S. Cabo Verde, S. Viegas, C. Viegas
109	C-WG05S1P35	**Observations of elevated aerosol particle number and mass concentration events in Vilnius city** S. Kecorius, K. Plauškaitė, S. Byčenkienė and V. Ulevicius
110	C-WG05S1P36	**Mobile platform measurements of PM mass and number concentrations and black carbon in the Greater Athens Area** E. Diapouli, S. Vratolis, V. Vasilatou, M. Gini, A. Tsakis, L. Chasapidis, F. Akritidis, A. Konstantopoulos, G. Mocnik, S. Pothos and K. Eleftheriadis
111	C-WG05S1P37	**PM concentration and chemical speciation measurements at two sites in Athens, Greece** S. Vratolis, E. Diapouli, V. Vasilatou, M. Gini, Th. Maggos, D. Saraga, Th. Ntoka and K. Eleftheriadis
112	C-WG05S1P38	**Determination of refinery emission pollutants**

		impact on an urban atmosphere M.A. Barrero, M. Goikoetxea and L. Cantón
113	C-WG05S1P39	**Determination of water content in atmospheric particulate matter** C. Farao, C. Perrino, S. Canepari, E. Marconi, M.L. Astolfi
114	C-WG05S1P40	**Long-range transport influence on PM2.5 measurements performed in Southern Italy** S. Trippetta, R. Caggiano, S. Fiore, A. Lettino, M. Macchiato and S. Sabia
115	C-WG05S1P41	**Particulate air pollution exposure during commuting in three European cities** P. Taimisto, A. Pennanen, E. Vouitsis, Z. Samaras, M.P. Keuken and T. Lanki
116	C-WG05S1P42	**Two years of measurements at a regional background site in the Balearics: first results** J. Pey, C. Bujosa, S. Caballero, X. Querol, A. Alastuey, M Sicard, B. Artíñano
117	C-WG05S1P43	**Effect of flooring, cleaning and foot traffic on indoor air particulates** N. Mansouri, I. Colbeck
118	C-WG05S1P44	**Personal monitoring of ambient particulate matter – online monitoring and offline filter sample analysis** J. Schnelle-Kreis G. Abbaszade, J. Cyrys, J. Gu, M. Pitz, A. Peters, R. Zimmermann
119	C-WG05S1P45	**Evolution of PM10, PM2.5 and PM1 in a semi-arid industrial environment** M. Santacatalina and A. Carratalá
120	C-WG05S1P46	**Emission measurement of PM size distribution from road wear** M. Maasikmets, E. Teinemaa, T. Arumäe
121	C-WG05S1P47	**PM10 sampling inlets comparison: EPA vs EU** P. Panteliadis, H.J.P.Helmink, P.C.Koopman, M.Hoonhout, D.de Jonge and J.H.Visser
122	C-WG05S1P48	**Source apportionment and sector analysis of organic aerosol in southern Sweden** J. Genberg, M. Sporre and E. Swietlicki
123	C-WG05S1P49	**PM2.5 PCA-APCS Source Apportionment of a site monitored near a waste incinerator plant located in Bologna Area** M. Rossi, L. Pasti
124	C-WG05S1P50	**Source apportionment of PM1 aerosols sampled with an HR-ToF-AMS at an urban background site and an industrialized coastal site using PMF** V. Crenn, V. Riffault, S. Sauvage and D. Petitprez

125	C-WG05S1P51	**The effect of local heating on indoor and outdoor air quality in a rural settlement** M. Braniš and J. Kozáková
126	C-WG05S1P52	**Origin of low-molecular-weight mono and dicarboxylic acids in urban, industrial and suburban environments** G.A. Blanco, M.I. Turnes-Carou, P. López-Mahía, S Muniategui-Lorenzo and D. Prada-Rodríguez
127	C-WG05S1P53	**Modelling of particulate matter concentration at regional and local scale** P. Brotto, F. Cassola, A. Mazzino, T. Giannaros, K. Markakis, A. Poupkou, D. Melas and P. Prati
128	C-WG05S1P54	**Comparison of receptor models using synthetic organic aerosol mass spectra** H. Hagino, and T. Morikawa
129	C-WG05S1P56	**Indoor PM2.5 Source Apportionment from Primary School in Rural Area, Portugal** N. Canha, S.M. Almeida, M.C. Freitas, H.T. Wolterbeek, J. Cardoso, C.A. Pio, A. Caseiro
130	C-WG05S1P57	**Characteristics of heavy metals in PM2.5 at Fukuoka, Japan, based on daily analysis of year-round samples** N. Kaneyasu, A. Takami, K. Sato, S. Ymamamoto, Y-P. Kim and I-S. Kim
131	C-WG05S1P58	**An application of positive matrix factorization and cluster analysis to discriminate the sources of PM10 in a coastal site near Venice (Italy)** M. Masiol, S. Squizzato, D. Ceccato, G. Rampazzo, B. Pavoni
132	C-WG05S1P59	**Source Apportionment of PM2.5 at Burnaby South and Abbotsford, British Columbia, using Positive Matrix Factorization** R. So, R. Vingarzan, S. Meyn, E. Dabek-Zlotorzynska, D. Mathieu, L. Ding, T. Dann, V. Celo, D. Wang
133	C-WG05S1P60	**Application of Positive Matrix Factorization to particle size distribution data from a suburban site in South East Queensland, Australia** Mark Hallas, Adrian J. Friend, Godwin A. Ayoko
134	C-WG05S1P61	**Impact of the Traffic on the Air Particulate Matter from the Urban Area of Setúbal, Portugal** S.M. Almeida, Alexandra V. Silva, A.I. Pedro, A. Ferreira
135	C-WG05S1P62	**Contribution of Residential Wood Combustion to Ambient PM2.5 in a Suburb in Eastern Finland** T. Yli-Tuomi, T. Siponen, R.P. Taimisto, M. Aurela, K. Teinilä, A. Frey, R. Hillamo, J. Pekkanen, R.O. Salonen, T.

		Lanki
136	C-WG05S1P63	**Aerosol chemical characterization and source quantification in a semi-urban area of Indo-Gangetic plains** Hooda, Rakesh K, A.-P. Hyvärinen, S. Gilardoni , a, V.P. Sharma, E. Vignati, T.S. Panwar, b, Viisanen, Y. and H. Lihavainen
137	C-WG05S1P64	**Determination of the elemental composition and the source profiles of particulate matters in Bolu** E. Özlü and S. Yenisoy-Karakaş
138	C-WG05S1P65	**Characterization of PM2.5 in a residential area of Beijing, China** R.R. Shen, K. Schäfer, P. Suppan, N. Schleicher, U. Kramar, S. Norra, J. Schnelle-Kreis, L.Y. Shao, J. Wang, J. Y. Wang, K. Cen, Y.S. Wang, S. Schrader
139	C-WG05S1P66	**Anthropic and natural sources of PM10 in central Mediterranean Sea by bulk and size-segregated samples** S. Becagli, R. Traversi, M. Marconi, C. Ghedini, S. Nava, M. Chiari, F. Lucarelli, G. Calzolai, A. di Sarra, G. Pace, D. Meloni, C. Bommarito, D. M. Sferlazzo , R. Udisti
140	C-WG05S1P67	**The contribution of Rome-Ciampino airport to the surrounding air quality** A. Di Menno di Bucchianico, G. Cattani, A. Gaeta, A. Caricchia, F. Troiano, R. Sozzi, A. Bolignano, F. Sacco, S. Damizia, S. Barberini, R. Caleprico, T. Fabozzi, C. Ancona, L. Ancona, G. Cesaroni, F. Forastiere, G.P. Gobbi, F. Costabile, F. Angelini, F. Barnaba, M. Inglessis, F. Tancredi, L. Palumbo, L. Fontana, A. Bergamaschi, I. Iavicoli
141	C-WG05S1P68	**PM2.5 source apportionment in Milan by UNMIX receptor model** G. Lonati, C. Colombi and S. Cernuschi
142	C-WG05S1P69	**Source apportionment of ambient PM10-1 and PM1 in Granada** G. Titos, H. Lyamani, A.Alastuey, M. Pandolfi, J.A. Bravo-Aranda and L. Alados-Arboledas
143	C-WG05S1P70	**The effect of local wood combustion on fine particles in suburban small house areas in Helsinki Metropolitan Area, Finland** A. Kousa, J. Niemi, A. Svens, K. Teinilä, R. Hillamo and T. Koskentalo
144	C-WG05S1P71	**Overview of the impact of wood burning emissions on carbonaceous aerosols and PM in the Alpine region** H. Herich, M.F.D. Gianini, Ch. Piot, J. Cozic, J.L. Jaffrezo , J.L.

		Besombes, A.S.H. Prevot, and Ch. Hueglin
145	C-WG05S1P72	**Indoor-outdoor relationships of airborne particles and nitrogen dioxide inside Parisian buses** R. Molle, E. Géhin, S. Mazoué and A. Ionescu
146	C-WG05S1P73	**Fungal Bio-Aerosols Quantification - Comparison between q-PCR and Ergosterol Analysis** Naama Lang-Yona, Karen Dannemiller, Naomichi Yamamoto, Noa Burshtein, Jordan Peccia, Oded Yarden, Yinon Rudich
147	C-WG05S1P74	**Comprehensive evaluation of dust cleaning in a subway indoor** W. R. Kim, H. W. Park, Y. M. Jo
148	C-WG05S1P75	**Results from the second Netherlands Research Program on Particulate Matter (BOP II)** E. van der Swaluw, M. Keuken, E. Weijers, M. Schaap, G. Kos, J. Matthijsen, H. Denier van der Gon and R. Hoogerbrugge
149	C-WG09S1P01	**Single molecule water catalysis of atmospheric OH oxidation reactions** Theo Kurtén, Ditte Linde Thomsen, Solvejg Jørgensen, Signe Baggesen, Cecilie Aalling, Henrik Kjærgaard
150	C-WG09S1P02	**Intercomparison of dust prediction models in the framework of the WMO SDS-WAS programme** E. Terradellas, S. Basart, M. Schulz, J. M. Baldasano, J.-J.Morcrette, G. Pejanovic, L. Menut, A. Benedetti, O. Jorba, S. Nickovic and F. Benincasa
151	C-WG09S1P03	**Secondary organic aerosol formation during summer 2010 over Central Europe** B. Langmann, K. Sellegri and E. Freney
152	C-WG09S1P04	**Simulation and evaluation of ozone and its precursor gases over Indian region using the high resolution CHIMERE chemical transport model** Chinmay Jena, Sachin D. Ghude, G. Beig and D.M. Chate
153	C-WG09S1P05	**Climate change impacts on atmospheric gas and particulate mercury levels and deposition rates** A. G. Megaritis, B. N. Murphy, and S. N. Pandis
154	C-WG09S1P06	**Air Quality in Paris - A modeling study** A. G. Megaritis, K. Skyllakou, C. Fountoukis, and S. N. Pandis
155	C-WG09S1P07	**Development of a microphysical model for the H2SO4 - H2O clouds on Venus** A. Määttänen, S. Bekki, F. Montmessin, S. Lebonnois
156	C-WG09S1P08	**Evaluation of the Marco Polo Venice and the Treviso airports impact in two hot spots areas** E. Pecorari, G. Valotto, G. Rampazzo, S. Sollecito, D.

		Bassano, F. Bertoldo and E. Rampado
157	C-WG09S1P09	**Nucleation studies with regional aerosol-climate model REMO-HAM** J.-P. Pietikäinen, S. Mikkonen and A. Laaksonen
158	C-WG09S1P10	**Research Needs Identified In a First-Generation Regional Air Quality Model for Polycyclic Aromatic Hydrocarbons** E. Galarneau, P.A. Makar, Q. Zheng, J. Zhang, and M.D. Moran
159	C-WG09S1P11	**Modelling dust aerosol impacts on heating rate profiles over the Iberian Peninsula and Atlantic Ocean** D. Santos, M. J. Costa, R. Salgado and A. M. Silva
160	C-WG09S1P12	**Modelling PM2.5 chemical composition with CAMx in southwest Spain** C. Milford, N. Castell, C. Marrero, A. Sánchez de la Campa, R. Fernández-Camacho, S. Rodríguez, J. D. de la Rosa and A. F. Stein
161	C-WG09S1P13	**Simulation of mineral dust particle contribution to urban aerosol loading in Greater Beijing with the model system COSMO-ART** S. Schrader, B. Vogel, H. Vogel, K. Schäfer, R. R. Shen, P. Suppan, S. Norra
162	C-WG09S1P14	**Effects of modal representation of aerosol distribution on aerosol activation and optical properties** Korhola, T., Kokkola, H., Korhonen, H., Partanen, A.-I., Laaksonen, A. , Romakkaniemi, S.
163	C-WG09S1P15	**Aerosol observations and predictions in the southeastern Europe during the extreme summer 2007** E. Athanasopoulou, E. Gerasopoulos, H. Vogel, S. Kazadzis, E. Liakakou, M. Gratsea, and B. Vogel
164	C-WG09S1P16	**Application of a SOA parameterization for a-pinene and limonene photooxidation to different conditions** Manuel Santiago, Marta G. Vivanco and Ariel F. Stein
165	C-WG09S1P17	**PM modelling: old challenges and new possibilities** S. Tsyro, D. Simpson, H. Fagerli, W. Aas and M. Schulz
166	C-WG09S1P18	**Modelling the microphysics of Martian CO2 ice clouds** C. Listowski, A. Määttänen, F. Montmessin, F. Lefèvre
167	C-WG09S1P19	**Aerosol generation in atmosphere – data development and modelling**

		V.A. Zagaynov, D.V.Vodyanik, S.F. Timashev, A.A. Lushnikov, Yu.G. Biryukov, I.E. Agranovski, V.V. Maksimenko
168	C-WG09S1P20	**Evaluation of the hydrophobic SOA species estimated by the CHIMERE model considering experiments in a chamber** Marta G. Vivanco and Manuel Santiago
169	C-WG09S1P21	**Influence of Schmidt Number on dispersion modelling using CFD tools: Assessment of urban breathability for urban design and management** M. Tomé, C.A. Alves, R. Santos
170	C-WG09S1P22	**The influence of ion-induced nucleation on atmospheric aerosols based on data from the CERN CLOUD experiment** E.M. Dunne, K.S. Carslaw, J. Almeida,, and the CLOUD collaboration
171	C-WG09S1P23	**Numerical study of the effect of dilution process on the measurement of particle number emissions** Yan Wang, Bo Yang, Eric M. Lipsky, Allen L. Robinson, Topi Ronkko, Jorma Keskinen, K. Max Zhang
172	C-WG09S1P24	**Water bus emission factor model in Venice area** E. Pecorari, G. Rampazzo, A. Ferrari, G. Cuzzolin
173	C-WG09S1P25	**Verification of the NOx emission inventories over South Korea** Na Kyung Kim, Yong Pyo Kim, Yu Morino, Junichi Kurokawa, and Toshimasa Ohara
174	C-WG09S1P26	**Modelling the chemically speciated PM2.5 over the French Northern region using the WRF-Chem system coupled to EMEP and regional emission inventories.** Maxence Mendez, Vincent Crenn, Valérie Fèvre-Nollet, Patrick Lebègue, Denis Petitprez, Véronique Riffault, Nicolas Visez, Rafael Borge
175	C-WG09S1P27	**New method for estimating cigarette smoke emissions** Victoria Agranovski
176	C-WG09S1P28	**The contribution from natural sources to primary and secondary PM emissions over the metropolitan areas of Athens and Thessaloniki** V. Aleksandropoulou, Kjetil Torseth and M. Lazaridis
177	C-WG09S1P29	**Effect of the Lagrangian integral time scale estimation on particle deposition** G. Lecrivain, T. Barth and U. Hampel
178	C-WG09S1P30	**Sulphuric Acid Aerosols in Industrial Processes – Simulation, Estimation of Coagulation and CPC**

		measurement L. Brachert, S. Sinanis and K. Schaber
179	C-WG09S1P31	**Microscopic observation of aerosol particle deposition in turbulent channel flows** T. Barth, G. Lécrivain, J. Preuß and A. Lehmann
180	C-WG09S1P32	**Experimental and Numerical Investigation of Hygroscopic Aerosols Transport, Kinetics and Deposition in an Enclosure** M.A. Zatevakhin, A.A. Ignatiev, Y.N.Vashlyaev, A.A. Zaitsev, A.A. Lukyanov, A.S.Mikheev, D.V.Sumin, O.V.Supotnitskaya
181	C-WG09S1P33	**Mathematical study of inhalable fraction in low velocity conditions** A.K. Gilfanov, I.T. Mukhametzanov, S.K. Zaripov
182	C-WG09S1P34	**Transnational assessment of emerging health relevant air quality parameters (Joaquin)** S. Adriaenssens, F.Fierens, E.Trimpeneers, D.Celis, E. Van der Swaluw, R. Hoogerbrugge and K.V. Wyche
183	C-WG09S1P35	**Development of a workflow for integration of fresh slaughterhouse porcine lungs into an active lung simulation** K. Stiglbrunner, M. Forjan, Z. Bureš and A. Drauschke
184	C-WG09S1P36	**Ion-induced vs. base-induced sulfuric acid nucleation** O. Kupiainen, T. Olenius, I.K. Ortega, T. Kurtén, and H. Vehkamäki
185	C-WG09S1P37	**Parameterization for two-component H2SO4 - H2O nucleation applicable for very low relative humidities and correct at the one-component limit** A. Määttänen, J. Julin, I. K. Ortega and H. Vehkamäki
186	C-WG09S1P38	**First modelling study on new particle formation and growth in Southern African savannah environment** R. Gierens, L. Laakso, V. Vakkari, D. Mogensen, and M. Boy
187	C-WG09S1P39	**Comparing simulated and experimental molecular cluster distributions** T. Olenius, I.K. Ortega, O. Kupiainen, T. Kurtén, S. Schobesberger and H. Vehkamäki
188	C-WG09S1P40	**Simulation of Aerosol Nucleation Bursts: A Case St**udy J. Salm, A. Luts, U. Hõrrak, M. Vana and H. Tammet
189	C-WG09S1P41	**Efficient second-order time-integration for simulation of single-species aerosol dynamics** C. Winkelmann, M. Nordlund, A. Kuczaj, S. Stolz and B.J. Geurts
190	C-WG09S1P42	**To the theory of drop shattering in high-speed flows**

		A. G. Girin
191	C-WG09S1P43	**Particulate Fugitive Emissions in Harbours: characterization and emission factors estimation** A.V.Silva, S.M.Almeida, A.I. Miranda, F. Martín
192	C-WG09S1P44	**Simulation of aerosol growth in chamber conditions** M. Vesterinen, H. Kokkola, H. Korhonen, H. Keskinen and K.E.J. Lehtinen
193	C-WG09S1P45	**Oxidation of SO2 by O2−(H2O)n molecular clusters – a density functional theory study** N.T. Tsona, N. Bork and H. Vehkamaki
194	C-WG09S1P46	**Determining the particle diameter growth rate from the fraction of charged particles** J. Leppä, S. Gagné, L. Laakso, K. E. J. Lehtinen, M. Kulmala and V.-M. Kerminen
195	C-WG09S1P48	**Determining the proton affinity of atmospheric molecular ions** K. Ruusuvuori, T. Kurtén, I. K. Ortega and H. Vehkamäki
196	C-WG09S1P49	**Particle generation in electric arc: experiment and modelling** V.A. Zagaynov, E.V. Zhukova, A.A. Lushnikov, Yu.G. Biryukov, I.E. Agranovsky, V.V. Maksimenko
197	C-WG09S1P50	**Impact of horizontal grid resolution on predicting fine PM with a regional 3-D Chemical Transport Model** C. Fountoukis, A.G. Megaritis, D.S. Koraj, H.A.C. Denier van der Gon, P.E. Charalampidis, C. Pilinis, and S.N. Pandis
198	C-WG09S1P51	**Development of an observation-based box model to investigate secondary inorganic particle behaviors in the urban atmosphere** J. Xue, Z.B. Yuan, J.Z. Yu, A.K.H. Lau and T. Yao
199	C-WG09S1P52	**Simulation of Droplet Nucleation and Growth in a Laminar Counterflow via the Quadrature Method of Moments** A.O. Alshaarawi, K. Zhou and F. Bisetti
200	C-WG09S1P53	**Vertical wind as the dominating factor for spatial-temporal distribution of stratospheric aerosol** V.I. Gryazin and S.A. Beresnev
201	C-WG09S1P54	**Presents to the nearest neighbours: contribution of transboundary transport to the PM10 and PM2.5 concentrations in Central Europe with focus on NRW** H. Hebbinghaus, S. Wurzler, M. Memmesheimer, G. Piekorz, E. Friese, H. J. Jakobs, C. Kessler, A. Ebel
202	C-WG09S1P55	**Validation of ECHAM5-SALSA aerosol climate model against EARLINET lidar network**

		H. Niskanen, E.,Giannakaki, H. Korhonen, K. E. J. Lehtinen, T. Mielonen, A. Lindfors, M. Komppula, L. Alados-Alboledas, U. Wandinger, D. Balis, G. Pappalardo and H. Kokkola
203	C-WG09S1P57	**Numerical simulations of mixing conditions and aerosol dynamicsin the Cern CLOUD chamber** J. Voigtländer, J. Duplissy, L. Rondo, A. Kürten, F. Stratmann, and the CLOUD collaboration
204	C-WG09S1P58	**Experimental Studies on Tin Oxide Dry Aerosol Deposition in Piping assembly under Flow and High Thermal Gradient conditions: Comparison with SOPHAEROS code** Rajni Modi, Arshad Khan, Sunil Ganju, Manish Joshi, Pallavi Khandare, B. K. Sapra and Y. S. Mayya
205	C-WG09S1P59	**Evaluation of black carbon estimations by the regional aerosol-climate model REMO-HAM** A.I. Hienola, J.-P. Pietikäinen, A.-P. Hyvärinen, H. Lihavainen and A. Laaksonen
206	C-WG09S1P60	**Effects of vapor properties on modelled particle growth in the model UHMA** A. Rusanen1 and M. Boy
207	C-WG09S1P61	**Scanning Mobility Particle Sizer: Fast data Inversion and uncertainty analysis** L. Coquelin, N. Fischer, T. Mace, C. Motzkus, F. Gensdarmes, G. Fleury, L. Lebrusquet
208	C-WG09S1P62	**Novel informatics software for automated individual aerosol component property predictions and complex ensemble predictions – an online community facility** D. Topping, M. Bane, M. Barley, D. Lowe, R. Pinning and M. McFiggans
209	C-WG09S1P63	**Contributions of Traffic Emissions to the Ambient Aerosol in an Industrial Area** Sílvia M. Garcia, Gonçalo Domingues, Clara Santos, Carla Gomes, Alexandra V. Silva, S. Marta Almeida
210	C-WG09S1P64	**Evaluating the impact of flooring types on exposure to fine (PM2.5) and coarse (PM2.5 – 10) particles within the residential micro-environment** Lisa Bramwell, Jing Qian, Sumona Mondal, Andrea R. Ferro
225	C-WG10S1P01	**Dynamics of Spray Flames in Oscillating Flow with Droplet Grouping** D. Katoshevski and J. B. Greenberg
226	C-WG10S1P02	**Nonlinear oscillations and deposition of aerosol in tubes** D.A. Gubaidullin, R.G. Zaripov, A.L. Tukmakov and L.A.

		Tkachenko
227	C-WG10S1P03	**Dispersion and dissipation of weak waves in aerosols** Gubaidullin Damir, Nikiforov Anatoly, Teregulova Eugenia and Fedorov Yury
228	C-WG10S1P04	**Gravito-photophoresis of aerosols: the insufficiency of "accommodation" forces action** M.S. Vasiljeva and S.A. Beresnev
229	C-WG10S1P05	**The Polydispersity of Primary Particles in Aggregates undergoing Sintering** M.L. Eggersdorfer and S.E. Pratsinis
230	C-WG10S1P06	**Temperature and particle vertical profiles: suitability of the ML concept under weak cyclonic conditions** J. Giménez, J.F. Nicolás, C.Pastor, R.Castañer, E. Yubero, M.J. Cuesta-Bolao, J. Crespo and S. Caballero
231	C-WG10S1P07	**Two-phase polydisperse spray in a wake of shattering drop** A. G. Girin
232	C-WG10S1P08	**Ab initio molecular dynamics study of sulfuric acid clusters with ammonia/dimethylamine** V. Loukonen, I-F. W. Kuo, M. J. McGrath and H. Vehkamäki
233	C-WG10S1P09	**A turbulent model for the study of dust mobilisation in closed enclosures** J.R. García-Cascales, F.J. Sánchez-Velasco, R. Otón-Martínez and F. Vera-García, A. Bentaib, N. Maynet
234	C-WG10S1P10	**Microgravity experiments on particle motion in the region of negative thermophoresis** A.A. Vedernikov, S.A. Beresnev and A.V. Markovich
235	C-WG10S1P11	**High order operator splitting adaptive time marching Monte Carlo for aerosol dynamics** Kun Zhou and Fabrizio Bisetti
236	C-WG10S1P12	**Modeling of the behavior of droplets deposited on the smooth and rough fiber surfaces** J.M. Gac and L. Gradoń
237	C-WG10S1P13	**Parameters affecting deposition on fibrous filters** Sarah J. Dunnett, Charles F. Clement
238	C-WG10S1P14	**Application of filter utility factor in the filtration of dust and liquid aerosol** T. Jankowski
239	C-WG10S1P15	**Simultaneous removal characteristics of particulate and nitrogen oxides by the SCR catalyst packed high temperature pleated filter bags** Y.O. Park, N.Hasolli
240	C-WG10S1P16	**Dust Cake Cleaning Characteristics of PPS Pleated**

		Bags with Double Venturi and Standard Venturi Y.O. Park, N. Hasolli
241	C-WG10S1P17	**Filtration of airborne carbon nanotubes with nanofiber filters** Y.K. Bahk and J. Wang
242	C-WG10S1P18	**Cellulose nanofibrils filters for environmental applications** L. Alexandrescu, K. Syverud, F.Belosi, G.Santachiara, F. Prodi, A. Donateo
243	C-WG10S1P19	**Aerosol retention in the secondary side of a tube bundle: Insights into a key scenario for nuclear safety** R.D. Tardáguila, C. Lopez, L.E. Herranz, M. García
244	C-WG10S1P20	**Deposition efficiency of charged aerosol particles in cylinder array** T.S. Zaripov, A.G. Egorov
245	C-WG10S1P21	**Inertial deposition of aerosol particles on a porous cylinder** O.V. Grigorieva, S.K. Zaripov
246	C-WG10S1P22	**Soot Nanoparticle Aggregate Filtration in Layer-Coated Diesel Particulate Filters** N. D. Vlachos, A.G. Konstandopoulos
247	C-WG10S1P23	**Experimental study on small cyclones for combustion engine gas cleaning** B. Sagot and J. Giardi
248	C-WG10S1P24	**The calculating method of resuspension based on the combination deterministic and statistical approaches** D.V.Tsaplin and V.N. Piskunov
249	C-WG10S1P25	**Analysis of asymptotic behavior of disperse systems with particle coagulation and breakage** V.N.Piskunov
250	C-WG10S1P26	**Analytical tests for simultaneous coagulation and condensation of composite particles** V.N.Piskunov
251	C-WG10S1P27	**Collapsing self-similarity in systems with coagulation and fragmentation of particles** V.N.Piskunov, I.V.Piskunova
252	C-WG10S1P28	**Thermophoretically Modified Brownian Coagulation** M. Arias-Zugasti and D. E. Rosner
253	C-WG10S1P29	**Calculation of the mobility radius of fractals in the continuum regime from their geometry**

		A.D. Melas, A.G. Konstandopoulos, L. Isella and Y. Drossinos
254	C-WG10S1P30	**Virtual generation of realistic soot particles: Impact to their morphological and optical properties.** A.Bescond, J.Yon, C. Rozé, F. X. Ouf
255	C-WG10S1P31	**3D study of fractal combustion aerosols using Electron Tomography** D. Lottin, D. Ferry, D. Delhaye, F.-X. Ouf and J. Yon
256	C-WG10S1P32	**Impaction dynamics of TiO2 agglomerates with different properties** M. Ihalainen, T. Lind, T. Torvela, K.E.J. Lehtinen and J. Jokiniemi
257	C-WG10S1P33	**Study of fluorescent imaging quantitative evaluation in protective equipment validation** S. Yang, C.H. Luo, M.Y. Syu, C.Y. Wen, K.H. Lin, S.H. Chiu and C.P. Chang
258	C-WG10S1P34	**Vibrational Spectroscopy of the Atmospherically Relevant Ions $A^-(H2SO4)m(HNO3)n(H2O)o$ with A^- = $HSO4^-$, $NO3^-$** N. Heine, T.I. Yacovitch, C. Hock, D.M. Neumark, C. Brieger, T. Wende, G. Meijer and K.R. Asmis
259	C-WG10S1P35	**Microhydration of Conjugate Base Anions Probed by Gas Phase Vibrational Spectroscopy** K.R. Asmis, N. Heine, T. Wende, L. Jiang, G. Meijer, T.I. Yacovitch, D.M. Neumark
260	C-WG10S1P36	**Heat effects at self-similar regime of droplet diffusion growth and the vapor-gas outflow** A.E. Kuchma and A.K. Shchekin
261	C-WG10S1P37	**High temperature oxidation of tungsten particles with account of Stefan flow** S.G. Orlovskaya, M.S. Shkoropado and F.F. Karimova
262	C-WG10S1P38	**Heat and mass transfer and thermal decomposition of firm aerosols when laser radiation action** L.I. Ryabchuk and S.K.Protas
263	C-WG10S1P39	**Flow and Heat Transfer in a Particle Laden Differentially Heated Cavity** J. Kalilainen, P. Rantanen, T. Lind, A. Auvinen, A. Dehbi, S. Güntay and J. Jokiniemi
264	C-WG10S1P40	**Modelling of spray drying of multicomponent aerosols** J.M. Gac and L. Gradoń
265	C-WG10S1P41	**The effect of droplet size on the evaporation and mass accommodation processes of water: a**

		molecular dynamics study Jan Julin and Ilona Riipinen
266	C-WG10S1P42	**Design of a simulation facility for workplace relevant aerosols of semi-volatile organic hydrocarbons: Set-up and first results** G.C. Dragan, E. Karg, H. Nordsieck, J. Schnelle-Kreis and R. Zimmermann
267	C-WG10S1P43	**Measurement of neutral sulphuric acid dimer concentration during CLOUD** A. Kürten, L. Rondo, S. Ehrhart, J. Curtius and the CLOUD collaboration
268	C-WG10S1P44	**Nucleation and condensation on presence of aerosols in boundary-layer flows** L.L. Bonilla and M.D. Camejo
269	C-WG10S1P45	**Particle nucleation in urban subtropical atmosphere** F. Salimi, L. Morawska, Z. Ristovski and M. Mazaheri
270	C-WG10S1P46	**Growth of sulfuric acid nano-particles at dry and wet conditions** L. Škrabalová, D. Brus, V. Ždímal and H. Lihavainen
271	C-WG10S1P47	**Using A09 Particle Size Magnifier for resolving formation and growth rates below 2 nm** K. Lehtipalo, A. Franchin, T. Nieminen, S. Schobesberger, J. Kangasluoma, J. Mikkilä, J. Vanhanen, T. Petäjä, and M. Kulmala
272	C-WG10S1P48	**Two amine campaigns; H2SO4 detection with different methods** K. Neitola, D Brus, U. Makkonen and H. Lihavainen
273	C-WG10S1P49	**Investigation of proton behaviour in water-sulphuric acid clusters using Path Integral Molecular Dynamics** J.L. Stinson, I.J. Ford, S.M. Kathmann and A. Michaelides
274	C-WG10S1P50	**Absorbing aerosols at high relative humidity: closure between hygroscopic growth and optical properties** J. Michel Flores, R. Z. Bar-Or, N. Bluvshtein, A. Abo-Riziq, A. Kostinski, S. Borrmann, I. Koren, and Y. Rudich
275	C-WG10S1P51	**Detecting correlations between the morphological parameters of multi-fractal samples of fractal-like aggregates** M. Woźniak, F.R.A. Onofri, S. Barbosa, J. Yon, C. Caumont, J. Mroczka
276	C-WG11S1P01	**Electrostatic and diffusion loss of charged nanoparticles in cylindrical tube connections with electric potential difference** D.K. Song, W.S. Hong and W.H. Shin
277	C-WG11S1P02	**Charge control of particles in air using centrifugal**

		force acting under applied electric field S. Matsusaka and K. Satoh
278	C-WG11S1P03	**Data inversion and calibration of a particle number concentration monitor** L. Hillemann, A. Zschoppe
279	C-WG11S1P04	**Structured chain-like aggregates by coagulation of charged particles** L. Knobel and H.-J. Schmid
280	C-WG11S1P05	**Influence on the bipolar stationary charge distribution** L. Knobel, A. Jain and H.-J. Schmid
281	C-WG11S1P06	**Break-up of charged ionic salt solution droplets at super-Rayleigh limits** Asit Ray and Kuo-Yen Li
282	C-WG11S1P07	**Performance of 85Kr, Soft X-ray and AC Corona Charging Sources for Particles <20 nm** J.J. Swanson, A.M. Boies, A. Collins
283	C-WG11S1P08	**Characterization of charging effects on different particles and discharge electrodes** Wen-Yinn Lin, Yuan-Yi Chang, Jin-Yuan Syu, Shao-Hao Lu, Chih-Chieh Chen
284	C-WG11S1P09	**Selective electrostatic deposition of airborne engineered nanoparticles on a patterned substrate of silicon cantilever sensor** H. S. Wasisto, S. Merzsch , A. Waag, E. Uhde, I. Kirsch and E. Peiner
285	C-WG11S1P10	**Post-corona diffusion charging versus radial ion profile in axisymmetric arrangement** Jidenko Nicolas, Alonso Manuel and Borra Jean-Pascal
286	C-WG11S1P11	**Sub-second diffusion charging** N. Jidenko, D. Maro, F. Gensdarmes, D. Boulaud and J.-P. Borra
287	C-WG11S1P12	**Atmospheric small-ion mobility downwind and upwind of AC high-voltage power lines** M.D. Wright, A.J. Buckley, J.C. Matthews and D.L. Henshaw
288	C-WG11S1P13	**Charging and collection of fine mists from a wet scrubber using activated oxidation catalysts** Bangwoo Han, Hak-Joon Kim and Yong-Jin Kim
289	C-WG11S1P14	**Removal performance of an electrostatic precipitator with edge to plate geometry for particulates in combustion gases for marines** H.J. Kim, B. Han, G.B. Cho and Y.J. Kim
290	C-WG11S1P15	**Enhancement of the filtration performance of metallic foam filter for diesel particulates by**

		electrostatic charging and collection H.J. Kim, B. Han, G.B. Cho and Y.J. Kim
291	C-WG11S1P16	**Numerical simulations of electrosprays including induced gas flow** A.K. Arumugham, J. Grifoll and J. Rosell-Llompart
292	C-WG10S1P52	**Hybrid QMOM-Orthogonal-Collocation Method: Application to Aerosol Dynamics under Coagulation** M. Arias-Zugasti

Friday 7th September

08:45-09:45 Plenary 5. **Helmuth Horvath**
Photophoresis – the forgotten force
Room: Auditorio
Chair: F.J. Olmo

09:45-10:00 Best Poster Awards

10:00-10:30 Coffee-break

10:30-12:50 **Session WG01S7O. Aerosol Cloud Interaction**
Room: Auditorio
Chairs: M. Gysel / Z. Kanji

10:30	WG01S7O01	**Combustion Aerosol over Marine Stratus: Long Range Transport, Subsidence and Aerosol-Cloud Interactions over the SE Pacific** A. D Clarke, J. Kazil, G. Feingold, S. Freitag, C. McNaughton, J. Snider, T. Lynn Campos, V. Breckhovskikh
10:50	WG01S7O02	**Aerosol cloud interactions of trade wind cumuli - A single cloud contact analysis** F. Ditas, B. Wehner, H. Siebert, R.A. Shaw, H. Wex, T. Schmeißner, G. Roberts, A. Wiedensohler
11:10	WG01S7O03	**Aerosol optical properties before, during, and after cloud events at Puijo** A. Leskinen, A. Arola, H. Portin, S. Romakkaniemi, A.-P. Hyvärinen, A. Laaksonen, K.E.J. Lehtinen and M. Komppula
11:30	WG01S7O04	**Mixing state resolved hygroscopicity closure between sub- and supersaturation in Paris** Zs. Jurányi, M. Gysel, T. Tritscher, E. Weingartner, M. Laborde and U. Baltensperger
11:50	WG01S7O05	**Immersion freezing of biological particles** S. Hartmann, T. Š. Temkiv, B. G. Pummer, S. Augustin, T. Clauss, D. Niedermeier, H. Wex, J. Voigtländer, U. G. Karlson, H. Grothe and F. Stratmann
12:10	WG01S7O06	**Ice formation via deposition mode nucleation on hydrophobic and hydrophilic surfaces** J.B.C. Pettersson, X. Kong, E.S. Thomson, and N. Markovic´

12:30	WG01S7O07	**Cloud particle detection at the AIDA chamber & over the UK and Northern Canada** M. Krämer, J. Meyer, A. Afchine M. Schnaiter O. Möhler S. Benz A. Abdelmonem, M. Gallagher, J. Dorsey, P. Brown, A. Wooley, C. Schmitt, R. Newton and D. Baumgardner
Reserve paper	WG01S7B00	**Inhibition of Heterogeneous Ice Nucleation of Mineral Dust Particles Exposed to Ozone** Z.A. Kanji, A. Welti, C. Chou, and O. Stetzer

10:30-12:50 **Session SS03S1O. Source apportionment**
Room: Legado Andalusí
Chairs: A. Prevot / X. Querol

10:30	SS03S1O01	**Towards a European Common Protocol for Receptor Modelling** C.A. Belis, F. Karagulian, B. R. Larsen, F. Amato, O. Favez, I. El Haddad, R.M. Harrison, A. Prevot, U. Quass, R. Vecchi, M. Viana, P. Paatero, P.K. Hopke
10:50	SS03S1O02	**Application of PMF to the Source Apportionment of Polycyclic Aromatic Hydrocarbons** Roy M. Harrison, Eunhwa Jang and Mohamed S. Alam
11:10	SS03S1O03	**Comparing source apportionment results by a chemistry transport model against PMF analyses for north western Europe** M. Schaap, C. Hendriks, R. Kranenburg, T.A.J. Kuhlbusch, U. Quass and J. Vercauteren
11:30	SS03S1O04	**Multilinear engine 2 applied to long-term on-line data of non-refractory submicron aerosol in the city of Zurich** F. Canonaco, J. Slowik, U. Baltensperger, A.S.H. Prévôt
11:50	SS03S1O05	**Aging fingerprints on the carbon functional groups in 2-stroke scooter exhaust particles with STXM/NEXAFS** E. Coz, S. Platt, I. El Haddad, J. G. Slowik, A. S. H. Prévôt, S. Steimer, G. Grzinic, M. Lampimäki, B. Artíñano and M. Ammann
12:10	SS03S1O06	**Considering the different thermal behaviour of wood-burning and diesel emissions for 14C-based source apportionment of elemental carbon** S. Szidat, Y.L. Zhang, G. Ciobanu, P. Zotter, N. Perron, M.C. Minguillón, L. Wacker, U. Baltensperger, and A.S.H. Prévôt

12:30	SS03S1O07	**Safe PMF: Minimizing the Impact of Erroneous Data in Source Apportionment** P. Paatero and P.K. Hopke
Reserve paper	SS03S1B00	**PMF vs CMB for source apportionment of PM: advantages, limitations, complementarity of the two models explored by applications at different types of environments** C. Piot, M.F.D. Gianini, J. Cozic, L. Polo, J.-L. Besombes, J.-L. Jaffrezo and C. Hueglin

10:30-12:50 **Session SS04S1O. Chemical characterization of combustion aerosols**
Room: Faraday
Chairs: R. Niessner / F. Ouf

10:30	SS04S1O01	**Soot Aerosol – Hard nuts to crack for an analyst** R. Niessner
11:10	SS04S1O02	**Organic emissions from modern small scale wood combustion appliances – Chemical characterization and toxic potential of fine particular matter** J. Orasche, J. Schnelle-Kreis, G. Abbaszade, H. Hartmann,H. Ruppert, R. Zimmermann
11:30	SS04S1O03	**On-line characterization of aerosols from transient biomass combustion** E. Z. Nordin, A. C. Eriksson, R. Nyström, E. Pettersson, J. Rissler, E. Swietlicki, M. Bohgard, C. Boman and J. Pagels
11:50	SS04S1O04	**Impact of iron content on structure and thermo-chemical characteristics of multicomponet soot aerosol** H. Bladt, J. Schmid, E. Kireeva, O. B. Popovicheva, N. P. Ivleva and R. Niessner
12:10	SS04S1O05	**Black carbon sources characterized using the soot-particle aerosol mass spectrometer (SP-AMS)** J.C. Corbin, A. A. Mensah, M. Gysel, M. Laborde, A. Keller, J. Kim, A. Petzold, and B. Sierau
12:30	SS04S1O06	**Chemical and physical characterization of combustion aerosols** J. Jokiniemi

Reserve paper	SS04S1B00	**Detailed chemical characterization of ultrafine particles from vehicle exhaust** F. Donaz, L. Polo, C. Piot, J. Cozic, B. Golly, N. Marchand, J.L. Besombes and J.L. Jaffrezo

10:30-12:50 **Session WG11S1O. Electrical effects**
Room: Cine 3
Chairs: A. Bologa / C. Yurteri

10:30	WG11S1O01	**Indirect Photoelectric Diffusion Charging of Aerosols** B. Grob and R. Niessner
10:50	WG11S1O02	**High resolution mobility and mass spectra of corona-generated ions** H.E. Manninen, A. Franchin, E. Järvinen, J. Kangasluoma, S. Schobesberger, T. Petäjä and M. Kulmala
11:10	WG11S1O03	**Study of the corona discharge in the syngas at various gas temperatures and pressure** A. Bologa, H.-R. Paur, H. Seifert and K. Woletz
11:30	WG11S1O04	**Stability of the cone-jet mode in electrohydrodynamic spraying** J.L. Castillo, S. Martin, A. Perea and P.L. Garcia-Ybarra
11:50	WG11S1O05	**Electrospray deposition of nanoparticles onto airborn microparticles** C.U. Yurteri, N. Ellis, J.R. van Ommen
12:10	WG11S1O06	**Determination of the Transition Regime Collision Rate in the Presence of Potential Interactions from Mean First Passage Time Calculations** C. J. Hogan Jr., R. Gopalakrishnan, H. Ouyang
12:30	WG11S1O07	**Charge Distribution of Primary Nanoparticles Generated by Spark Discharge** K.Barmpounis, T.V. Pfeiffer,G. Biskos, A. Schmidt-Ott
Reserve paper	WG11S1B00	**Selective electrostatic deposition of airborne engineered nanoparticles on a patterned substrate of silicon cantilever sensor** H. S. Wasisto, S. Merzsch , A. Waag, E. Uhde, I. Kirsch and E. Peiner

10:30-12:50 **Session SS05S1O. Field observations and modeling of special events**
Room: Gutenberg
Chairs: M. Krämer / S. Wurzler

10:30	SS05S1O01	**Physico-chemical properties of airborne radiocesium released from the Fukushima nuclear accident** N. Kaneyasu, H. Ohashi, F. Suzuki, and T. Okuda
10:50	SS05S1O02	**Environmental Impact of Fukushima Fallout in Southeast Spain** F. Piñero-García, J. Drożdżak and M.A. Ferro-García
11:10	SS05S1O03	**Atmospheric dispersion and ground deposition induced by the Fukushima Nuclear Power Plant accident at local scale: simulation and sensitivity study** I. Korsakissok, A. Mathieu and D. Didier
11:30	SS05S1O04	**Observations in Germany, France, and Great Britain during eruptions of the Eyjafjallajökull volcano in 2010** S. Wurzler, P. Bruckmann, J. Friesel, J. Geiger, H. Hebbinghaus, W. Sponsors and Exhibitors

Airmodus Ltd

Gustaf Hällströmin katu 2 A
00560 Helsinki
Finland

Tel: +358 44 3038 378
E-mail: info@airmodus.com
HYPERLINK "http://www.airmodus.com" www.airmodus.com

Airmodus is a group of aerosol physicists specialized in aerosol particle measurement technology, having long experience both in laboratory and field experiments. The company is based in Helsinki and as a spin-off company from the University of Helsinki it has straight contact to the leading research in the field of aerosol physics. We specialize in providing tools for measuring the smallest sub - 2 nm aerosol particles.

Airmodus offers Particle Size Magnifiers that allow you to detect particles as small as 1 nm in diameter; easy to use Condensation Particle Counters with a cut-off size fit for your measurement needs; and special mass spectrometer inlets for detection of challenging gaseous compounds (e.g. sulfuric acid, ammonia, amines).

Alava Ingenieros Group has been providing high technology solutions in the Testing, Measurement, Communications Security, Defence and Preventive Maintenance fields since it was first founded in 1973. The group offers consultancy, engineering, distribution, training and technical services, providing turn-key projects for several sectors including Research Centres, Universities Aerospace, Automotive, Security, Defence, Communications and Finance, as well as Testing, Public Services and Industry in general.

Alava Ingenieros Group, as technological partner of TSI in Spain and Portugal, bring you the possibility to know the new solutions launched by TSI, which are described in the previous lines. Besides, Alava Ingenieros Group launches new solutions from other technological partners, such as Unitec and Sigma Space, for the following applications:

- Long term measurements of vertical aerosol distribution
- Tracking of volcano ash and aerosols
- Observation of multiple cloud layers
- Air quality monitoring

We look forward to seeing you at our booth No 11-13

Cambustion Ltd

J6 The Paddocks
347 Cherry Hinton Road
Cambridge CB1 8DH
United Kingdom

Tel: +44 1223 210250
Email: cambustion@cambustion.com
www.cambustion.com

Cambustion instrumentation is already used in over 25 countries for both academic research and commercial R&D, with local representation in China, France, India, Japan and North America.

The new Centrifugal Particle Mass Analyzer (CPMA) allows classification of ultrafine aerosol according to mass: charge ratio. With a touch screen interface plus analog and digital connectivity to other aerosol instruments (e.g. CPCs) the CPMA facilitates a wide range of aerosol studies.

Our DMS series instruments offer the fastest (from 200 ms $T_{10\text{-}90\%}$ at 10 Hz) real-time electrical mobility size/number spectra available from 5nm – 2.5µm, with unrivalled sensitivity. Applications include ambient monitoring, combustion aerosol, workplace exposure and engineered nanoparticle research.

With fully integrated sampling and dilution options, DMS series instruments can be used for both ambient applications and straightforward direct sampling of high concentration aerosol sources through software selection of appropriate dilution.

www.certio.com

Certio Environmental is the result of the implementation of a process of concentration of environmental sector companies working under internatio-nally recognized quality systems

Improving Sustainable Development

Certio Environmental was created with the aim of providing improved services in sustainable development through the provision of inspection, testing, inspection and maintenance of systems that ensure the environmental quality

Specialization

The main objective is to bring specialized services in four business lines: Air, Water, Soil and Noise.
In Air business line our specialization is:

- ✓ Environmental control networks for measuring the air quality in emission and inmission levels: remote stations, data transmission systems, processing data centers and presentation of the information for the intended audience
- ✓ Maintenance of Control Air Quality Networks
- ✓ Supply, start up, reparation and maintenance of Air quality analyzers (O3, CO, SO2, NOx, BTX, PM10, PM2,5….)
- ✓ ENAC Accreditation Calibration Lab. according UNE-EN ISO/IEC 17025
- ✓ ENAC Accreditation Inspection Activities in Environmental Area, according UNE-EN ISO/IEC 17020
- ✓ CEMs
- ✓ Meteorological measurement systems

Customer proximity

Deep knowledge of the needs of our clients allows us to detect, analyze and evaluate problems, offer solutions and streamline processes. Solutions based on new technologies to add value in Environmental Control Systems and Industrial Automation Systems. Marketing teams of environmental pollution control and automatic measure, from leading international manufacturers

Copley Scientific Limited

Colwick Quays Business Park
Private Road No. 2
Colwick
Nottingham NG4 2JY
United Kingdom

Tel: +44 (0)115 961 6229
E-mail: sales@copleyscientific.co.uk
www.copleyscientific.com

Copley Scientific is a major supplier of air sampling and aerosol characterisation equipment for academic research and industrial applications. In the pharmaceutical industry, the company is also recognised as the world's leading manufacturer and supplier of inhaler test equipment and is a major provider of testing systems for other pharmaceutical dosage forms.

Having offices in the UK and Switzerland, Copley Scientific works in partnership with US based aerosol particle science experts MSP Corporation, whose air sampling and aerosol characterisation products the company distributes throughout Europe. Such products include the market leading range of MOUDI cascade impactors, the real-time fibre monitor model 7400AD, the Water-based Condensation Particle Counter (CPC) and the wide-range particle spectrometer (WPS) with electrical ionizer, covering the particle size range: 5 nm to 10 microns.

Dekati Ltd.
Osuusmyllynkatu 13
33700 Tampere
Finland

Tel: +358 3357 8100
E-mail: sales@dekati.fi
www.dekati.com

Dekati Ltd. develops, manufactures and markets instrumentation needed in fine particle measurement and sampling. In 1995, Dekati introduced the world's first real-time fine particle concentration and size distribution measurement instrument. Since then, our R&D department has continually increased the range of products. Through the extensive global sales network, we are able to serve our customers around the world.

Dekati develops new products in close co-operation with the world's leading universities and companies. Our mission is to provide our customers with innovative fine particle measurement solutions that guarantee accurate results.

Dekati instruments are used for example in the following application areas:

- Combustion Processes (Diesel, Gasoline, Oil, Coal, Bio-fuels etc.)
- Environmental Ambient Aerosol Research and Monitoring
- Pharmaceutical Drug Screening and Inhalator R&D
- Nanotechnology
- Material Processing

Visit www.dekati.com for more details on our company and our products, or contact us at sales@dekati.fi for further information.

Droplet Measurement Technologies

2545 Central Avenue
Boulder
Colorado, 80301
United States

Tel: +1 303-440-5576
E-mail: info@dropletmeasurement.com
www.dropletmeasurement.com

Droplet Measurement Technologies offers accurate and sensitive instruments for real-time measurement of aerosol particle physical, optical, chemical and biogenic properties. The Ultra-High Sensitivity Aerosol Spectrometer (UHSAS) measures particle size from 60 nm to 1000 nm, the new Photoacoustic Extinctiometer (PAX) and Photoacoustic Soot Spectrometer (PASS) measure particulate light absorption and scattering at different wavelengths, producing BC mass and climate-relevant properties like single scattering albedo (SSA) from a single instrument. The Single Particle Soot Photometer (SP2) measures incandescence from BC-containing particles providing BC mass (independent of mixing state), number concentration and size distribution. Both techniques measure particles in-situ, eliminating filter artifacts. The CCN-100 and Single Particle Ice Nucleus (SPIN) spectrometer measure the concentrations of CCN and IN and the Waveband. Integrated Bioaerosol Sensor WIBS-4 measures the size spectra of primary biological aerosol particles (PBAP).

DMT's extensive line of electro-optical particle analyzers are used by scientists worldwide for airborne and ground-based measurement applications in atmospheric and climate research, air quality monitoring, meteorology, aircraft certification, spray characterization, weather modification and cloud seeding,. In addition to black carbon, DMT instruments characterize aerosols, dust, volcano ash, sprays, cloud droplets, ice crystals, fog and precipitation, and cloud condensation nuclei.

For more information, please visit us in the exhibition hall, call +1 303-440-5576, visit our website www.dropletmeasurement.com, or email info@dropletmeasurement.

Ecotech Pty Ltd

1492 Ferntree Gully Road
Knoxfield
Victoria 3180
Australia

Tel: +61 3 9730 7800
E-mail: info@ecotech.com
www.ecotech.com

With our expanding range of scientific research instrumentation and sophisticated data collection, validation and reporting software, Ecotech provides solutions that ensure air quality and climate data are accessible to everyone without compromising on quality and reliability.

Our Aurora integrating nephelometers range from single to multiple wavelength versions and incorporate both polar and particle correlating options. Using an innovative LED light source, the Aurora 3000 nephelometer simultaneously measures at 525nm (green), 450nm (blue) and 635nm (red) to enable wide and in-depth analysis of particulate matter.

Complimenting this range and also working with other manufacturer's aerosol instruments, is our sample conditioning system. Allowing the simultaneous measure of two parallel aerosol instruments in real time, this system gives scientists the ability to analyse the difference in humidity on the same sample.

With more than 35 years designing and supplying air quality instrumentation Ecotech is regarded as one of the world's leading suppliers in air monitoring. Our commitment to R&D ensures that we stay at the forefront of innovation.

GRAW Radiosondes GmbH & Co. KG

Muggenhofer Str. 95
90429 Nuremberg
Germany
Tel.: +49 911 3201 100
Fax: +49 911 3201 150
E-mail: info@graw.de
Website: www.graw.de

GRAW is a well-established company developing and manufacturing Upper Air Sounding Systems since 1938. GRAW's customers are academic research and meteorological institutions worldwide.

Our product portfolio includes:

- Radiosondes
- Ground stations
- Visualization and evaluation software for meteorological data
- Antenna systems
- Accessories for balloon ascents
- Complete Upper Air Sounding Systems

As a 100% daughter of the family-owned NORIS Group, GRAW has access to more than 200 professionals worldwide but still benefits from the flexibility and fast decisions of a family owned business.

Have we piqued your interest? Please visit our website to see our complete range of products or call us.

GRIMM Aerosol Technik GmbH & Co. KG
Achim Edfelder
Dorfstrasse 9
83404 Ainring
Germany

Tel: +49 (0) 8654 578-33
E-mail: ae@Grimm-Aerosol.com

www.grimm-aerosol.com

GRIMM Aerosol Technik GmbH & Co.KG was founded over 25 years ago by Dr.-Ing. Hans-Jurgen Grimm in Bavaria/Germany. Today, GRIMM Aerosol Technik is one of the worldwide leading companies in the field of high-tech aerosol measurement instrumentation due to its innovations and quality manufacturing.

GRIMM Aerosol Technik offers a wide range of complete solutions for the continuous measurement of fine and ultrafine aerosols.

Instruments such as Environmental Dust Monitors, Aerosol Spectrometers, Particle Counters and Sizers, Filter Testers, and Aerosol Generators consistently meet the requirements of a world-wide increasing number of customers in research and industry. Specialists in-house will advise about the correct instruments for particular applications, e.g. for ambient air, emission, occupational health, filter efficiency and / or exhaust gas measurements, for quality control and for pharmaceutical, atmospheric or epidemiological studies.

Recently expanded production facilities are located in Pouch/Saxony-Anhalt/Germany. World-wide first-class customer service is offered through our U.S. subsidiary and our offices in Canada, UK, Middle East and Asia, and supplemented by a close network of international representatives.

INGENIEROS ASESORES, S.A.

www.ingenierosasesores.com

Ingenieros Asesores, S.A. was established in 1985 and its only mission is satisfying companies' demand of environmental services, encompassing all type of solutions, from the design of environmental strategies, to the measurements of pollutant parameters.
Our strategy has focused on offering these solutions on a technological base. The services that we offer differ from others due to our exclusive specialization in environment and our advanced technological proposals.

Automatic Systems Department for Environmental Control:

The environmental legislation increasingly requires automatic control of pollutant parameters, both air and water.
Ingenieros Asesores S.A., specializes in all aspects of environmental control, having developed a set of action items that allow you to meet any demand in this field, from the simplest sensor to the comprehensive control system more sophisticated, addressing the following activities:

- Air pollution monitoring networks
- Emissions measurement systems
- Mobile laboratories
- Communication Systems
- Public Information
- Calibration and audit

Our company is certified under ISO 9001 for supply, installation, maintenance and calibration of instruments and systems for continuous monitoring of air pollution and water.

RAMEM-IONER® is a Spanish company dedicated to the development of innovative aerosol instruments. RAMEM-IONER will be introducing at EAC 2012 in Granada its HRIMS (High Resolution Ion Mobility Spectrometer), an instrument based in a planar, high resolution DMA for the study of the early stages of nucleation.

Visit us at booth number 4.

Magee Scientific is the originator of the Aethalometer®, the most-widely-used instrument for the real-time measurement of Black Carbon aerosol particles in the atmosphere. These particles reduce visibility; adversely impact human health; and contribute to regional and global climate change. Aethalometers are installed on all continents: from cities in China to the South Pole, from the Sahara Desert to the Amazon basin.

Research into methods for the real-time measurement of light absorbing aerosols began in Berkeley in approximately 1978. The first-ever Aethalometer® was deployed in a field study in the summer of 1980: the first aircraft measurements were made in 1982, and in 1986 an Aethalometer started making measurements of aerosol Black Carbon at the most remote location on the planet, the South Pole Observatory. Magee Scientific Company was established that same year to develop the Aethalometer further and make it available to the aerosol research and monitoring community. From 1999 to 2001, the instruments were also distributed by Andersen Instruments Inc. and subsequently Thermo Environmental Instruments as identical hardware, but with the chassis painted in 'Andersen' or 'Thermo' colors and name. Distribution by Andersen/Thermo has now been discontinued.

Aethalometers have been used in increasing numbers over the years: a large number of reports have been published in the open scientific literature. A compendium of these reports is found at the literature link.

www.matter-aerosol.ch

Matter Aerosol (formally Matter engineering) specialises in the measurement and characterisation of nanoparticles from combustion processes and nanoparticles in ambient air. Matter Aerosol combines over 50 years of experience in instrument design and development with latest research results about nanoparticles, for application in laboratories to real-world problems.

Key Competencies:

- Equipment - design, development and production of equipment to sample, dilute, measure and characterise nanoparticles from combustion and ambient air.

- Services - nanoparticle emission measuring and testing programs for combustion engines, boilers, particle traps, fuels and additives at our partners' test benches or at the customer's site.

- Transfer - conferences and seminars on nanoparticle measurement.

Metrohm Applikon, headquartered in Schiedam, the Netherlands has more than 35 years' experience in delivering solutions for laboratory, at-line and on-line wet chemical analysis.

Part of the worldwide Metrohm AG group, Metrohm Applikon has access to Metrohm's know-how and expertise in ion analysis.

MARGA (**M**onitor for **A**e**R**osols and **G**ases in ambient **A**ir) is an on-line ion chromatograph that measures the concentration of soluble inorganic species in aerosols and their related gas phase components in ambient air. Hourly simultaneous results for gases and aerosols can be accessed from a remote workstation, with result quality being maintained by an internal standard and detailed system diagnostics.

Jointly developed with ECN, The Netherlands**, MARGA** is distributed world-wide through Metrohm Applikon's distributor network; most members of which belong to the Metrohm group of companies.

www.palas.de

With more than 60 submitted patents, the Palas® GmbH has effectively set standards in aerosol technology since 1983. Today, Palas® offers a complete product range for the continuous aerosol generation and measurement from 5 nm to 100 µm.

Our innovations result in superior quality and durability of the products that lead to unique technical and economic advantages for our customers.
Our core competencies are:

- Particle generation
- Particle measurement systems (for high pressures, temperatures, processes, environment and workplace, inhalation)
- Nanoparticle measurement systems
- Filter test systems
- Continuous fine dust monitoring systems
- Dilution systems
- Cleanroom particle technology
- Calibration systems

Well-known industrial enterprises and research institutions worldwide have decided in favour of Palas® products and have thus established Palas® as a worldwide market leader.

Sunset Laboratory Inc

Main Office and Sales

E-mail: ben@sunlab.com
http://www.sunlab.com

Sunset Laboratory Inc. has specialized in the analysis of air pollution for carbon aerosols since 1984. As well as performing the OCEC analysis, Sunset Laboratory also provides instrumentation for carbon aerosol analysis. Our equipment is suitable for the laboratory or in the field, and ready for use with the NIOSH method 5040, IMPROVE, and EUSAAR 2 protocols. Clients include researchers working for government regulatory agencies, private companies, commercial laboratories, and universities.

Topas GmbH

Tel: +49 (351) 21 66 43 - 0
Fax: +49 (351) 21 66 43 55
E-Mail: office@topas-gmbh.de
www.topas-gmbh.de

Topas GmbH Dresden is a specialist company in the field of particle technology and filter testing systems. Our standard product range comprises:

- aerosol generators (mono - and polydisperse, solid and liquid particles)
- particle size measuring instruments for aerosols and liquids
- aerosol dilution systems
- electrostatic aerosol neutralizers
- process aerosol monitors
- filter testing technology and instruments
- clean room measuring equipment
- pore size measuring instruments

Topas also provides solutions for special applications like the dispersion of complex powders, test stands for particle filters and for adsorptive filters, filter media testing, blow-by measuring etc. Our corporate philosophy allows us to meet of a variety of customer needs. Many years of experience, our know-how as well as close cooperation with universities, research centres and industrial partners is the ideal basis for the development of new and innovative solutions. Our reliable measuring and testing equipment has proven successful worldwide.

TSI

For more than 50 years TSI Particle Instruments have been trusted by researchers to provide reliable, repeatable results. During EAC in Granada TSI's engineers will give you an overview of new products in the field of nanotechnology including the new NanoScan 3910 and the Optical Particle Sizer (OPS) Model 3330. Stop by and learn about:

- Sizing of Nanoparticles in the Gas and Liquid phase
- Workplace safety
- Experience and Solutions for Nanoparticle Characterization for scientific research, Industrial R&D, and process and quality control.

We look forward to seeing you at our booth No 11-13

URG Corporation

116 South Merritt Mill Rd.
Chapel Hill, North Carolina 27516 USA

Tel: 919-942-2753
E-mail: info@urgcorp.com
www.urgcorp.com

URG Corporation manufactures the **Ambient Ion Monitor (AIM) System** for the *continuous direct* measurement of particulate nitrate, sulfate, ammonium in PM2.5 plus gas measurements of nitric acid, SO_2 and ammonia. The **AIM System** analyzes particles, gases and organics. The **AIM System** incorporates a **Dionex Reagent-Free Ion Chromatograph**. The **AIM System** has detection limits of 0.1μg/m^3 for each of the required analytes and 0.081μg/m^3 for ammonia. The multi-pollutant data is instantly available on an hourly basis.

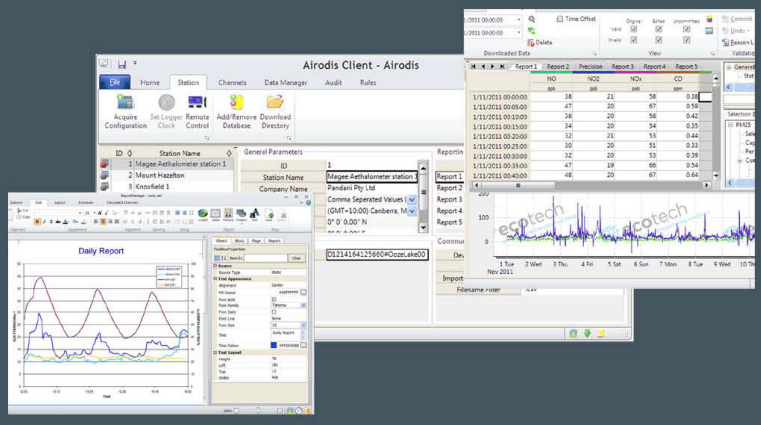
URG provides a wide variety of instruments for indoor and outdoor air sampling. Our **Annular Denuder System (ADS)** collects both acidic and basic gases and is designed to meet USEPA's Compendium Method IO-4.2. URG's complete collection of **aluminium cyclone inlets** are Teflon© coated, a patented process that minimizes the losses of reactive gases such as HNO_3 and NH_3 to the internal surfaces of the cyclone. URG provides **stainless steel cyclones** and **filter holders** for diesel emissions.

URG air sampling instrumentation is used in Europe, Asia, North America, Australia, Antarctica, Africa and South America.

Our latest innovations...

Ecotech's quality and expertise in manufacturing integrating nephelometers is well known, so this year visit us to find out what else we can do for you.

- Wet/dry sample conditioning system to compliment any aerosol instrument
- Airodis data evaluation & reporting software
- WinAQMS data acquisition systems
- Aurora 4000 polar nephelometer
- Aurora series of 1 & 3 wavelength nephelometers



Visit booth 6 to discuss our innovative solutions for conditioning, measuring and reporting

Plenary 1

Characterization of Responses to Carbon Nanotubes and Carbon Nanofibers

V. Castranova

National Institute for Occupational Safety and Health, Morgantown, West Virginia, USA
Keywords: nanoparticles, carbonaceous particles, lung/particle interaction, occupational health
Presenting author email: vic1@cdc.gov

Methods have been perfected to arrange carbon atoms in a crystalline graphene lattice with a tubular morphology. A single-walled carbon nanotube (SWCNT) is composed of a single cylindrical sheet of graphene and has a diameter of 0.5-2 nm. Multi-walled carbon nanotubes (MWCNT) consist of multiple tubes within a tube and have diameters of 10-80 µm, depending on the number of concentric tubes forming the structure. CNT can range in length from 0.5-30 µm. Carbon nanofibers are composed of graphene layers arranged at an angle to the fiber axis. CNF range from 70-200 nm in diameter and 10-100 µm in length.

CNT exhibit high tensile strength, possess unique electrical properties, are resistant to acid or high temperature, and can be easily functionalized. Therefore, application as structural materials, in electronics, as heating elements, in batteries, in production of conductive and stain resistant fabric, for bone grafting and dental implants, as well as in targeted drug delivery are being developed. CNF are strong, flexible fibers which are currently being used to produce strong but light weight composite materials.

CNT and CNF can be aerosolized readily upon agitation with peak airborne particulate concentrations being associated with workplace activities such as: weighing, transferring, mixing, blending, or sonication. Most airborne CNT or CNF found in workplaces are loose agglomerates of micrometer (µm) diameter. However, due to their low density, they remain in workplace air for a considerable time and a large fraction of these structures are respirable. Since inhalation of CNT or CNF by workers is possible, it is critical to evaluate the possible adverse effects of such exposure.

In rat and mouse models, pulmonary exposure to SWCNT, MWCNT or CNF has been reported to cause the following dose-dependent pulmonary reactions: 1) acute pulmonary inflammation and injury, 2) rapid and persistent formation of granulomatous lesions at deposition sites of large CNT agglomerates, and 3) rapid and progressive alveolar interstitial fibrosis at deposition sites of more dispersed CNT or CNF structures. On an equal mass lung burden basis, SWCNT are more fibrogenic than MWCNT or CNF. In addition, functionalization of MWCNT with carboxylic groups has been shown to decrease their inflammatory and fibrotic potency.

Pulmonary exposure to CNT has also been associated with various systemic effects. Pulmonary exposure to SWCNT has been shown to induce oxidant stress in aortic tissue and increase plaque formation in an atherosclerotic mouse model. Pulmonary exposure to MWCNT depresses the ability of coronary arterioles to respond to dilators. These cardiovascular effects may be due to neurogenic signals from sensory irritant receptors in the lung. The involvement of such a neuro-mediated mechanism is supported by the fact that pulmonary exposure to MWCNT induces upregulation of mRNA for inflammatory mediators in selected brain regions, and pulmonary exposure to SWCNT upregulates the baroreceptor reflex. There is also evidence that pulmonary exposure to MWCNT can induce levels of inflammatory mediators in the blood, which may affect the cardiovascular system.

Since CNT and CNF have been shown to be biologically active in animal models and workplace aerosolization has been measured, it appears prudent to develop strategies to minimize workplace exposure. Evidence indicates that engineering controls and personal protective equipment are effective in significantly decreasing inhalation of CNT and CNF by workers. In addition, administrative controls, worker training, and implementation of good handling practices have been recommended by NIOSH.

Monday, September 3, 2012

Session WG01S1O. Optical Properties

Optical properties of SiO_2 particles : inversion data from laboratory IR absorption spectra.

Denis PETITPREZ[1], Hervé HERBIN[2],

[1]Laboratoire de Physico-Chimie des Processus de Combustion et de l'Atmosphère (PC2A), UMR CNRS 8522, Université Lille 1, Cité Scientifique - Bâtiment C11, 59655 Villeneuve d'Ascq, France

[2]Laboratoire d'Optique Atmosphérique (LOA), UMR CNRS 8518, Université Lille 1, Cité Scientifique - Bâtiment P5, 59655 Villeneuve d'Ascq, France

Keywords: optical properties, SiO_2, refractive index
Presenting author email: Denis.Petitprez@univ-lille1.fr

Due to their ability to absorb and to scatter radiations, airborne particles play an important role in the energy budget of the earth-atmosphere system. It is assumed that aerosols are one of the atmospheric constituents participating to the cooling effect, but estimates are highly uncertain owing to the large spatial and temporal variability of aerosol concentration and physical properties.

The measurements from space-borne instruments are the only means for observing aerosol distributions from local to global scale. In particular, thermal infrared imagers such as MODIS or SEVIRI are routinely used to detect aerosols. Nevertheless, these broadband sensors are not suitable to distinguish the aerosol composition. Recent high spectral resolution sounders such IASI or Tanso-FTS are able to overcome these limitation. However, to fully exploit the hyperspectral instruments capabilities it is essential to have reference optical properties of various particles and mainly refractive indices.

Indeed, the knowledge of refractive indices is essential because it describe the proportioning of scattering and absorption of light by such particle matter. Moreover, the refractive index is strongly depending on the aerosol composition, size and shape.

The aim of this work is to measure high resolution transmittance spectra of model airborne SiO_2 particles in the infrared region and to use a Mie inverse algorithm to retrieve complex refractive indices. Refractive index measurements are generally performed by measuring absorbance or transmittance with bulk material of interest or particles diluted in solid pellets. In this study, we have recorded transmittance spectra of calibrated airborne particles by IRTF spectroscopy.

Aqueous solutions of calibrated SiO_2 microspheres (Bangs Laboratories, Inc.) were generated using an atomizer (TSI 3076). After drying, the continuous flow of aerosol particles was directed into a 10 m absorption length multipass cell within an IRTF spectrometer (Antaris Thermo Scientifique). The size distribution of the particles was measured at the exit of the multipass cell using an aerodynamic particle sizer spectrometer (TSI APS 3321). Concentration between 500 and 6000 particles per cubic centimetre were used for each 3 particle diameter: 0.5, 1 and 2 µm. 300 IRTF records were collected and averaged at a spectral resolution of 2 cm^{-1}. The IRTF spectra for SiO_2 microspheres (Ø = 2 μm) is displayed Fig1 showing an intense band around 1100 cm^{-1} .

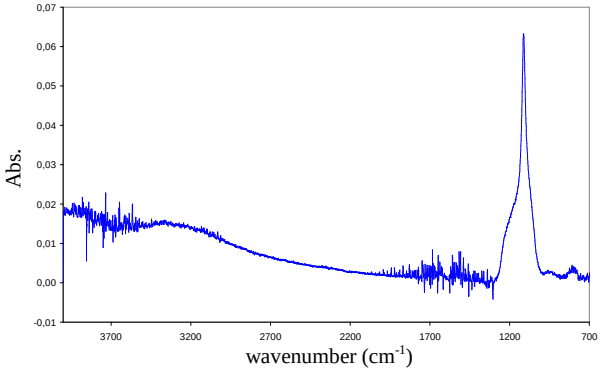

Fig. 1: Absorption spectra of calibrated SiO_2 particles Ø = 2 μm, $[SiO_2]$ = 1430 particle.cm^{-3}.

The complex refractive indices of particles are obtained at each wavenumber by combining the Mie theory, the Kramers-Kronig relations, and a Levenberg-Marquardt algorithm. This inverse model allows avoiding some errors introduce by the extrapolated formulas of Kramers-Kronig relations. This methodology has the advantage to can be applied for any spherical particles.

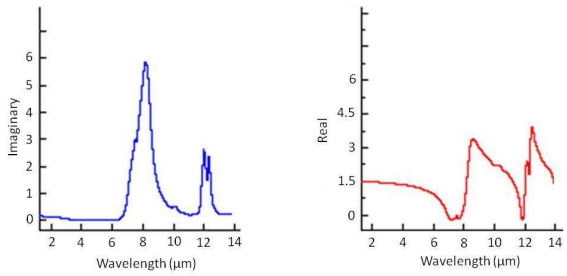

Fig. 2: Retrieved imaginary and real refractive indices of SiO_2 particles.

Experiments with particles (Ø = 0.5 μm and Ø = 1 μm) are currently in progress highlighting size dependence.

Profiling of the aerosol hygroscopicity in the planetary boundary layer

B. Rosati[1], E. Weingartner[1] , P. Zieger[1], G. Wehrle[1], U. Baltensperger[1] and the PEGASOS collaboration

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland
Keywords: hygroscopicity, growth factor, OPS, refractive index.
Presenting author email: bernadette.rosati@psi.ch

The aerosol direct effect relates to the interactions that aerosols have with the incoming solar radiation. Depending on the composition of the particles they can either scatter or absorb the light. Laboratory studies are typically performed at dry conditions but the ambient relative humidity (RH) is usually much higher therefore leading to hygroscopic growth which strongly influences the particle size and refractive index and hence the optical properties (Zieger et al., 2011). The knowledge of these aerosol properties is crucial for climate forcing calculations and for the validation of remote sensing measurements with in-situ ones. This is of particular importance if the chemical composition and thus the hygroscopicity changes with altitude (Morgan et al., 2010). Therefore, measurements of vertical profiles are essential to enable more accurate model calculations and improve remote sensing retrievals.

Within the **P**an-**E**uropean **G**as-**A**ero**so**ls-climate interaction **S**tudy (PEGASOS) a Zeppelin is used to explore the planetary boundary layer. The WHOPS (white-light humidified optical particle spectrometer) is a newly developed instrument to investigate the particles' hygroscopic and optical properties on this platform. The idea is to first dry the ambient aerosol and then select a specific mobility diameter with a differential mobility analyzer (DMA). The monodisperse particles are then exposed to a well defined RH (typically 95%) and again measured with a white-light optical particle spectrometer (OPS-Welas) to finally retrieve information on the hygroscopic growth factor and mixing state. Intermittently, the humidifier can be bypassed allowing the comparison of dry mobility and dry optical diameters to deduce information on the particles' optical properties (e.g. refractive index) (Flores et al., 2009). The WHOPS is highly suitable for airborne measurements since it records data at a high sampling rate of 1 Hz and detects diameters up to 10 µm for the humidified particles. First measurements will be conducted in Spring/Summer 2012 at Cabauw (Netherlands) and in the Po Valley (Italy). In the latter case, flights are also planned over the Adriatic Sea to investigate marine aerosols. In addition, atmospheric aging processes will be explored by drifting in a freshly emitted plume. We will present laboratory studies which include tests and calibration measurements with known inorganic salts, as well as first airborne measurements using the WHOPS.

Figure 1 shows an example measurement of ammonium sulfate (AS) for two different dry mobility diameters (300 nm and 500 nm). The red and blue lines are the dry and the humidified (RH=95±3%) optical measurements, respectively. In the top graph the influence of doubly charged particles and their growing behavior is nicely seen. The diameter set by the DMA and measured by the OPS compare quite well: The maximum dry (singly charged) optical diameters are 328 nm and 487 nm, respectively. The differences to the respective mobility diameters can be explained by two reasons: first, the OPS was calibrated with latex spheres with a different refractive index (1.59) compared to AS (1.52–1.55) and secondly the calculated scattering cross sections of latex spheres are only weakly diameter dependent at 300 nm which introduces higher uncertainties to retrieve an unambiguous diameter for a certain scattering intensity.

The apparent hygroscopic growth factors at RH=95% are lower than predicted by Köhler theory. This can be related to the high refractive index used for the calculations. In an improved retrieval the refractive index of water (1.33) will be considered for the wet particles using volume weighted mixing rules.

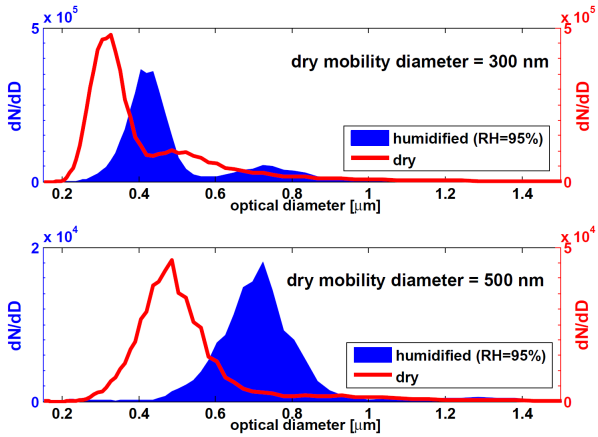

Figure 1: Laboratory experiments with AS; red: dry size distributions; blue: humidified size distributions; for two dry mobility diameters selected by a DMA.

The effect of hygroscopicity on the aerosol extinction

V. Gácser, A. Molnár

Department of Earth and Environmental Sciences, University of Pannonia, Veszprém 8200, Hungary
Keywords: Visibility, Aerosol extinction, Relative humidity, Hygroscopic growth.
Presenting author email: vera.gacser@chello.hu

It is well known that visibility, which is an important factor in our everyday life, is the function of the shortwave light extinction, first of all the extinction of the aerosol particles. The light extinction of the particles is determined by Mie scattering of the fine particles. Since aerosol particles in the optically active size range (0.1-1.0 μm) are mainly composed of hygroscopic (sulfate, nitrate and organic) compounds, these particles can take up significant quantity of water from the atmosphere. With increasing ambient relative humidity the size of the particles increases; and consequently their optical properties change considerably (Malm and Kreidenweis, 1997; Liu et al. 2008) having an important influence on the control of the visibility.

In a previous study the relationship between the extinction coefficient and the relative humidity were studied in two sampling campaigns in Budapest in 2009. The data of these campaigns revealed that hygroscopic growth is substantially different in winter and in summer. In winter the growth rates (at 80 and 90% RH) were two times higher than in summer.

The aim of this present work is to study how the seasonal variation of the hygroscopic growth rate can be considered as a general phenomenon. In this work the hygroscopic behavior of aerosol extinction coefficient under different environments is presented. The extinction coefficients are derived from visibility data measured regularly at urban as well as non-urban locations for a longer period (1995-2002) in Hungary (Integrated Surface Hourly Observations, NOAA National Data Center).

The extinction coefficients were calculated from visual range observations using the Koschmieder formula, and dry extinction coefficients were estimated by the gamma-approach (Zhou et al., 2001):

$$\sigma_{ext} = 10^{c} \times (1 - \frac{RH(\%)}{100})^{-\gamma}$$

According to our results this seasonality can be observed at all monitoring sites (in large and small cities and other places); the smallest and the highest rates are found in summer and winter, respectively. On the other hand, the seasonal change in the hygroscopic growth rates is rather variable; it can be very different even at locations not far from each other. E.g. the growth rates of the extinction coefficient at two sites in Budapest (Budapest-Lőrinc and Liszt Ferenc Airport) are shown in Fig.1. At Budapest-Lőrinc site, at 80% relative humidity the mean growth rates are ~1.7 and ~3.2 in summer and winter, respectively, while at Liszt Ferenc Airport the corresponding values are ~1.1 in summer and ~1.7 in winter.

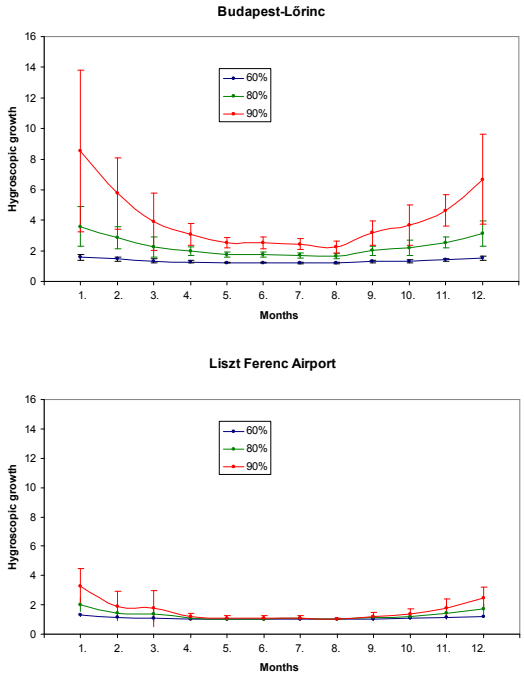

Fig. 1: Seasonal variation of the hygroscopic growth rate of the extinction coefficient at Budapest-Lőrinc and at Liszt Ferenc Airport at 60%, 80% and 90% RH.

The seasonal difference in hygroscopic behavior of extinction coefficient is probably due to the change in the chemical composition of the aerosol particles. We suppose that volatile and semi volatile compounds can play an important role in this variability. On the other hand, the spatial variation of the growth rates can be effected significantly by the local aerosol sources.

Nephelometric study of fine aerosol fraction in Beijing

M.A. Sviridenkov[1], A.S. Emilenko[1], V.M. Kopeikin[1] and Wang Gengchen[2]

[1]A.M. Obukhov Institute of Atmospheric Physics, Russian Academy of Sciences, Moscow, 119017, Russia

Keywords: atmospheric aerosols, optical properties, microstructure, urban pollution
Presenting author email: misv@mail.ru

Beijing, one of the biggest megacities, is characterized by high mean level of the aerosol pollution and its significant variability. IAP RAS in collaboration with IAP CAS has started study of the pollution of Beijing air basin in 1990s. Optical properties of the fine aerosol fraction were investigated using a nephelometer-polarimeter PhAN. Some results of 2003 - 2004 were presented at EAC-2005 (Sviridenkov *et al*., 2005). In the present paper, the results of measurements in the period from 2003 to 2010 (except for 2008) are summarized.

Measurements were usually carried out in fall season (in 2005 - in August). The nephelometer was installed in the building of the IAP CAS, located in the northern part of Beijing. Observations were conducted in two modes – continuous automatic recording of the single characteristic - aerosol scattering at the angle of 45° and wavelength of 510 nm, and periodic measuring of 7 parameters (angular scattering coefficients D at the scattering angle of 45° and wavelengths of 410, 510 and 630 nm and their polarized constituents at the scattering angle of 90° and wavelengths of 450 and 520 nm). The set of parameters, measured by PhAN, allows to solve the inverse problem and to retrieve both size spectra of the fine fraction and the values of the particle refractive index. Inversion results are most reliable in the size range 0.05 – 0.6 μm (Panchenko *et al.* 2008). Measured in routine regime D(45°, 510 nm) is closely correlated with volume scattering coefficient and volume concentration of fine aerosol fraction. In parallel with optical measurements, aerosol probes were sampled to fibre filters for further determination of BC content. In 2003, 2004, 2005 and 2007, observations were also taken at Mountain Observatory Xinglong located at 150 km to the north-east from Beijing at the height of 1 km.

Aerosol concentration in Beijing is characterized by both significant mean level and strong variability. Typical example of a temporal behaviour of D(45°, 510 nm) is shown in Figire 1. It can be seen in Figure 1 that periods of gradual growth of the aerosol pollution with duration of several days are interrupted by the air mass change accompanied usually by rains. In the final stage of smog formation, the visual range decreases sometimes up to values of hundred meters. Analysis of transformation of the aerosol microstructure and BC content during smog formation revealed the tendency of decreasing the particle refractive index and BC fraction and increasing the effective radius with growth of the aerosol loading.

Mean aerosol size distributions of fine aerosol fraction for Beijing and Xinglong are shown in Figure 2. They all are unimodal with modal radius in the interval of 0.1 - 0.2 μm (except for August 2005 in Beijing). Although the average aerosol concentration at Xinglong is much less than in Beijing, it is several times greater than in rural areas and even in such cities as Moscow.

Observed darkening of the aerosol

J.P. Putaud, F. Cavalli, A. Dell'Acqua, C. Gruening, and S. Martuins Dos Santos

European Commission, Joint Research Centre, Ispra, VA, 21027, Italy
Keywords: aerosol, absorption, scattering, single scattering albedo.
Presenting author email: jean.putaud@jrc.ec.europa.eu

The Po Valley in Northern Italy can be identified from space as one of the most polluted areas in Europe (e.g. Koelemeijer et al., 2006). It is therefore a region where the effects of European policies and international protocols for abating air pollution should be most visible.

Aerosol remote sensing and in-situ measurements at the ground have been performed at the station for atmospheric research located in Ispra (45°49'N, 8°38'E), Italy, for more than 18 and 8 years, respectively. Instruments were run according to the quality assurance programs developed by within the networks AERONET (AErosol RObotic NETwork), EUSAAR (EUropean Supersites for Atmospheric Aerosol Research), and ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure network). The station was favorably audited in 2010 by the World Calibration Centre for Aerosol Physics (WCCAP).

Measurements show that while the aerosol extinction coefficient and optical thickness (AOT) decreased over the last decade, the aerosol absorption coefficient and optical thickness (AAOT) did not decrease that much. This means that not only the aerosol cooling power has been vanishing, but also that the aerosol single scattering albedo decreased (Fig. 1). A simple climate forcing simulation shows that the aerosol is consequently getting closer to shift from a cooling to a heating climate forcer in this region.

The changes in aerosol optical properties we observed can be related to changes in the particulate matter ($PM_{2.5}$) chemical composition, with increasing percentages of carbonaceous compared to inorganic species.

These data show that to avoid fast climate change over the next decade, policies should now address more specifically short-lived climate warming agents, among which elemental carbon (EC). EC is also perhaps one of the targets to be aimed at for reducing adverse health effects of air pollution.

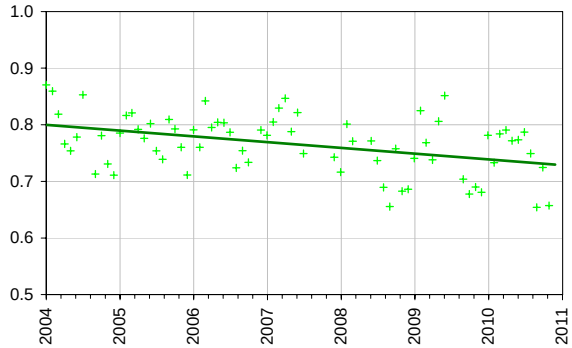

Figure 1. Monthly mean aerosol single scattering albedo at 550 nm observed in Ispra (IT) at ground level in dry conditions. The straight line represents the least square linear fitting curve.

Presenting author email: chiqui@goa.uva.es

The dependency of the aerosol absorption coefficient on wavelength is usually described by the absorption Ångström exponent, α_a. Depending on the particle's characteristics, the spectral dependence of the aerosol absorption coefficient is given by the empirical expression (Ångström, 1964; Bond, 2001; Moosmüller and Chakrabarty, 2011):

$$\frac{\sigma_a(\lambda)}{\sigma_a(\lambda_0)} = \left(\frac{\lambda}{\lambda_0}\right)^{-\alpha_a}, \quad (1)$$

where $\sigma_a(\lambda)$ is the absorption coefficient, λ is the wavelength, λ_0 is an arbitrary reference wavelength (usually taken as 1 μm in extinction studies) and α_a is the absorption alpha exponent or absorption Ångström exponent, which represents the aerosol complex refractive index influence on the wavelength. This power law expression characterizes the steepness of the slope of the curve σ_a *versus* λ.

For measurements of the absorption coefficient $\sigma_a(\lambda_1)$ and $\sigma_a(\lambda_2)$ taken at any two different wavelengths λ_1 and λ_2 respectively, the absorption Ångström exponent is given by:

$$\alpha_a = -\frac{\ln \frac{\sigma_a(\lambda_1)}{\sigma_a(\lambda_2)}}{\ln \frac{\lambda_1}{\lambda_2}}. \quad (2)$$

In this way, if the absorption coefficient at one wavelength and the absorption Ångström exponent are known, the absorption coefficient can be computed at any other wavelengths within the range of validity of this formula. In practice, measurements of the aerosol absorption coefficients are made at two or more wavelengths, and the absorption Ångström exponent is estimated from these measurements using Eq. 2.

Over recent years, absorption Ångström exponents of aerosol particles have been observed by the Atmospheric Optics Group from the University of Valladolid (GOA-UVa) at a number of sites around the world. Measurements have been performed over different time periods, in short campaigns or in continuous measurements. Several instrumentation have been used (integrating plate, integrating sphere, PSAP) and each study reports the data in particular conditions and different wavelength ranges. We have collected our existing data representing 13 individual campaigns and compare the results for different places and conditions. All the alpha values have been calculated for the pair of wavelengths 400-650 nm for easier comparison.

Campaign	Mean	Median	Min	Max	Std

Measuring the optical properties of single particles and aerosol ensembles using cavity ring down spectroscopy

B.J Mason, R.E.H. Miles, S.-J. King, K. Manfred, J.S. Walker, A.E. Carruthers, A.J. Orr-Ewing and J.P. Reid

Presenting author email: bm6225@bristol.ac.uk

Aerosols, both natural and anthropogenic, influence climate change by directly scattering and absorbing light from the sun and indirectly by acting as cloud condensation nuclei. Both these effects, however, have a large uncertainty associated with them as presented in the 2007 IPCC report of climate change (Forster, Ramaswamy et al. 2007). The refractive index (RI) of a particle can be used directly to describe its absorbing and scattering properties and can thus be directly related to its climate radiative forcing. Laboratory measurements of the RI of a range of anthropogenic and naturally occurring aerosols allow us to better estimate their total effect on radiative forcing.

In recent years ensemble aerosol cavity ringdown spectroscopy (A-CRDS) has been used to retrieve the RI of various atmospherically relevant aerosols such as single, mixed component and coated systems (Rudich, Riziq et al. 2007). Atmospheric relative humidity (RH) varies significantly with altitude, latitude and urbanisation meaning that it is important to know how the RI of an aerosol varies with water fraction. Sodium nitrate ($NaNO_3$) can be introduced directly into the atmosphere from fertiliser and indirectly from reactions with sea salt aerosol. As yet, using A-CRDS for absolute measurements of the RH dependent refractive index of an aerosol at multiple relative humidities has not been attempted. In this work we present A-CRDS determination of the refractive index of $NaNO_3$ at 30, 40 and 50 % RH (figure 1). The accuracy to which we can retrieve the RI as a function of RH and the inherent uncertainties involved have been previously analysed by members of our group (Miles, Rudic et al. 2011).

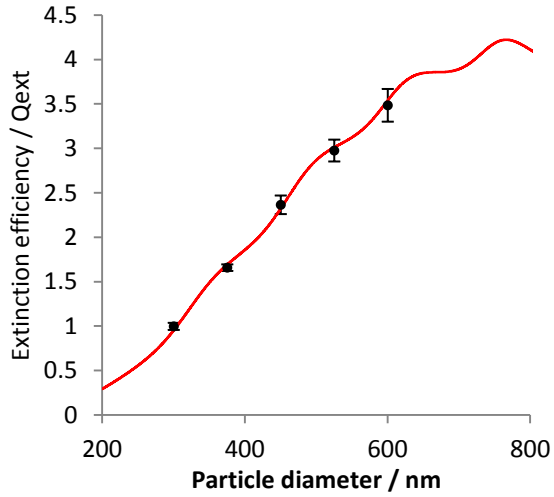

Figure 1. Typical experimental data set of $NaNO_3$. Particles of different sizes at 30 % RH are selected by the DMA and optically probed using the CRDS. The red line shows the fit of the experimental data to Mie theory (RI = 1.441 ± 0.02).

A significant source of error for ensemble A-CRDS arises from the assumption that the aerosol fraction selected by the DMA is monodisperse. This is incorrect for two reasons: firstly the DMA intrinsically selects doubly charged particles (DCPs) in addition to singly charged particles and secondly because the size distribution passed by the DMA, due to its transfer function, can have a significant effect on the optical measurement. Quantification of such effects is important as even a small (~1%) fraction of DCPs can have a significant effect on the observed RI.

Our aim is to take advantage of the sensitivity of A-CRDS and to couple it with accurate measurements of the change in optical properties with environmental conditions whilst avoiding many of the inherent uncertainties in ensemble measurements. To achieve this we are benchmarking an innovative new single particle A-CRDS instrument able to determine the optical properties of individual aerosol particles in the accumulation mode. In such experiments a particle is levitated by a vertically propagating Bessel beam optical trap which bisects a horizontal optical cavity. By changing the power of the Bessel beam a trapped particle can be moved in and out of the optical cavity to perform the ring down measurement. The change in optical properties with environmental conditions can be directly monitored on the same particle by controlling the relative humidity of the surrounding gas phase. This allows the effect on the aerosol optical properties of hygroscopic changes in particle size to be measured. The size of the particle can be measured independently from elastic light scattering.

A key advantage over the ensemble technique is the ability to precisely measure the time-dependence in optical properties of aerosol during transformation on a single particle basis (eg. hygroscopic growth, heterogeneous aging). We believe this new technique represents a significant advance in the accuracy with which measurements of aerosol optical properties and studies of aerosol processing can be made.

Presenting author email: michael.kahnert@smhi.se

Light absorbing carbon is one of the most important classes of short-lived climate forcing agents. Owing to the high absorption cross section, LAC aerosols cause a positive radiative forcing at the tropopause, and a negative forcing at the surface. To quantify the radiative impact of LAC requires reliable information on the extinction cross section, single scattering albedo, and asymmetry parameter.

Because of the high morphological complexity of LAC aerosols, solving the light-scattering problem is a challenging task. Freshly emitted LAC particles can be described as aggregates consisting of small spherules. As the aerosols age in the atmosphere, the fractal dimension increases, and the LAC aggregates become internally mixed with soluble compounds, such as sulphate and organic matter (OM). The objective of this study is to test the suitability of simplified model particles by comparing their radiative properties to those obtained from reference computations performed for realistic encapsulated aggregate models.

We perform detailed light scattering computations for model particles consisting of LAC aggregates encapsulated in a sulphate shell. Figure 1 shows an example for one of the model particles considered. The reference computations brace the range of relevant sizes, wavelengths, and volume fractions. In parallel, we perform computations for external mixtures of homogeneous, spherical LAC and sulphate particles, internal encapsulated geometries described by a homogeneous LAC sphere coated by a concentric spherical sulphate shell, and homogeneous internal mixtures of LAC and sulphate. For the latter, we test different effective medium theories (EMT) for computing the effective refractive index of the LAC-sulphate mixture. Remarkably enough, the core-shell model does not provide the most accurate description of the optical properties of encapsulated LAC aggregates. This model usually underpredicts the absorption cross section C_{abs}, and it often overpredicts the scattering cross section C_{sca}. Thus, the single-scattering albedo ω is significantly overestimated. The Maxwell-Garnett EMT reproduces the reference computations somewhat better than the core shell model. However, it tends to over-estimate C_{abs} and underestimate C_{sca}. The Bruggemann EMT and the inverse

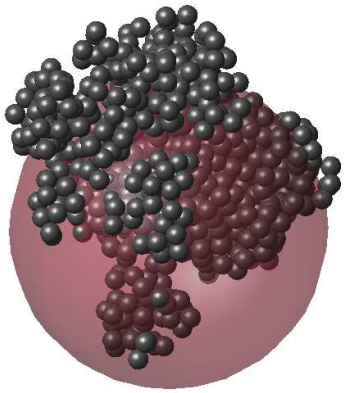

Figure 1: Example of model particle used in this study.

Maxwell-Garnett rule perform, in general, slightly worse than the Maxwell-Garnett EMT, although not as poorly as the core-shell model. As expected, the external mixture model performs worst.

Physically, the problems observed for the core-shell model are caused by the fact that a massive LAC sphere absorbs much less electromagnetic energy than an LAC aggregate, since the electromagnetic field does not penetrate deeply into a compact sphere of highly absorbing material. On the other hand, the homogeneous mixture model distributes the LAC mass too evenly within the sulphate host particle, thus allowing too much LAC mass to interact with the external field. We propose an improved model for encapsulated LAC aggregates based on a concentric core-shell-shell geometry. The model particles have a spherical sulphate core, a concentric LAC inner shell, and a concentric sulphate outer shell. The absorbing material is distributed such that more LAC mass can interact with the external field as compared to the core-shell model, yet not as much mass as in the homogeneous mixture model. The core-shell-shell particles reproduce the radiative properties computed for the encapsulated LAC aggregates reasonably well for all sizes, wavelengths, and volume fractions considered. The improvements over the other model particles are particularly pronounced at visible wavelengths near the maximum of the solar spectral radiance.

Airborne particles, primarily bacteria, virus, and fungi, are a primary means of disease transmission in humans and other animals. Due to renewed concerns over biological airborne contaminants such as new strains of flu or anthrax, many researchers have investigated the real-time technique that can be continuously monitored for potentially harmful biological aerosols.

Recently, the focus on fluorescence-based optical sensors has been to improve characterization by individual fluorescence spectral analysis. The fluorescence spectrum varies from material to material, and the evidence obtained from laboratory measurements indicates that effective differentiation from likely interferents should be possible with broadband spectral differentiation (Pan *et al*., 2011; Kaye et al., 2005). There has also been a focus on developing simpler, more robust, and lower-cost real-time sensors for intelligent network deployments.

The aerosol fluorescence sensor (AFS; Biral, Bristol, UK) is a promising monitoring device for the continuous real-time detection of airborne microorganisms, which is based upon the principle of Ultra-violet light induced fluorescence (UV-LIF) targeting the intrinsic fluorescence response from common amino acids found in living matter. The sensor uses an UV optical excitation source of 280 (+20/-40) nm to illuminate an airstream flowing drawn continuously through the sensor detection volume. Fluorescence from all particles instantaneously present within a sensing volume is measured using two photomultiplier detectors optically filtered to detect radiation in the bands 305-385 nm (UV) and 415-550 nm (Vis), enabling a generic discrimination between different aerosol populations.

This study describes the continuous real-time fluorescence characteristics of bacterial bioaerosols (*E. coli, B. subtilis and S. epiderdmids*) with various cell viabilities using the AFS. To control cell viability, the test bacterial bioaerosols were continuously exposed at various surrounding temperature with very short-time in the thermal electric tube furnace and passed into the AFS (Jung *et al*., .2009).

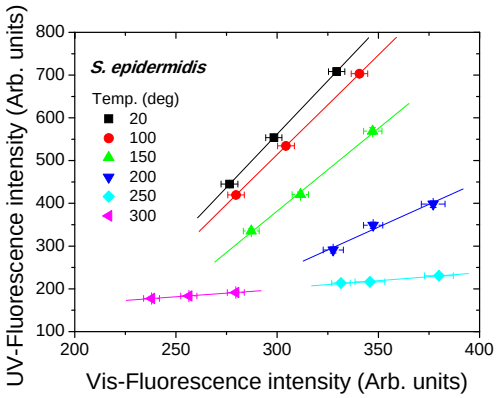

Figure 1. Variation of fluorescence characteristics of *S. epidermidis* bioaerosols under various thermal conditions.

Laboratory data show that these UV- and Vis-fluorescence intensities from the bacterial bioaerosols were decreased with increasing surrounding temperature following the decrease of bacteria viability.

In particular, this slope reduction value has statistically significant relationship ($p<0.05$) with the bacterial cell viability reduction. These experimental results provide basic information about the feasibility of AFS for real-time cell viability assessment of bacterial bioaerosols and may contribute in various applications such as indoor air quality, public health, and military defense against bioterrorism.

For fuel management and/or ecological reasons prescribed burnings are conducted each year across Australia. Smoke from prescribed burnings could be the major source of air pollution in urban environment during the period of intensive prescribed burning. To investigate the impact of prescribed burning on air quality and the characteristics of prescribed burning particles, field measurements were conducted during the end period of a prescribed burning event in September 2011, Brisbane, Australia.

In this project, time series of ambient particle number concentration, submicrometer particle size distributions (0.009-0.414 µm) and supermicrometer particle size distributions (0.523-19µm) were measured by a TSI condensation particle counter (WCPC 3787), a TSI scanning mobility particle sizer (SMPS) and a TSI UVAPS, respectively. An Aerodyne time of flight aerosol mass spectrometer (AMS) was used to characterize the composition of the submicrometer, non-refractory aerosol. Particle elemental carbon (EC), organic carbon (OC), Levoglucosan (a biomass burning marker) and volatile organic compounds (VOCs) were also measured. Brisbane air quality data for September 2011 was collected from the Department of Environment and Resources Management.

The prescribed burning event started on 14 Sep 2011 and stopped on 21 Sep 2011. The measured and collected data are grouped according to the burning event (14-21 September) and the non-burning event (1-13 and 22-30 September). 24-hour average PM_{10} and $PM_{2.5}$ concentrations in September 2011 are presented in Figure 1. It can be seen from Figure 1 that both 24-hour average PM_{10} and $PM_{2.5}$ concentrations significantly increased during the prescribed burning event. The 24-hour average PM_{10} concentrations in 18 and 19 Sep were higher than the Australian ambient air quality standard (50 µg m^{-3}). The 24-hour average $PM_{2.5}$ concentrations during 17 - 19 Sep were higher than the Australian advisory ambient air quality standard (25 µg m^{-3}) and there were two days that $PM_{2.5}$ concentrations were more than twice as the advisory standard.

A summary of the statistical analysis of average submicrometer PN concentrations ($\times 10^3$ p cm^{-3}), supermicrometer PN concentrations (p cm^{-3}), PM_{10}, (µg m^{-3}) $PM_{2.5}$ (µg m^{-3}) concentrations, as well as maximum 8-hour CO (ppm), maximum 4-hour O_3(ppm), maximum 1-hour NO_2 (ppm), 24-hour SO_2 (ppm), 24-hour Benzene (ppb), 24-hour Toluene (ppb), 24-hour Total Xylenes (ppb) and 24-hour Formaldehyde (ppb) concentrations is given in Tables 1. From Table 1, it can be seen that, except Total Xylenes all pollutant levels during the burning period are higher those during the non-burning period, especially for submicrometer particle number concentration.

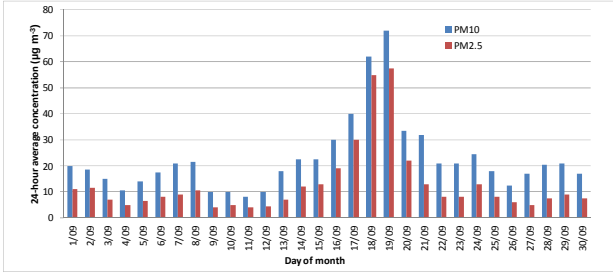

Figure 1. The 24-hour average PM_{10} and $PM_{2.5}$ concentrations of Brisbane city in September 2011.

Table 1. Summary of the statistical analysis of average concentration of the pollutants (units: as above)

	Burning		Non-burning		Ratio*
	Average	S.D	Average	S.D

AMS results indicated that the mass loadings were more than 20µg m^{-3}, which is not typical for Brisbane measurement site. Particles (PM_1) contained a substantial amount of organics (75% +/- 10% of the total AMS mass). High f44 (tracer for oxygenated organic compounds) value 0.16 (0.12-0.2) indicates that organic component was highly oxygenated, suggests that the particles at the measurement site were aged.

Physical and chemical properties of aerosol particles from wild fires in South Africa

Submicron aerosol particles are well known to affect our lives via direct and indirect climate effects as well as adverse health effects (Seinfeld and Pandis, 2006). In Southern Africa wild fires form a large source of aerosol particles especially during the dry season, from June to September (Swap et al., 2003).

The main source of information on aerosol particles from wild fires in southern Africa are the SAFARI 1992 and 2000 campaigns (Swap et al., 2003), which, while intensive, had instrumentation limitations. In the SAFARI 2000 campaign the lower detection limit of the aerosol size distribution measurements was 100 nm and the chemical analysis of the aerosol particles were determined from filter samples.

In this study, we utilise long-time measurements of aerosol size distributions from 12 to 840 nm in two measurement locations in South Africa, i.e. in Botsalano game reserve close to the Botswana border from July 2006 to February 2008 (Laakso et al., 2008) and in Welgegund (www.welgegund.org), 100 km south-west of Johannesburg, from May 2010 to September 2011. At the Welgegund measurement site we also had an Aerodyne ACSM online aerosol mass spectrometer (Ng et al., 2011) for chemical composition measurements of the sub-micron aerosol and a Thermo model 5012 MAAP running on a PM1 inlet, which was used to estimate the black carbon content in the aerosol.

The ground-based measurements were related to wild fires by combining 96-hour HYSPLIT back-trajectories and MODIS Burned Area product. Only cases when fire-generated aerosol could be clearly separated from the pre-existing aerosol were used. 82 plumes were identified, of which 20 also had online chemical composition data available.

The median chemical composition of the fire-generated aerosol (Figure 1) was dominated by organic compounds. However, in the night time plumes the fraction of organic compounds was 13 percentage points lower than in day time plumes, suggesting photo-oxidation of volatile organic compounds to contribute significantly to the total mass.

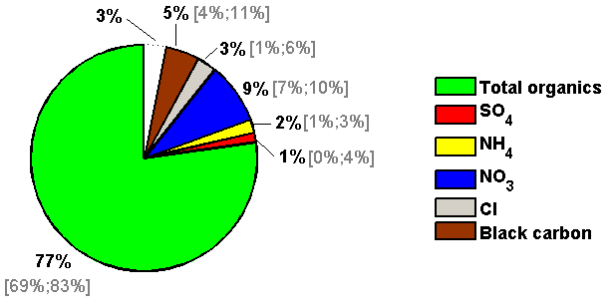

Figure 1. Median chemical composition of fire-generated aerosol from ACSM and MAAP. The median fractions of different compounds do not add up to 100%, hence the unaccounted 3% in the graph. The 25th and 75th percentiles are given in gray.

In Augsburg, a city of 260.000 inhabitants, close to Munich in the south of Germany, the Helmholtz Zentrum München is operating since 2002 an urban background aerosol monitoring site. A long term source apportionment study based on daily measured organic PM constituents suggests a rather strong impact of wood combustion on the ambient aerosol in Augsburg (Schnelle-Kreis et al. 2007). This holds true for the PM10 values as well as for the concentrations of the health relevant polycyclic aromatic hydrocarbons (PAH). Motivated by these findings, an intense measurement campaign was conducted in Augsburg in order to address the impact of wood combustion (WC) on the ambient aerosol in the winter season 2010. On the one hand different on-line and off-line mass spectrometry based methods were applied at a central stationary measurement site. This includes a High Resolution Time of Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne Research Inc.) based on a thermal desorption-electron ionisation process, a home-built thermal ionisation mass spectrometer for detection of alkali ions from particles (Alkali AMS, University of Gothenburg, Svane *et al.* 2004) and a home-built thermal desorption-REMPI laser ionisation mass spectrometer for single particle resolved detection of polycyclic aromatic hydrocarbons (TD-REMPI-ATOFMS, Joint Mass Spectrometry Centre, Helmholtz Zentrum München, Oster, *et al.* 2011). Figure 1 shows Augsburg ambient aerosol mass spectra recorded by the three different aerosol mass spectrometers during the campaign.

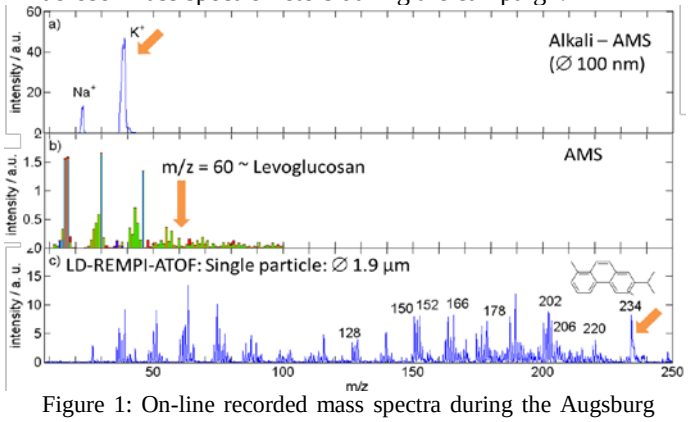

Figure 1: On-line recorded mass spectra during the Augsburg winter 2010 measurement campaign

The high potassium content of the particles recorded by the Alkali-MS reflect the wood combustion contribution (Fig. 1, upper trace). The AMS spectrum is dominated by organic fragments (due to the 70 eV electron ionization). However, the enhanced peak at m/z=60 can be explained partially due to a levoglucosan fragment (Fig. 1, middle trace). The single particle mass spectrum of a 1.9 µm particle recorded by TD-REMPI-ATOFMS depicts a rich pattern of PAH masses (128, 166, 178, 202 m/z). Furthermore the peak at 234 m/z is due to the molecule retene, which is a well-known marker for coniferous wood combustion. In addition to on-line aerosol mass spectrometry PM 2.5 was continuously sampled on filters with a daily resolution while PM1 was collected for several days even with hourly time resolution. The filter samples were analysed with a newly developed in-situ-derivatization thermal desorption gas chromatography time-of-flight mass spectrometry method which allows detecting non polar (e.g. polycyclic aromatic hydrocarbons) as well as polar (levoglucosan) compounds simultaneously (IDTD-GC-TOFMS, Orasche, 2011). The comparison between on-line (e.g. AMS) and off-line analyses (IDTD-GC-TOFMS) show good accordance. To complete the stationary measurements also mobile measurements were carried out in the city of Augsburg, using a further High Resolution Time-of-Flight Aerosol MS which was set up in a mobile atmospheric pollution laboratory (Paul Scherrer Institute, Mohr, *et al.* 2011).

In the contribution the whole measurement campaign (on-line, off-line and mobile measurements) are summarized and concluded.

The health effects of organics in wood combustion aerosols are currently further investigated in the framework of the Helmholtz Virtual Institute of Complex Molecular Systems in Environmental Health, HICE (www.hice-vi.eu).

Biomass burning aerosol exerts a significant direct radiative forcing by scattering and absorption of solar radiation (IPCC, 2007) and causes a large uncertainty on the estimates of aerosol radiative forcing driven climate change. Biomass burning aerosol layers are highly variable in time and space and can occur throughout the entire troposphere and lower stratosphere. To determine the impact of particle layers containing absorbing materials like black carbon (BC), on the Earth's radiation budget, it is necessary to learn more about their particle size distributions and mixing state, the aerosol aging, and optical properties. These layers can be characterized directly using airborne in-situ measurements.

During the CONCERT 2011 (Contrail and Cirrus Experiment) campaign in September 2011 eleven research flights were conducted over Central Europe with the DLR research aircraft Falcon. CONCERT 2011 focussed on microphysical, chemical and radiative properties of contrails and natural cirrus clouds, but also several elevated aerosol layers from different origins were detected with extended aerosol in-situ instrumentation.

On 16 September 2011 an elevated biomass burning aerosol layer was measured at altitudes between 10000 m and 11500 m above sea level over north-eastern Germany. Backward trajectories show that this layer originated from boreal forest fires in Northern America around 3 - 5 days before measurement. The biomass burning layer was not only detected by the Falcon, but also by several ground-based LIDAR stations, e.g. at IfT in Leipzig. The combination of airborne and ground-based data provides information on the vertical and horizontal extent of this layer which is necessary to quantify the layer's radiative effects. In our presentation we show data from a Single Particle Soot Photometer (SP2) which demonstrate that a distinct fraction of the particles (6 – 13 %) contains a BC core core (> 70 nm BC mass equivalent diameter) surrounded by a volatile coating. Such coatings can enhance the absorption of BC particles (e.g. Schwarz et al., 2008). The calculated coating thickness of the BC particles in the biomass burning layer is unusually high and distinctly larger than the coating thickness of freshly emitted boundary layer aerosol particles (Fig. 1). BC mass concentrations of the layer reach up to 0.13 µg m^{-3} in the BC (core) mass equivalent diameter range of roughly 70 nm up to 440 nm with the mode of distribution in-between 140 and 220 nm.

We performed additional calculations of optical properties for the biomass burning layer. The imaginary part of refractive index is lower than that of tropical biomass burning layers observed during the SAMUM campaign (Weinzierl et al., 2011). The Ångström exponents of absorption are larger than expected for pure black carbon but agree well with brown carbon (BrC), which can be produced during biomass burning events.

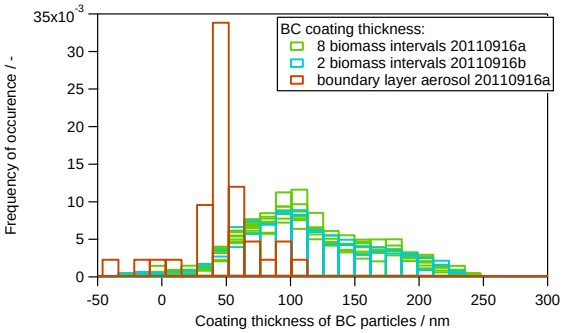

Fig. 1: Coating thickness of BC particles from observed layer (green and blue) in comparison to boundary layer BC particles (red).

Comparison of methods for generating bioaerosols

J. Löndahl[1], O. Nerbrink[2], N. Burman[1], A. Thedeby[1], A. Massling[3], T. Santl Temkiv[3], M. Bohgard[1], U. Gosewinkel Karlson[3]

Keywords: bioaerosols, generation of aerosols, atmospheric aerosols, bacterial activity
Presenting author email: jakob.londahl@design.lth.se

Bioaerosols include viable bacteria, viruses, dead bacterial cells, pollen, fungi and cell fragments, as well as numerous organic compounds derived from biomolecules as, for example, sugars, amino acids and methyl-derivatives. It has been shown that airborne bacteria may be viable also in the harsh conditions at high altitudes in the atmosphere and transmit diseases as well as act as cloud condensation nuclei (CCN) and ice nuclei (IN). Furthermore, they are able to influence cloud chemistry (Santl Temkiv, 2012).

In order to study the properties of bioaerosols in a laboratory setting it is necessary to use a generation methodology that preserves bacterial viability and minimize coating with redundant solvent impurities as this will increase particle size and distort chemical analysis. Few studies describe generation of bioaerosols, especially with respect to aerosol coating, background concentration and viability. The objective of this work is to compare various aerosol generators for bacteria, spores and vesicles.

Seven aerosol generators are investigated: atomizer (TSI Inc., Model 3075), Collison nebulizer (BGI Inc., 3-jet), vibrating orifice aerosol generator (VOAG, TSI model 3450), electrospray (TSI Inc., Model model 3480) and a bubble flask, a medical nebulizer (Dolema, Aeroneb ProX) and a custom-built liquid bubbler.

At this point, exclusively *Rhodoccocus sp.* (a common soil bacterium) is studied. Particle number size distributions were measured with a scanning mobility particle sizer (SMPS, design: Lund University) and an aerodynamic particle sizer (APS, TSI Inc., Model 3321) in a 1 m^3 stainless steel chamber ("Bio-cube") with controlled ventilation, temperature and relative humidity. Bacterial viability is analysed by counting colony forming units (CFU) on gelatin membrane filters and – in future studies – possibly also by fluorescence.

Figure 1 shows the particle number size distribution of the particles produces with the TSI atomizer. There is a peak of bacteria at 0.75 µm. The number concentration of bacteria were around 4 cm^{-3}, while the background salt particles in the range 10 to 200 nm (GMD 40 nm) had a concentration around 3000 cm^{-3}. The bubble flask generated lower bacterial concentrations, but also lower background. The VOAG produced uniform, but comparably large droplets (typically 20-40 µm). When dried, the background particles therefore had a size around 500 nm, while the bacteria had a peak at about 1.7 µm which indicates a significant coating. The electrospray could not be used for bacteria, since they are too large, but may be appropriate for bacterial outer membrane vesicles and spores.

The full matrix of generation methodologies is not yet available, but the preliminary results clearly show that many of the methods commonly used for generation of bioaerosols are unsuitable for examination of key properties of the particles such as CCN or IN ability. A surface coating of bioaerosols may significantly alter these abilities especially when soluble substances are involved. Any background in the measurements may also make a systematic evaluation difficult.

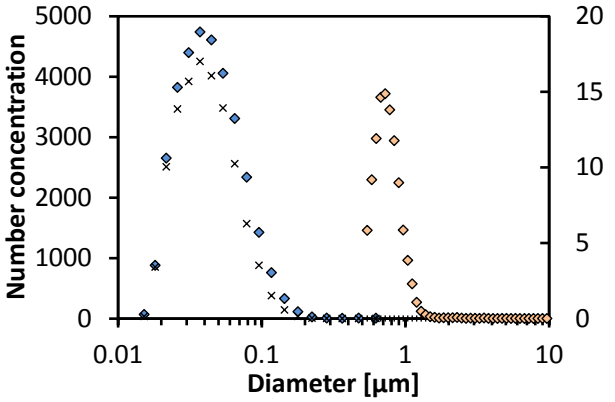

Figure 1. Particle number size distribution for bacterial solution (filled makers) and distilled water (x) produced with nebulizer.

It is often difficult to provide bioaerosols from distilled water of high purity since the organism typically need some surrounding additives (salts etc.) for survival.

It seems that the electrospray method is suitable for particles up to 200 nm. This instrument leaves a minor surface coating due to a small initial droplet size. For larger particles it may be crucial to estimate the amount of surface material in order to draw conclusions about particle properties while they are airborne.

Seasonal and spatial characteristics of fungal spore tracers in Taiwan

G. Engling[1], S.H. Chen[1] and B.J. Tsuang[2]

[1]Department of Biomedical Engineering & Environmental Sciences, National Tsing Hua University, Hsinchu 300, Taiwan
[2]Department of Environmental Engineering, National Chung-Hsing University, Taichung, Taiwan
Keywords: bioaerosol, ambient PM, molecular tracer, arabitol
Presenting author email: guenter@mx.nthu.edu.tw

Biological aerosol particles are found in ambient air in form of pollen, fungi, bacteria, viruses, algae, and plant fragments. Recent estimates have shown that such bioaerosols may constitute a substantial component of atmospheric particulate matter (PM) on global scale, and specifically in coarse aerosol particles (Jaenicke *et al* 2007, Heald and Spracklen 2009). Fungal spores in particular are an important type of bioaerosol (Elbert *et al* 2007).

A new approach for estimating fungal spore contributions to ambient PM was proposed by Bauer *et al* (2008a), utilizing molecular source tracers, i.e., the sugar alcohols arabitol and mannitol. Recent measurements by our group, applying the method introduced by Bauer *et al* (2008a,b), revealed that fungal spore contributions to coarse PM can be rather high in tropical regions (up to 26% of organic carbon (OC) and up to 18% of PM_{10} (Zhang *et al* 2010).

Ambient conditions, such as temperature and relative humidity, will influence biological activity, including fungal spore release rates. Furthermore, fungal species in different locations likely have varying polyol contents. It is, therefore, important to determine the abundance of these tracers in ambient PM as a function of environmental conditions and location.

For this study, size-resolved PM samples were collected at several locations across Taiwan, including urban, rural, coastal, and mountain sites, using Hi-vol samplers. The polyols arabitol and mannitol, as well as other carbonaceous species, were quantified in the PM samples by high-performance anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD).

While only fine particles ($PM_{2.5}$) were collected at an urban site in northern Taiwan (Taipei) and at a remote forest site in the southern part of the island (Liouguei, Kaohsiung County), both fine and coarse PM ($PM_{2.5-10}$) samples were obtained from a remote high-altitude site in central Taiwan (Bei Tung-Yen Shan, 2080 m asl) and at a coastal site at the northern tip of Taiwan (Fuguei Jiao).

The preliminary results from this study showed distinct temporal patterns in the ambient concentrations of the fungal spore tracers, as well as a particle-size dependence. Surprisingly high arabitol concentrations of up to 50 ng/m^3 were observed during summer in $PM_{2.5}$ at the urban site. Utilizing the conversion factors from Bauer *et al* (2008a,b), these ambient levels correspond to contributions to organic carbon (OC) of roughly 10%. In contrast, during winter and spring the ambient tracer concentrations decreased drastically to values below 1 ng/m^3, indicating minimal fungal activity during the cold season (Figure 1).

At the mountain site, the absolute tracer levels were comparatively smaller throughout the year, likely due to the lower ambient temperatures in the alpine environment. Nevertheless, the tracer concentrations showed again a clear seasonal pattern with lowest values in autumn and winter, and relatively high levels during spring. No diurnal patterns were observed in the tracer levels at any of the sites and during any season. Ambient concentrations of arabitol and mannitol were well correlated, especially in coarse PM, indicating common sources, i.e., fungal spores.

In summary, characteristics of molecular fungal spore tracers in size-resolved PM were observed in various subtropical environments, showing clear spatial and temporal patterns in the ambient tracer concentrations. Additional work is needed, and is in progress in our lab, in order to investigate fungal spore characteristics as a function of different fungal species and other environmental conditions.

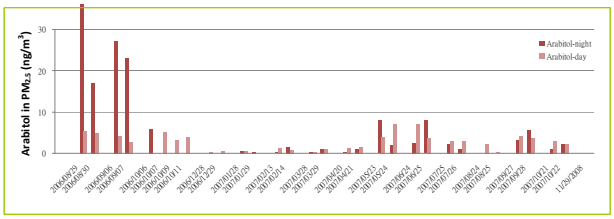

Figure 1. Ambient concentrations of arabitol in $PM_{2.5}$ at the urban site (Taipei).

Numerical modelling of pollen concentrations: a comparison to measured concentrations

K. Zink[1], A. Pauling[1], B. Clot[1] and M.W. Rotach[2]

Pollen allergies are a very common disease in modern society. Pollen forecasts are frequently used to help doctors and patients in their diagnosis and treatment of the allergenic symptoms. Traditionally, these forecasts are based on pollen monitoring, climatological information about the typical pollen seasons and the current weather forecasts. The main drawbacks of this approach are its limitations regarding spatial and temporal resolution. A new approach that has just been set into operation is the use of numerical weather prediction systems to calculate the dispersion of pollen grains in the atmosphere.

The model system COSMO-ART

The numerical modelling of pollen concentrations requires several input variables and parameterizations within the model. The full life cycle of pollen grains has to be accounted for, starting with the growing of the plant, the ripening and release of the pollen grains, their transport within the atmosphere and ending with their removal from the atmosphere by sedimentation and deposition. The transport and removal processes can be calculated using the equations that were developed for other aerosol types, such as mineral dust or sea salt. At MeteoSwiss, we are using the NWP system COSMO-ART, an extension of the COSMO model developed at the Karlsruhe Institute of Technology (Vogel *et al*, 2009). It is designed for the distinct calculation of **A**erosols and **R**eactive **T**race gases, but also includes modules for soot, mineral dust, sea salt, and pollen. The calculation of the emission flux of pollen grains requires knowledge about the sources (i.e. plant distribution maps), the current state of the pollen season and a parameterization of the biological and meteorological processes leading to pollen emission.

Parameterizing pollen emission

Helbig *et al* (2004) have developed an emission parameterization that has been used for tree pollen emission. It has been implemented into COSMO-ART and used for simulations of birch (Vogel *et al*, 2008) and ragweed pollen (Zink *et al*, 2011). However, this parameterization shows some drawbacks, especially when applied to smaller plants, such as ragweed or grasses. To overcome some of these drawbacks and to strengthen the biological processes, we have developed a new parameterization. It focuses on the description of the individual steps that lead to the ripening of the pollen grains, the rupture of the anthers, the removal of the grains from the flowers, and their entrainment into the atmosphere.

Case study: simulating an entire pollen season

We have implemented the new emission parameterization into COSMO-ART. A first test, taking the birch pollen season of 2010 as an example, has shown that the simulations using the new emission parameterization score similarly compared to the ones using the Helbig *et al* (2004) parameterization (see Figure 1). In both cases, statistical analyses have been used to compare the numerical values to measurements of pollen concentrations.

It should be noted that in the first test phase of 2010, the new parameterization has not been tuned yet. On the contrary, we are using the data of 2010 to adapt the parameters used in the formulations. The pollen season of 2011 will then be used as a case study to compare the performance of the two model variations.

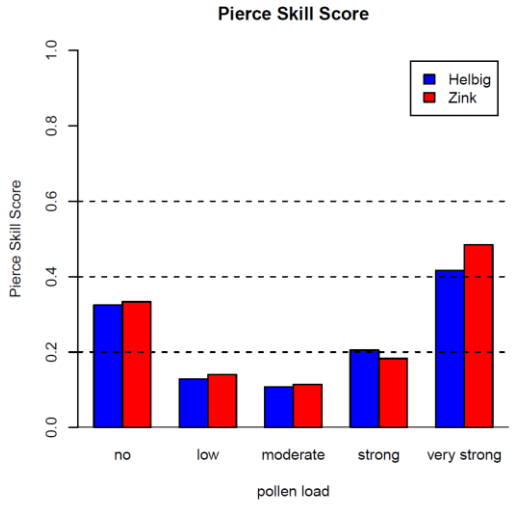

Figure 1. Pierce Skill Score (for formulas and explanations see Wilks, 2006) for different pollen classes using the new (Zink) and old (Helbig) emission parameterizations.

Session WG03S1O. Chemistry of Organic Aerosol: Laboratory Study 1

Simultaneous study of gas and particulate products formed from isoprene oxidation: laboratory and field measurements

C. Rio[1], S. Rossignol[1], S. Fable[1], L. Chiappini[1]

[1]Institut National de l'Environnement Industriel et des Risques (INERIS), 60 550 Verneuil-en-Halatte, France
Keywords: Isoprene, SOA, Gas-particle distribution, Smog chamber.
Presenting author email: caroline.rio@ineris.fr

Isoprene is one of the most abundant non-methane hydrocarbons emitted by vegetation into the troposphere. For a long time, it has been generally accepted that isoprene oxidation did not contribute to global SOA burden because of the volatility of its main oxidation products (methacrolein, methyl vinyl ketone…) (Pandis, 1991). It is only recently that isoprene oxidation contribution to SOA formation has been proven (Edney, 2005; Kroll, 2006).

There are still remaining uncertainties on the importance of isoprene contribution to atmospheric SOA and further studies combining ambient measurements of tracers, identified in laboratory experiments, coupled with atmospheric modeling are needed to better parameterize SOA yields and quantitatively model SOA production from isoprene oxidation (Carlton, 2009).

Therefore, the first part of this work focuses on laboratory experiments to study isoprene oxidation under realistic conditions in the EUropean PHOtoREactor (EUPHORE) in Valencia during the period 13–22 September 2010 (Figure 1(a)): seed aerosols (10 µg/m^3) were present in the chamber before isoprene and H_2O_2 introduction (70 ppb and 4 ppm respectively) under sunlight irradiation and a relative humidity close to 30 %. Moreover this study of the (isoprene + OH) reaction was performed under free-NOx condition.

A method recently developed in our laboratory (Rossignol, 2012) was used to investigate the chemical composition of both gas and particulate phases of SOAs formed.

This method consists in using stainless steel Tenax-TA adsorbent tubes previously coated with PFBHA (to specifically study carbonyl compounds) or MTBSTFA (to specifically study hydroxyl compounds) to collect the gas phase. Particulate sample are collected onto filters (quartz and Teflon-Quartz) subsequently exposed to PFBHA or MTBSTFA before analysis. These tubes and filters are subsequently analyzed by thermal-desorption coupled with gas chromatography and mass spectrometry (TD-GC-MS) analysis.

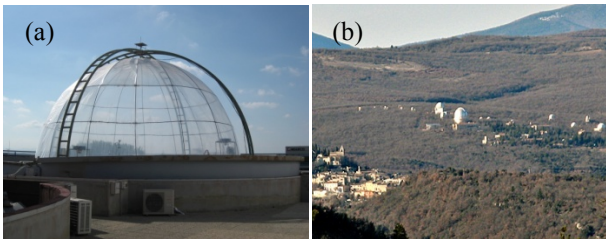

Figure1: (a) EUPHORE smog chamber, (b) St.Michel l'Observatoire with OHP in the background

About thirty compounds have been positively or tentatively identified in gas and/or particle phases. Some of these are monofunctionalized such as methacrylic acid or methacrolein, others are polyfunctionalized such as malic acid. These compounds have been quantified and for those identified in both gas and particulate phases, an experimental partitioning coefficient was calculated.

In a second time, these results will be compared to real atmosphere samples during a field campaign which will take place in June 2012 at the Observatoire de Haute provence (OHP; situated in southeast France) (Figure 1(b)) as a part of the CANOPEE field campaign. This work falls within the framework of a research program about the study of combined model-measurement of intra canopy chemistry. Not only gas and particles samplings will be realized but particles formation and isoprene emission will be observed at the same time.

Results obtained in both smog chamber and field campaign during isoprene oxidation will be presented and discussed.

Do Organic Aerosols Shrink?

N.M. Donahue[1], E. S. Robinson[1], A. Ahern[1], E. Trump, and R. Saleh[1]
[1]Center for Atmospheric Particle Studies, Carnegie Mellon University, Pittsburgh, Pennsylvania, 15213, USA
Keywords: dilution, organic aerosol, aerosol dynamics.
Presenting author email: nmd@andrew.cmu.edu

There is considerable current controversy about whether atmospherically relevant organic aerosols show significant semi-volatile behavior or whether they are less volatile than they were once thought to be. Furthermore, "less volatile" could mean that the organic aerosol is comprised of constituents that simply have a lower saturation vapor pressure than thought, or it could mean that relatively volatile organic compounds have some strange affinity for the condensed phase and thus remain in a disequilibrium state with an excess in the particle phase.

We have addressed this question experimentally and theoretically via a number of avenues. Using single particle measurements of prepared external mixtures, often with isotopic labeling, we observe the mixing behavior of organic particles via gas-phase vapor exchange (which necessarily requires evaporation of constituents from their original particles). Using the common model α-pinene SOA system, we have injected aliquots of fresh α-pinene SOA into a clean receptor chamber at dilution ratios of 100-1000 and observed the evaporation behavior of the aerosol. We have performed these experiments over a range of relative humidities, testing the hypothesis that absorbed water might plasticized the potentially glassy but demonstrably water soluble SOA. Finally, we have added water to an initially stable α-pinene SOA system, generated at low RH, to explore the sensitivity of the SOA mass and composition to absorbed water.

For test external mixtures we can indeed observe rapid mixing, though some systems with relatively low saturation concentrations remain externally mixed over the timescale of our experiments. We can thus observe systems that do and do not mix with each other.

The α-pinene SOA does contain some organic matter that evaporates more slowly than simple models based on SOA growth experiments predict: roughly 1/3 of the SOA evaporates very quickly, while the remaining 2/3 evaporates slowly over the course of many hours, never appearing to reach a stable equilibrium value. However, the general behavior is not a function of relative humidity and thus does not appear to have anything to do with the makeup of the condensed phase. We thus conclude that it is most likely that the SOA includes a portion of quite low volatility compound, which either simply evaporate slowly or which decompose on a several hour timescale into volatile fragments.

Finally, the slow humidification experiments allow us to follow the influence of water on the phase partitioning of organics over a wide range of RH and total organic aerosol loading.

We have developed a dynamical model of these mixtures, and will present comparisons of the modeled evaporation / equilibration of the organic systems studied with the observed behavior.

Gas phase formation of extremely oxidized α-pinene reaction products and their role in aerosol particle formation

High-sensitivity, high-resolution time-of-flight mass spectrometers (TOFs) have become increasingly more common in atmospheric science during the last years. In this work, we have taken advantage of the newest instrumentation, using a novel combination of TOFs for α-pinene oxidation studies, with a focus on the ability of the gas-phase products to form aerosol particles.

The TOF instruments used were:

1) Atmospheric pressure interface TOF (APi-TOF; Junninen et al., 2010)
2) Proton transfer reaction TOF (PTR-TOF; Jordan et al., 2009)
3) Acetate chemical ionization APi-TOF (Ac-CIMS; Bertram et al., 2011)
4) Nitrate chemical ionization APi-TOF (NO3-CIMS; Jokinen et al., 2011)

The APi-TOF measures naturally charged ions formed by cosmic rays and radon decay. This method is extremely sensitive, but selective, to very stable negative or positive ions. The PTR-TOF is the most widespread and well-characterized MS of the four, capable of measuring volatile organic compounds (VOCs) with proton affinities higher than water. The Ac-CIMS detects acids stronger than acetic acid, and is thus sensitive to most gas-phase acids. The NO3-CIMS detects ions that are either charged by clustering with, or by transferring a proton to, NO_3^-. In practice this means that it is mainly selective to very strong acids.

Initially, only the APi-TOF was used to detect and identify a new group of highly oxidized multi-functional organics (HOMs) from α-pinene ($C_{10}H_{16}$) ozonolysis at the Jülich plant atmosphere chamber (JPAC). The HOMs typically contained all the original ten C atoms, while reaching O:C ratios of 0.7-1.3. The spectra resembled APi-TOF spectra acquired in a boreal forest to stunning detail (Ehn et al., 2012). The HOMs are expected to have extremely low vapor pressures, and thus can play an important role in new aerosol particle formation. Motivated by these results, a novel measurement setup was deployed at JPAC to study the oxidation process of α-pinene, and relate the products to aerosol particle formation. The setup included a PTR-TOF, Ac-CIMS, and an NO3-CIMS. A particle size magnifier (PSM) was deployed to count the newly nucleated particles in the size range where they are formed (1-2 nm). In addition to these instruments, the standard JPAC setup includes basic particle (CPC, SMPS) and gas-phase (O_3, RH, OH (by tracer), etc.) measurements.

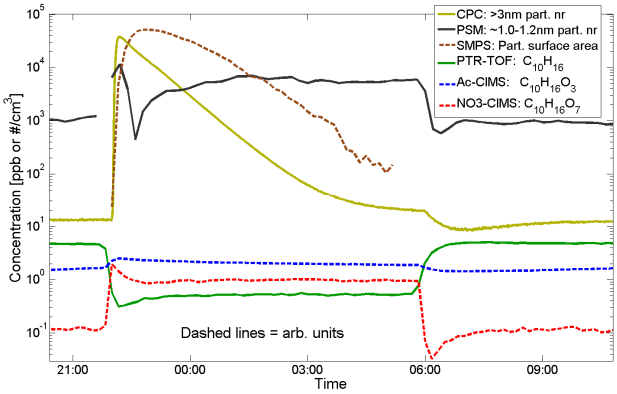

Fig. 1. Selected traces from 6 different instruments during one OH-initiated nucleation event from α-pinene. UV lights were on 22:00-06:00. Dashed traces in a.u.

As an example of the strength of the measurement setup, traces from 6 different instruments are presented in Fig. 1. The bottom three traces depict example gas-phase molecules, with α-pinene in green, and two oxidation products in blue and red (currently only in a.u.). The red trace is an example of the newly discovered HOMs. The upper traces are particle signals, which show sharp increases in both PSM (1.0-1.2 nm) and CPC (>3 nm) number at 22:00 when the UV lamps are turned on, coinciding with a large increase of $C_{10}H_{16}O_7$ (and many other HOMs).

The main findings from similar studies, under varying conditions to probe several different atmospheric conditions, will be presented.

α-Pinene and β-pinene ozonolysis
- Effect of CO on SOA formation and product distribution -

A. Kahnt*, Y. Iinuma, A. Mutzel, O. Böge and H. Herrmann

Leibniz Institute for tropospheric research (IfT), Department of Chemistry, Leipzig, D-04177, Germany
* Present address: Department of Pharmaceutical Sciences, University of Antwerp, Antwerp, B-2610, Belgium
Keywords: SOA, Smog chamber, Aerosol characterisation.
Ariane.Kahnt@ua.ac.be

The past studies have shown that an HO_2/RO_2 ratio influences the SOA formation chemistry in alkene ozonolysis. Depending on the structures of alkenes, the production of SOA increases or decreases as the HO_2/RO_2 ratio increases. While the influence of high HO_2/RO_2 ratio on SOA yields is established, its impact on the product distribution is rarely studied. In the present study, we examine SOA formation from monoterpene ozonolysis in the presence of CO as an OH radical scavenger and different seed particle acidities. The addition of CO results in the formation of HO_2 radicals from the reaction of the scavenger with OH radicals, leading to a high HO_2/RO_2 ratio in the system. CO is an attractive OH radical scavenger for aerosol chamber experiments because it achieves an HO_2/RO_2 ratio similar to that of ambient atmosphere under low NO_x conditions (< 100 ppt), which is typically between 0.25 – 1.33 (e.g., Stevens et al., 1997; Hanke et al., 2002; Mihelcic et al., 2003; Fuchs et al., 2008). Based on simulations using the COPASI 4.8 model, the HO_2/RO_2 ratio under the conditions applied in the present study is simulated to be 1 that is close to ambient conditions.

In the presence of CO, an increase in SOA formation was observed for the endocyclic α-pinene whereas an opposite was the case for exocyclic β-pinene. As shown in Figure 1 for the α-pinene ozonolysis, the presence of CO and acidic seed particles resulted in the highest organic mass increase at a given hydrocarbon conversion. Furthermore, an increase in SOA formation was observed for all the experiments using acidic seed particles for α-pinene.

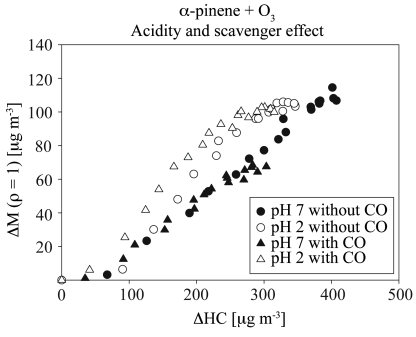

Figure 1. SOA growth curves from α-pinene ozonolysis with (triangle) and without (circle) CO as an OH radical scavenger. The different seed particle acidities are shown with filled symbols for pH 7 and open symbols for pH 2.

In contrast the ozonolysis of β-pinene resulted only in a marginal increase in organic mass in the presence of CO and acidic seed particles (see Figure 2).

As shown in Figure 2 the experiments performed without CO showed no acidity dependency in organic mass formation.

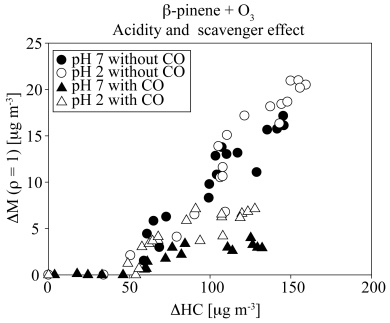

Figure 2. SOA growth curves from β-pinene ozonolysis with (triangle) and without (circle) CO as an OH radical scavenger and different seed particle acidities.

The results obtained in the present study support the differences in the products of α- and β-pinene ozonolysis as proposed by Docherty et al. (2005). While the ozonolysis of α-pinene at elevated HO_2 levels likely resulted in a C10 hydroperoxide, β-pinene oxidation led to a more volatile C9 ketone hydroperoxide. The enhanced SOA growth observed in α-pinene ozonolysis when the CO and acidic seed particles co-existed may be explained by an acid-catalysed reaction of the organic peroxides that led to the formation of higher molecular weight compounds.

The aerosol analysis supports this suggestion as only marginal differences in the relative contribution of carboxylic acid and carbonyl compounds to the detected total organic mass were observed regardless of the experimental conditions.

Is the chemical composition of α-pinene secondary organic aerosol dependent on particulate water content?

L. Pfaffenberger, P. Barmet, R. Wolf, J. G. Slowik, J. Dommen, A. S. H. Prévôt and U. Baltensperger

Laboratory of Atmospheric Chemistry, Paul Scherrer Institut PSI, Villigen, 5232, Switzerland

Keywords: AMS, Photochemical processes, SOA (Secondary Organic Aerosols), Water soluble organic compounds

Organic aerosols (OA) represent with 20-90% a major fraction of the submicron aerosol (Jimenez et al., 2009). Potential sources and processes which lead to the formation of secondary organic aerosol (SOA) are still rather poorly understood, although SOA contributes to a large amount to the OA burden. To determine properties relevant for aerosol yield, in particular volatility and degree of oxygenation, the formation and aging of particles have to be investigated more intensively.

Several laboratory studies showed the importance of aqueous phase SOA formation that is thought to be almost as important as SOA compounds that form in the gas phase and then partition to the aerosol phase (Ervens et al., 2011).

The uptake of water-soluble organic compounds depends on the water content of the particles and is higher for larger particle diameters. In this study, the aerosol chemical composition as a function of the vacuum aerodynamic diameter (d_{va}) is investigated using an Aerodyne aerosol mass spectrometer (AMS) equipped with a PM 2.5 lens.

In the PSI smog chamber, the aerosol precursor α-pinene was exposed to UV and xenon lights in the presence of a seed, various relative humidities and NO_x concentrations. NH_4HSO_4 was used as a hygroscopic seed to provide a large water volume capable of taking up soluble oxidation products like glyoxal and methylglyoxal. A wide diameter range, ~50 to 2500 nm, was covered by the particle phase instruments. The aging time in the chamber is related to the atmospheric oxidation time using the OH exposure derived from the decay of an OH tracer added into the bag (Barmet et al. 2011).

Fig. 1 shows the normalised mass spectra for two different diameter bins (100nm-500nm and 500nm-2500nm) averaged over the whole experiment duration in the lower panel and the difference in those spectra in % (upper panel). The presented experiment was conducted at 72 ± 1 % relative humidity and 1.0 ± 0.2 ppb NO_x.

Significant changes are seen in several masses referring to a change in chemical composition. *m/z* 44, a surrogate for the degree of oxygenation, is enhanced in the larger particles compared to the smaller ones.

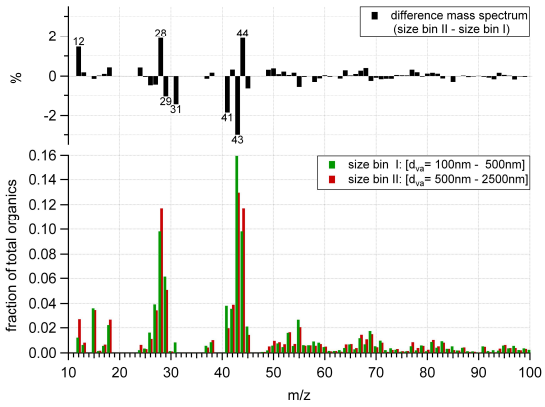

Figure 1: Normalized average mass spectra of two different diameter ranges (lower panel) and the difference [size bin II-size bin I] (upper panel).

This could be due to the larger available water contents which would favour aqueous phase processes and lead to more highly oxygenated products like acids. However, composition-dependent differences in particle vaporization time could also contribute to such differences. The relative importance of these effects will be assessed by analysis of single particle mass spectra acquired using a light scattering module integrated with the AMS.

Further investigations on the evolution of the chemical composition during the experiments and the dependency on the prevailing relative humidity will be part of this study.

This work was supported by EUROCHAMP-2, a research project within the EC 7th Framework Programme, as well as the Swiss National Science Foundation.

Kinetic multi-layer model of gas-particle interactions in aerosols and clouds (KM-GAP): linking condensation, evaporation and reactions of organics, oxidants and water

M. Shiraiwa[1], C. Pfrang[2], T. Koop[3] and U. Pöschl[1]

Keywords: gas-particle partitioning, semi-volatile species, oxidative aging, secondary organic aerosol.
Presenting author email: m.shiraiwa@mpic.de

We present a novel kinetic multi-layer model for gas-particle interactions in aerosols and clouds (KM-GAP) that treats explicitly all steps of mass transport and chemical reaction of semi-volatile species partitioning between gas phase, particle surface and particle bulk (Shiraiwa et al., 2011). KM-GAP is based on the PRA model framework (Pöschl et al., 2007), and it includes gas phase diffusion, reversible adsorption, surface reactions, bulk diffusion and reaction, as well as condensation, evaporation and heat transfer. The size change of atmospheric particles and the temporal evolution and spatial profile of the concentration of individual chemical species can be modeled along with gas uptake and accommodation coefficients. Depending on the complexity of the investigated system, unlimited numbers of semi-volatile species, chemical reactions, and physical processes can be treated, and the model shall help to bridge gaps in the understanding and quantification of multiphase chemistry and microphysics in atmospheric aerosols and clouds.

In this study we demonstrate how KM-GAP can be used to analyze, interpret and design experimental investigations of changes in particle size and chemical composition in response to condensation, evaporation, and chemical reaction. For the condensational growth of water droplets, our kinetic model results provide a direct link between laboratory observations and molecular dynamic simulations, confirming that the accommodation coefficient of water at ~270 K is close to unity (Fig. 1). Literature data on the evaporation of dioctyl phthalate as a function of particle size and time can be reproduced (Fig. 2), and the model results suggest that changes in the experimental conditions like aerosol particle concentration and chamber geometry may influence the evaporation kinetics and can be optimized for efficient probing of specific physical effects and parameters. With regard to oxidative aging of organic aerosol particles, we illustrate how the formation and evaporation of volatile reaction products like nonanal can cause a decrease in the size of oleic acid particles exposed to ozone.

So far the formation and aging of secondary organic aerosol (SOA) has generally been described by thermodynamic models assuming quasi-instantaneous gas-particle partitioning. If, however, the phase state of SOA is not liquid but (semi-)solid (Virtanen et al., 2010), this assumption may break down and the SOA partitioning may be kinetically limited (Shiraiwa et al., 2011). We suggest and intend to use KM-GAP for the investigation of such effects.

The effect of humidity on the ozonolysis of unsaturated compounds in aerosol particles and on particle phase

M. Kalberer, F.D. Pope, P.J. Gallimore, P. Achakulwisut J. Lee, J. F. Davies, V. Garrascon, S. Fuller, A. Björkegren and D. R. Spring

[1]Department of Chemistry, University of Cambridge, Cambridge, CB2 1EW, UK

Presenting author email: markus.kalberer@atm.ch.cam.ac.uk

Atmospheric aerosol particles are important in many atmospheric processes such as light scattering, light absorption, and cloud formation. Oxidation reactions continuously change the chemical composition of aerosol particles, especially organic components, which are often a dominant fraction. These ageing processes are poorly understood but are known to affect the cloud formation potential of aerosol particles.

In this study we investigate the effect of humidity and ozone on the chemical composition and phase of three model organic aerosol systems: oleic, maleic and arachidonic acid. Two experimental techniques are combined in this investigation. An electrodynamic balance (EDB) is used to levitate single particles and assess changes in particle size and mass (due to water uptake and/or loss of volatile ozonolysis products) and phase (liquid or solid) during and after chemical processing with ozone (Pope et al., 2010). An aerosol flow tube was used to investigate the chemical composition of the processed aerosol particles with off-line ultra high-resolution mass spectrometry (Gallimore et al., 2011).

The role of relative humidity (RH) in the oxidation scheme of the three carboxylic acids is very compound specific (Lee et al., 2012). RH was observed to have a major influence on the oxidation scheme of maleic acid and arachidonic acid, whereas no dependence was observed for the oxidation of oleic acid. In addition, the particle phase has a strong effect on the particle processing and the effect of water on the oxidation processes. Oleic acid is liquid under all conditions at room temperature (dry or elevated humidity, pure or oxidized particle). Thus ozone can easily diffuse into the bulk of the particle irrespective of the oxidation and RH conditions.

This is very different for maleic and arachidonic acid, which change their phase from liquid to solid upon oxidation or upon changes in humidity. In a solid particle the reactions of ozone and water with the organic particle are restricted to the particle surface. Only an exposure to high humidity, i.e. the formation of liquid particles allows for a diffusion of ozone into the particle bulk and an oxidative processing of the entire particle. Oxidation products of maleic acid and arachidonic acid are much more hygroscopic and therefore water is present in the liquid, oxidized particles in much higher mole fractions at elevated RH than in oleic acid particles.

The differences in the oxidation schemes of the three carboxylic acids are mainly explained by the very different reactivity (i.e. electron deficiency) of the Criegee intermediate (CI), one of the first reaction products in the oxidation scheme of all three systems (Figure 1). Reactions of the CI of oleic acid with other primary oxidation products leads to the formation of oligomers. In contrast, the maleic acid oxidation products are mostly monomeric and only dimers (but no higher oligomers) were formed in esterification reactions from stable oxidation products.

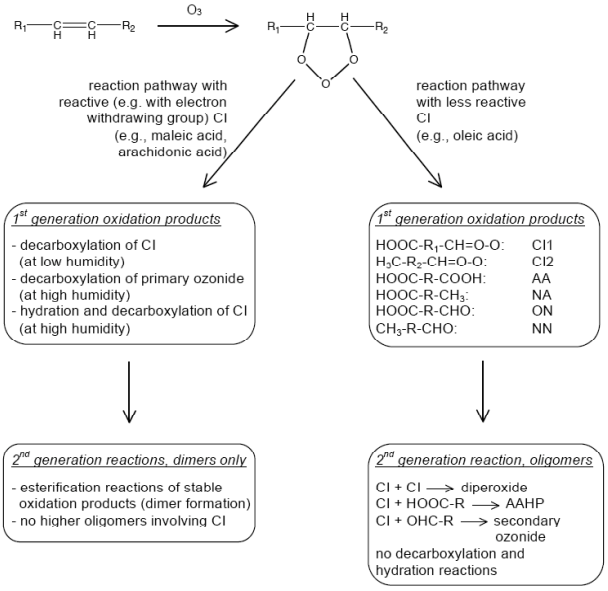

Figure 1. Schematic oxidation scheme of unsaturated compounds with ozone emphasizing the different reaction pathways due to the different reactivity of the Criegee intermediate.

In more complex and atmospherically relevant laboratory model systems such as secondary organic aerosol formed from terpenes ester formation are likely explaining a major fraction of the observed particle phase reactivity and especially the formation of short oligomers. In addition, in the ambient atmosphere high-mass oligomers are rarely observed. Thus the oxidation schemes of maleic where only a limited degree of oligomerisation is observed might be more representative of particle phase oxidation reactions occurring in the complex mixtures of ambient particles.

Composition, Reactivity, and Energetics of Sulphuric Acid Clusters Containing Ammonia and Amines

Bryan R. Bzdek[1], Joseph W. DePalma[1], Julia Laskin[2], Douglas P. Ridge[1] and Murray V. Johnston[1]

[1]Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware, 19716, USA

Keywords: aerosol kinetics, ambient nuclei, new particle formation, nucleation.
Presenting author email: bbzdek@udel.edu

New particle formation (NPF) may affect cloud albedo and climate by influencing global cloud condensation nuclei levels. To properly model the climate effects of NPF, its underlying mechanisms need to be fully understood. This work examines the composition, reactivity, and energetics of sulphuric acid clusters containing ammonia and amines.

The first portion of this work investigates the role of cluster size and charge on ammonium bisulphate cluster reactivity. Positively and negatively charged ammonium bisulphate clusters were analysed by Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS). Positively charged clusters differed significantly in composition from negatively charged clusters. Positively charged clusters exhibited enhanced neutralization to bisulphate, whereas negatively charged clusters were very acidic. With increasing cluster size, both polarity clusters converge towards ammonium bisulphate. Negatively charged cluster reactivity with dimethylamine (DMA) was also investigated by FTICR-MS. A specific cluster was selected and reacted with a constant pressure of DMA. As illustrated in Fig. 1, a plot of ion abundance as a function of trapping time was fit to the pseudo-first order rate law to determine the reaction kinetics and uptake coefficients. Two reaction types were observed: ammonia displacement by DMA and DMA addition to neutralize sulphuric acid to bisulphate. The displacement reaction was nearly collision-limited, whereas the addition reaction was very slow relative to exchange. These observations suggest: 1) amine-ammonia chemistry will only be evident and important in large ambient negative ions but will be evident in small ambient positive ions; 2) bisulphate is favored over sulphate at small cluster sizes; and 3) small (1-2 nm) ammonium salt clusters should easily exchange with amine to form aminium salts (Bzdek *et al*, 2011).

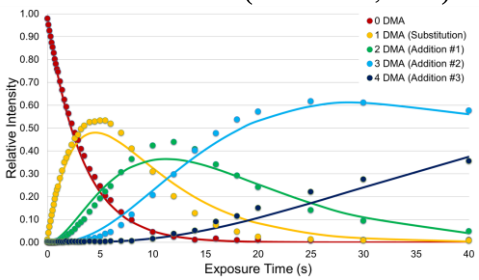

Figure 1. Reaction profile for exposure of $[(NH_4)(HSO_4)_2(H_2SO_4)_3]^-$ to DMA. Symbols are experimental values. Lines are fits to pseudo-first order kinetics.

The second portion of this work focuses on cluster growth mechanisms. Charged clusters were extracted into a FTICR-MS equipped with surface induced dissociation (SID), a method to fragment ions by impacting them onto a surface at known collision energy. Fig. 2 presents time- and collision energy-resolved fragmentation efficiency curves for dissociation of $[(NH_4)_6(HSO_4)_5]^+$. Upon collision, this cluster immediately dissociates to $[(NH_4)_3(HSO_4)_2]^+$, which further dissociates to $[(NH_4)_2(HSO_4)(H_2SO_4)]^+$ and $[(NH_4)_2(HSO_4)]^+$ with increasing collision energy. The experimental data were modeled using RRKM theory to determine the dissociation energetics (Laskin *et al*, 2000). Two other ammonium bisulphate clusters were also studied to determine the size dependence of cluster decomposition. Assuming that growth mechanisms are the reverse of decomposition mechanisms, association (growth) energetics can be determined from the decomposition energetics. Preliminary analysis suggests two cluster growth pathways exist: 1) stepwise growth by addition of sulphuric acid followed by ammonia; 2) growth by addition of an ammonium bisulphate monomer. The modeling suggests an activation barrier exists for the stepwise growth pathway, whereas none exists for the monomer growth pathway. The implications of these results will be discussed.

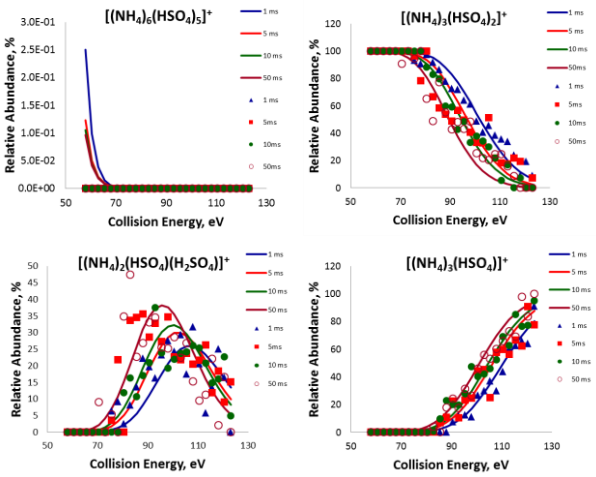

Figure 2. Fragmentation efficiency curves for $[(NH_4)_6(HSO_4)_5]^+$ decomposition. Symbols are experimental SID values. Lines are RRKM model fits.

Current levels of ambient air fine particulate matter are associated with mortality and morbidity in urban populations. Since large proportion of $PM_{2.5}$ emissions are derived from small scale combustion, it is important to reveal the possible health effects of the particle emissions from the combustion appliances. Especially there is a lack of knowledge concerning modern wood combustion systems. In this study, toxicological properties of PM_1 emissions from biomass combustion reactor operated by three different ways were examined.

Three different combustion conditions, efficient, erratic and poor, were generated in combustion reactor using wood chips as fuel. The efficient conditions corresponded to optimal biomass combustion and the poor conditions approach to conventional batch combustion. Instead, the erratic conditions represented malfunctioning of combustion appliance. The demanded combustion conditions were achieved by adjusting fuel feeding, air flows and air staging. (Table 1).

PM samples for toxicological analysis were collected on PTFE-filters from diluted flue gas by using Dekati® gravimetric impactor. Samples were extracted from filters using methanol. Mouse macrophage cells (RAW264.7) were exposed for 24 h to four doses (15, 50, 150 and 300 mg ml^{-1}) of emission samples.

The studied emission samples by all doses induced a statistically significant dose-dependent decrease in cell viability (MTT assay) when compared to control (Fig.1). However, the efficient combustion caused clearly more cytotoxicity than the other samples.

When cells cell cycle phases were analyzed (dose 150 mg ml^{-1}) statistically significant apoptosis was detected with erratic and poor combustion (Fig.2). All samples caused statistically significant decrease of G_1-phase when compared to control. Interestingly, only efficient combustion caused statistically significant increase in S-G2/M-phase which is considered as sign of cell cycle arrest caused by DNA damage.

The results indicated that even modern wood combustion appliances and optimal burning conditions may have health impact. Efficient combustion was causing highest cytotoxicity and clear cell cycle arrest. However, emissions from efficient combustion were negligible compared to two other situations and that is even more important when the aim is to reduce human exposure to PM.

Table 1. Emission parameters in averaged values.

Parameter	Efficient	Erratic	Poor
Number Conc.(1/MJ)	1.4E+14	5.5E+13	2.7E+13
PM_1 Mass Conc. (DGI)(mg/MJ)	8 ± 3	61 ± 47	135 ± 22
CO(mg/MJ)	7 ± 37	303 ± 633	2300±3300
CH_4 (mg/MJ)	0.3 ± 0.3	4 ± 21	115 ± 190
OGC (mg/MJ)	3.6 ± 1.4	7.1 ± 25	180 ± 340

Tobacco smoke is recognized as causal factor in various lung diseases. Both assessment of the toxicity and research into treatment options for smoke-related diseases require *in vitro* cell exposure systems for cigarette smoke. We have developed such a system (referred to as $ALICE_{CS}$) for cells cultured at the air-liquid interface using a combination. In this paper the $ALICE_{CS}$ is described and characterized with a combination of aerosol, photometric and biological measurement techniques.

Kentucky research cigarettes (prehumidified for at least 24h; RH = 60-70%) were smoked in a continuous flow mode (ca. 40 sec per cigarette) and the smoke was delivered via a stagnation point flow system to cells cultured at the air-liquid interface. The system is a scaled version of the one described by Tippe et al. (2002), where the cells are residing in up to 6 transwell inserts of a standard 6-well plate for cell cultures. The number size distribution of the smoke particles was determined with a scanning mobility particle sizer. The total aerosol mass generated per cigarette was determined by filter sampling and subsequent gravimetric analysis. The mass deposited on the cells and on other parts of the exposure system was measured using a combined gravimetric-photometric method. In addition, the cell-deposited mass was determined by a quartz crystal microbalance. Furthermore, the spatial homogeneity of the cigarette smoke on the cells was quantitatively investigated with a fluorescence imaging technique. Finally, the cytotoxicity and viability of a human epithelial cell line (A549) was investigated.

The total number and mass concentration of the cigarette smoke particles was about $1.5x10^7/cm^3$ and $380mg/m^3$, respectively. The CMD and σ_g was about 350 nm and 1.5, respectively. The average aerosol mass per cigarette was 38 mg and about 1% of this (0.36 mg) was deposited onto the 6 inserts. The corresponding cell-delivered dose of 14 $\mu g/cm^2$ per cigarette agreed to within 15% with the values obtained with the quartz crystal microbalance. The insert-to-insert variability of the dose was less than 10%. In addition, we determined the spatial uniformity of the cigarette smoke on the cells by placing a quartz fiber filter into the insert (instead of the cells). The exposed filter was imaged with a fluorescence imaging device (Caliper, Lumina II; excitation: 430nm; emission: 515-575nm) and analyzed quantitatively by evaluating the emitted light intensity along 36 radial trajectories (each shifted by 10 degrees). An example for the obtained fluorescence image of the filter and the corresponding light intensity profile along the trajectories is presented in Figure 1. This analysis revealed that the dose is uniformly distributed onto the cells with a pixel-by-pixel ($0.1x0.1\ mm^2$) variability of less than 7% (for the accumulated smoke of 4 cigarettes).

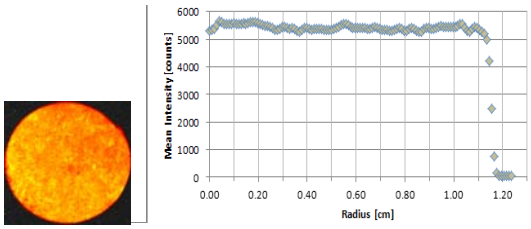

Figure 1. Left: Fluorescence image of a quartz fiber filter placed in a transwell insert where the cells are located (excitation: 430nm; emission: 515-575nm). Right: Emitted light intensity along a radial trajectory, where 0 represents the center of the spherical filter.

Finally, the $ALICE_{CS}$ was validated with human epithelial cells (A549). Cell viability (WST-1) and cytotoxicity (LDH) were measured for exposures with up to 6 cigarettes. No adverse effects on these parameters were observed for control experiments with clean air. However, exposure to 1 cigarette reduced the cell viability to about 30% and the cytotoxicity was increased to about 10%.

The $ALICE_{CS}$ is a viable tool for toxicity and health studies with highly concentrated aerosols such as cigarette smoke. To put the cell-delivered dose into perspective, we note that the estimated *in vivo* dose in the human lung is about $2x10^{-4}\mu g/cm^2$ per cigarette (assumed 60% deposition efficiency and 140 m^2 of exposed lung surface area). Thus, in spite of the relative small fractional *in vitro* deposition of about 1%, the $ALICE_{CS}$ delivers about 5 orders of magnitude more cigarette smoke onto the cells than encountered in a human lung.

The so called “Cyto-TP” is a thermal precipitator (TP) (Azong-Wara, 2009) for the exposure of living human epithelial lung cells to airborne nanoparticles for toxicity screening studies. It combines the advantages of nanoparticle settling aided by thermophoretic deposition with the features of a cell culture system at air-liquid interface (ALI), which makes it possible to deposit nanoparticles directly from the gas phase.

Thermophoresis is the motion of particles in gas phase within a temperature gradient towards the cold region (Hinds, 1999). The Cyto-TP establishes different temperatures on two parallel plates with 1 mm spacing. Particles entering the gradient will migrate onto the colder plate, where the cells are located. The cold plate’s temperature is kept at constant 37°C to not affect the cells negatively. The gradient (and the particle deposition) is controlled by setting the temperature of the warmer plate in the range of 42°C to 52°C. Thermophoresis causes a very low velocity and particles are deposited smoothly onto the cell surface. Cells are therefore not damaged by particle impaction. Unlike in similar concepts using electrophoresis for particle deposition, particles bear their natural charge level. Additionally the physicochemical properties of the particles are not affected like in suspensions. The concept of thermal precipitation and the cell hosting at Air-Liquid Interface is shown in figure 1.

A model was developed for the motion of nanoparticles within the Cyto-TP to simulate the deposition on the cells. The deposition density is homogeneous when temperature gradient and flow rate are in the optimal range. The simulation calculates the deposition efficiency on the cells. The Cyto-TP hosts two cell cultures, one for exposure and one for negative control, so two deposition efficiencies are determined where the latter should be zero.

To verify this model we deposited spherical fluorescent polystyrene latex (PSL) primary nanoparticles on the cells. The model becomes simple for spherical primary particles. By using fluorescent particles we could locate and count the deposited particles using a fluorescence microscope. We deposited PSL primary particles of four different sizes (50 nm, 100 nm, 500 nm, 1000 nm).

In this work we compare the simulated deposition efficiencies with the experimental results obtained by counting the particles after exposure. We analysed twenty areas of 100x100 µm on each cell culture for statistical reasons. We also determined the deviation of the total number of deposited nanoparticles in each area to gain a parameter of homogeneity. Good homogeneity is necessary to calculate the effective dose, deposited particles per cell, since the deposition density must be consistent on the whole surface of the cell culture. These measurements contribute to the validation of the Cyto-TP as a cell exposure system with a representative and controllable dosimetry.

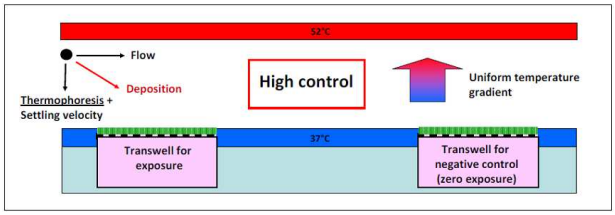

Figure 1. Overview of the concept of the Cyto-TP and cell hosting at Air-Liquid Interface. Deposition occurs due to thermophoresis and gravitational settling.

This presentation will focus on the dosimetric properties of the system. Technical aspects of the Cyto-TP will be discussed and the simulation model and first experiments for its verification presented.

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n°211464-2.

Presenting author email: elenaramos@ugr.es

Smectite together with kaolinite and illite, constitute the main part of the fine and ultrafine fraction in soils and sediments, as well as in airborne natural dust. Smectite has been identified by the World Health Organization as having the potential to produce moderate fibrosis in the lungs following long-term exposure (WHO, 2005). Harmful effects may be dependent on the dissolution rate in lung fluids. The aim of this study is to determinate the smectite dissolution rates in saline solutions that mimic synthetic lung fluids (SLF) to gain knowledge about the residence time of the inhaled clay particles in the human body.

Dissolution rates of K-montmorillonite were measured in modified Gamble's solutions at pH 4 (macrophages) and 7.5 (interstitial fluids) at 37ºC in stirred flow-through reactors. The particle size, measured by transmission electron microscopy, was of 500 nm in diameter. The effect of organic acids was investigated through the addition of 3 organic compounds present in the interstitial lung fluids: lactate, citrate and glycine. The effect of each organic compound was investigated separately through the addition of 3 different concentrations: 0.15, 1.5, 15 mmol L^{-1}.

The results showed that the addition of lactate or glycine does not markedly affect the montmorillonite dissolution rates at pH 4 irrespective of their concentration. However, at pH 7.5 there exists a slight inhibitory effect of lactate on the dissolution, probably due to a reduction in the number of reactive surface sites caused by lactate adsorption onto the montmorillonite surface. However, citrate enhances the dissolution rate by 0.5 orders of magnitude at pH 4 and more than one order of magnitude at pH 7.5, thus indicating the prevalence of the ligand-promoted over the proton-promoted dissolution mechanism under these experimental conditions. The enhancement of the dissolution rate in acidic citrate solution likely comes from the formation of surface complexes between the ligand and the edge surface of montmorillonite. In neutral conditions the effect may be also due to the decrease of the activity of Al^{+3} by formation of aqueous Al-Citrate complexes.

The kinetic data were used to estimate the reduction in size of an inhaled clay particle, by using a simple model (disk morphology of thickness *h* and radius *r*) and applying the following equation:

$$r^2 = r_0^2 - \frac{Rate_v}{\pi h} t$$

where *r* is the radius of the reacted particle at time *t*, r_0 is the inicial radius (250 nm), $Rate_v$ is the volumetric rate ($cm^3\ s^{-1}$) and *h* is the particle thickness.

The model showed that at pH 7.5 a particle of 500 nm in diameter could be reduced 25% in presence of citrate, whereas the reduction in saline solution would only be 10% after 10 years (Fig. 1).

We could conclude that the chemical clearance of inhaled phyllosilicates is limited in lung conditions and several years are necessary to halve the particles size, even in the presence of organic ligands.

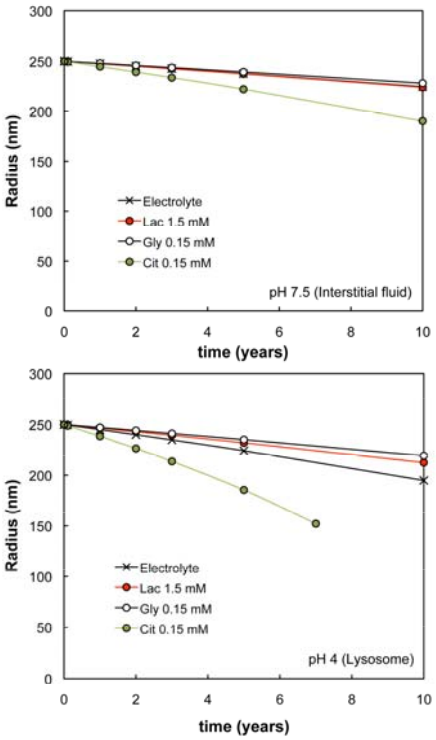

Figure 1. Decrease in the radius of a smectite particle during the dissolution in synthetic lung fluids.

Background:

Epidemiological studies show an association between the concentration of fine and ultrafine particles (PM10, PM2.5, PM0.1) in the atmosphere and the rate of mortality or morbidity due to respiratory and cardiovascular disease (Wichmann et al, 2000). The European Union therefore regulates the mass of ultrafine particle immissions, irrespective of their source, their chemical composition or their potential for adverse health effects, despite that the latter would be of utmost importance. Responsible for one third of the ultrafine particle emissions, domestic heaters are in the focus of interest. Especially the emissions of wood stoves containing a high amount of organic substances should be characterized regarding to their toxicological potential and thus adverse health effects in humans.

Material and Methods:

For the quantitative assessment of the toxicity of airborne particle emissions from domestic wood stoves the dose–response relationship is tested by *in-vitro* test systems using bioassays of cell cultures as sensor (Paur et al, 2011). Reproducible exposure of human lung cell cultures to aerosols at the air-liquid interface was achieved with the Karlsruhe Exposure System (Figure 1).

Figure 1. Karlsruhe Exposure System for Air-Liquid-Interface Testing of wood combustion aerosols (Mülhopt et al, 2007; Paur et al, 2008).

The bioavailability of particle bound Polycyclic Aromatic Hydrocarbons (PAH) (Gauggel et al., 2011) was tested using Ah-CALUX cells, i.e. a Ah-receptor transactivation assay, and two wood combustions runs.

Results:

Exposure of CALUX cells to wood combustion aerosol (Figure 2) in the KES was carried out during a 2.5 hours burn-off of 10 kg of beech logs and following dilution in a DEKATI dilution tunnel. Three cultures of the CALUX assay were exposed and compared to two cultures exposed to filtered aerosol. Upon exposure to biologically available PAH on wood combustion aerosol particles, CALUX cells presented with an increased luciferase activity and testimony of increased Ah-receptor activation.

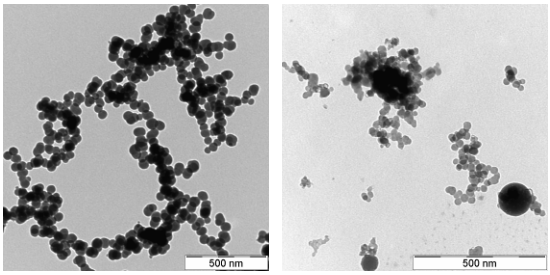

Figure 2. TEM images of particle emissions from a wood stove fired with 10 kg of beech logs.

An experimental comparison of dust resuspension due to human walking

Yilin Tian[1], Kyung Sul[2], Jing Qian[2] and Andrea Ferro[2]

[1]Institute for a Sustainable Environment, Clarkson University, Potsdam, NY, 13699, USA
[2]Department of Civil and Environmental Engineering, Clarkson University, Potsdam, NY, 13699, USA
Keywords: resuspension, dust, indoor air quality, respirable aerosols.
Presenting author email: tian@clarkson.edu

Resuspension is believed to contribute a considerable portion of human particulate matter exposure indoor (Yakovleva et al. 1999). In order to mitigate inhalation exposure of house dust, walking-induced particle resuspension was characterized as a function of flooring type (FT), surface dust loading (SDL), relative humidity (RH) and particle size. Distinct from previous studies, a consistent test mechanism was utilized instead of human participant to eliminate the impact of varied walking style, improve experimental reproducibility and facilitate a systematic comparison of the influencing factors mentioned above (Qian and Ferro 2008).

Developed by the Lawrence Berkeley National Laboratory, the resuspension mechanism is comprised of heel and toe plates controlled by electric actuators to simulate the human foot step. The resuspension mechanism is surrounded by a $0.13m^3$ plexiglass chamber with controlled temperature, relative humidity and filtered air supply. Air exchange rate inside the chamber was 1.38 ± 0.05 hr^{-1}.

Five types of flooring, including hardwood, vinyl, high density cut pile carpet, low density cut pile carpet and high density loop carpet were tested with two levels of RH (30-40% and 70-80%) and surface dust loading ($2g/m^2$ and $8g/m^2$), respectively. With a full factorial design, 60 randomized runs were conducted with 3 replicates for each treatment. The resuspension mechanism was equipped with a men's size ten tennis shoe and was operated for 30 continuous steps in each run with a consistent stepping frequency of 0.55 ± 0.03 Hz.

A portable laser particle counter was used to measure the particle size distribution between 0.4 μm and 10 μm. Resuspension rate coefficient r (1/h) was estimated based on the change in concentration of airborne particles following stepping motion of the resuspension mechanism using the method described in Qian and Ferro (2008).

Resuspension rate coefficients for house dust were found to vary from 10^{-4} h^{-1} to 10^{-1} h^{-1}, which is within the range of previous studies with actual humans walking (Manthena et al. 2008; Qian and Ferro 2008). Resuspension rate coefficients increase with the increase in particle size. Analysis of variance (statistic package: Minitab 16) results of main effects and two-factor interactions for each particle size bin with confidence level of 95% (α=0.05) are listed in Table 1 and Table 2, respectively.

Table 1. P-values for main effects of r

Particle size (μm)	Flooring type	RH	Surface dust loading
0.4-0.5	**0.004**	**0.054**	**0.000**
0.5-1.0	**0.005**	0.319	**0.000**
1.0-3.0	**0.000**	**0.025**	**0.003**
3.0-5.0	**0.000**	0.071	0.396
5.0-10.0	**0.000**	0.165	0.96

Table 2. P-values for two-factor interactions of r

Particle size (μm)	FY&RH	FY&SDL	RH&SDL
0.4-0.5	**0.019**	0.651	0.083
0.5-1.0	0.115	0.310	**0.014**
1.0-3.0	**0.007**	0.163	**0.008**
3.0-5.0	**0.000**	0.120	**0.004**
5.0-10.0	**0.000**	0.092	0.122

The statistical analysis results show that flooring type has a significant effect on resuspension rate coefficient for all particle size bins involved, while surface dust loading is influencing for particles less than 3.0μm in size. When the results for all floorings are combined, RH itself shows little effect on particle resuspension because the direction of effect of RH is opposite for carpet and hard flooring. The interactions between RH and flooring type as well as RH and surface dust loading verify that RH should be taking into account.

Keywords: Bioaerosols, DNA analysis
Presenting author email: i.germann@mpic.de

Biogenic aerosols are ubiquitous in the Earth's atmosphere, where they influence atmospheric chemistry and physics, the biosphere, climate, and public health. They play an important role in the spread of biological organisms and reproductive materials, and they can cause or enhance human, animal, and plant diseases (Després *et al* 2007).

Mainly pollen, as the reproductive units of plants can cause allergies. Plant debris circulated in air play a role for human health as they may contain toxic or contact-dermatitis causing components as reported for several plants from the *Euphorbiaceae* and *Astaraceae* plant family (Schempp *et al* 2002).

A genetic analysis method was chosen as it works successfully for analyzing bioaerosols (Després *et al* 2007). Filter samples were collected over a period of 1 year (March 2006–April 2007) with a High Volume Sampler separating fine and coarse particles at a total flow rate of ~ 300 L min^{-1}, corresponding to a nominal cut-off diameter of ~3 µm. The average sampling time was 7 days, corresponding to a sampled air volume of approximately 3,000 m^3, in central Europe (see also Fröhlich-Nowoisky *et al* 2009).

Altogether the extracted deoxyribonucleic acid (DNA) of 42 coarse and 42 fine particle filter samples were analyzed with 2 plant specific primer pairs. Positive PCR products were cloned and sequenced. For comparison with known sequences, databank queries using the Basic Local Alignment Search Tool (BLAST) were performed via the website of the National Center for Biotechnology Information (NCBI). Sequences were furthermore analyzed with the program Mothur, a comprehensive software package for community analysis.

Preliminary results show that ~1600 sequences could be attributed to ~50 plant families. ~1200 of them were analyzed with the program Mothur, and grouped into operational taxonomic units (OTUs), which correspond to around 300 species.

Figure 1 shows the distribution of the OTUs during the sampling seasons of the air filter samples. Within fall and summer there are a number of OTUs exclusively present in these seasons while only very few species are shared between the seasons. In spring species from the *Betulaceae* family containing the highly allergenic birches and other tree species dominate, in summer the grasses and herbs belonging to the *Convolvulaceae*. In autumn mainly weeds belonging to the *Euphorbiaceae* family are present, which contain plants with contact allergens. In winter late flowering weeds from the *Asteracea*e plant family, containing the highly allergenic mugwort and ragweed and trees from the *Betulaceae* plant family dominate the sequences. Thus, the DNA analysis of plants in the air displays mainly the flowering of the different plants, often allergenic plants, whose pollen release plays a big role for human health.

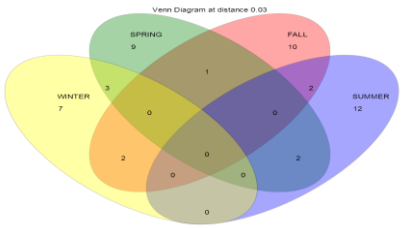

Figure 1: Venn Diagramm at distance 0.03 (97% sequence identity) created with Mothur. Numbers reflect the OTUs which are either unique for a season or shared between seasons

Presenting author email: jenny.rissler@design.lth.se

Since the deposition fraction of particles in the human respiratory tract is size dependent, lung dose estimations requires size resolved particle distributions, with respect to number, surface are or mass. Often the number size distributions are measured by DMA-techniques (Differential Mobility Analyzer) such as the SMPS, FMPS, DMPS, EEPS, DMS, etc. The DMA is sizing particles according to their electrical mobility diameter (d_m), which has been shown to determine the deposition probability also for agglomerated particles (Rissler et al., 2012), <400 nm. The surface area or mass size distributions are often estimated from the number distribution. Particle mass is believed to be a crucial parameter for the health effects of airborne particles. When converting number to mass, or vice versa, the effective density of the particles is needed, defined as:

$$\rho_{eff} = m_{APM}(d_m) / \left(\frac{\pi d_m^3}{6}\right).$$

For aggregated or agglomerated particles assuming spherical particles may lead to overestimation of the mass dose by several times (Rissler et al., 2012).

In this study, measurements of the effective density in an urban environment were performed, using a DMA–Aerosol Particles Mass analyzer (DMA-APM) technique (McMurry et al., 2002). In a DMA-APM system, the mass of individual particles of a population of a certain mobility diameter is measured. During the study the chemical and physical properties of the particles were further characterized with an SMPS, an Aerosol mass spectrometer, TEM images, OC/EC and hygroscopic growth. The characterization was part of a study of the health effect of urban particulate matter, where elderly (>55 yrs) volunteers with moderate obesity (body mass index >25 kg/m^2) were exposed to the aerosol from a busy street in Copenhagen, Denmark.

The effective density measurement revealed that the particles of the same d_m consisted of an external mixture containing one group of particles with effective density of ~1.5 g/cm^3 and another group of agglomerate particles of lower effective densities. The group of particles with higher effective densities increased in number fraction with increasing particle size. The low-density group of particles had densities that decreased with increasing size (from 0.25 g/cm^3 for 350 nm particles to 0.9 g/cm^3 for 75 nm). This is typical for particles with an agglomerated structure, such as soot. In several previous studies it was shown that for newly emitted agglomerate particles the relation between d_m and the mass often is well described by a power law function (Sorensen 2011; Rissler et al., 2012). This was also the case for the agglomerate particles in this study, showing that the soot particles did not restructure, at least not within a few hours after emission, despite the high humidity in the atmosphere.

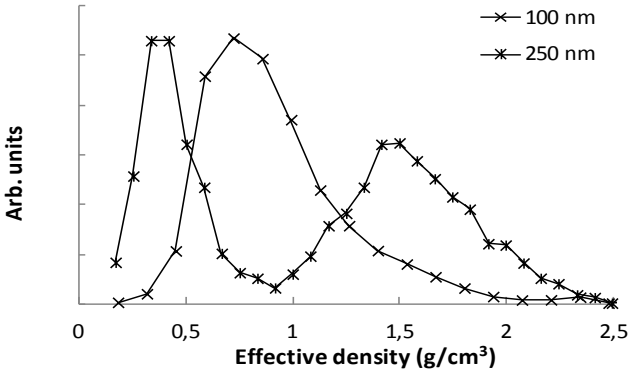

Figure 1. Two examples of DMA-APM spectra.

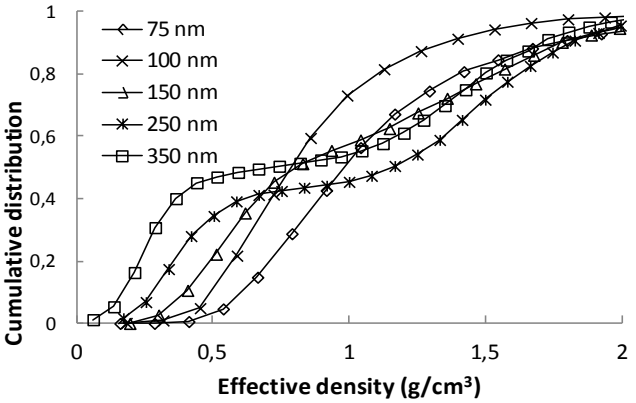

Figure 2. Cumulative distributions of effective densities.

By introducing a thermo denuder between the DMA and the APM it was showed that over 95% (by number) of the particles with high effective density evaporated at 300 °C, losing >85% of their mass. A closer study of the AMS data is needed to draw any further conclusions about the chemical composition or origin of these particles.

Session WG08S1O. New Instrumentation I

A new device for fast measurements of nanoparticle size distributions

Hans Grimm[1], Lothar Keck[1,] Markus Pesch[1], Matthias Richter[1], Hans-Joachim Schulz[1]

[1]Grimm Aerosol Technik GmbH & Co. KG, 83404 Ainring, Germany
Keywords: Instrumentation, Aerosol size distribution, Combustion particles, Vehicles emissions
Presenting author email: hjs@grimm-aerosol.com

Grimm has re-engineered the Fast Aerosol Particle Emission Spectrometer (FAPES) for fast measurements of nanoparticle size distributions in the range of 6.3 – 474 nm. The instrument comprises an integrated hot diluter and is particularly designed for measurements of combustion particles and for automotive applications.

The FAPES system has three unique features (Fig. 1). Firstly, it employs a strong bipolar charger (241-Am α-emitter) for establishing a well defined equilibrium charge distribution. Unlike for unipolar chargers, even the larger particles feature a low apportion of multiple charged particles and the different size fractions have well distinguishable mobilities. These two features are the base for an accurate reconstruction of the particle size distribution.

Secondly, the charged particles are classified with twelve individual Differential Mobility Analyzers (DMAs) of Vienna type design operated in parallel. The signal of each size channel originates from a single DMA and corresponds thus to a well defined and narrow size range. This well proven principle of size classification makes the FAPES a reference for fast particle sizers. Unlike for SMPS systems, each DMA voltage is kept constant and thus the sampling frequency is no longer limited by the scan-time for the DMA voltage. The 12 DMA voltages cover the broad range of 5 to 10000 V and the voltages of adjacent DMAs differ by a factor two to ease the correction of remaining multiple charged particles.

Thirdly, the detection of particles is accomplished with twelve Faraday Cup Electrometers (FCEs), one FCE for each DMA, and spatially separated from the mobility analyzing section. Therefore, the detected currents are unaffected from any variations of the high voltage and the FCEs feature a very low noise level. Due to the rinse air, the FCEs have a fast response time of T10-90 = 200 ms, which is the base of the fast overall response time of the FAPES (T10-90 = 0.7 s). The use of rinse air has a second advantage, namely to prevent contaminations on the isolation of the detection electrodes and thus leakage currents. In other products for fast measurements of nanoparticle size distributions, leakage currents between electrodes can degrade the size resolution in the course of the measurements, and cleaning of the surfaces is required. Such leakage current can be a major problem particularly for the measurement of engine exhaust because the soot particles are conducting. The FCE signals are insensitive to mechanical shocks and vibration.

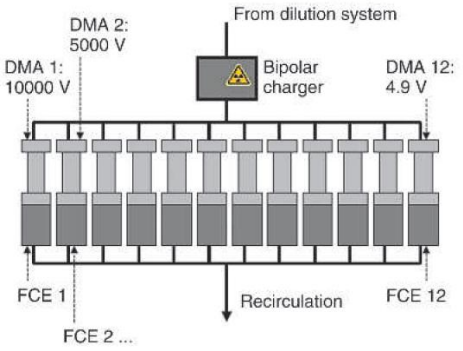

Figure 1: Principle of the FAPES

The concept of the sampling system is too "freeze" the state of the particles in the exhaust gas and to stabilize their condition for the analysis. This is achieved with a special integrated sample conditioning system with a heated dilution (temperature up to 500°C) right after the sample inlet. The diluter uses recycled sample air to achieve a variable dilution ratio of 1:5.7 – 1:40 in 7 steps. The recycled sample air is filtered, dried, and purified from organic gases with active carbon.

The main application of FAPES is measuring the particle size distributions in engine exhaust gas with high time resolution. As particle formation is connected to the fuel combustion process, such investigations can be used to optimize the efficiency of car engines. Moreover, they may assist the achievement of compliance with the new EURO5/6 regulations, which include a limit for particle number concentrations emitted by diesel and gas engines. The system is, however, also suitable for the fast measurements of size distributions at other applications. Monitoring the size of engineered nanoparticles in airborne state, nucleation events in industrial processes, or measurements in turbine exhaust are just examples.

Results for different applications are presented.

LOAC (Light Optical Particle Counter): a new small balloon-borne aerosol counter/sizer with some particle characterization capabilities

Presenting author email: jbrenard@cnrs-orleans.fr

The determination of the size distribution of tropospheric and stratospheric aerosols with conventional optical counters is difficult when different natures of particles are present (droplets, soot, mineral dust, secondary organic or mineral particles...). Also, a light and cheap aerosol counter that can be launched (and lost) under all kinds of atmospheric balloons can be very useful during specific events as volcano plumes or local pollution episodes.

These goals are achieved with a new generation of aerosol counter, called LOAC (Light Optical Aerosol Counter). The instrument was developed in the frame of cooperation between French scientific laboratories (CNRS) and the Environnement-SA company. LOAC (Figure 1) is light particle counter/sizer of ~500 grams, having a low electric consumption. The main difference with already existing optical counters is its geometry of observation. The measurements are conducted at two scattering angles: the first one, at 10°, is used to determine the aerosol particle concentrations in 20 size classes within a diameter range of 0.4-100 μm. With such an angle close to forward scattering, the signal is much more intense and the measurements are not strongly sensitive to the nature of the particles (Renard *et al.*, 2010). The second angle is at 60°, where the scattered light is strongly dependent on the particle refractive index and thus on the nature of the aerosols. The ratio of the measurements at the two angles is used to discriminate between different types of particles dominating the nature of the aerosol particles in the different size classes.

Since 2011, LOAC have performed flights under different kinds of balloons: Zero pressure stratospheric balloon, tropospheric balloons, and meteorological balloons. For the last case, the total weight of the gondola, including batteries, is ~1.5 kg.

The results obtained during these flights will be presented, as well as projects in which LOAC is already involved: ChArMEx, (low altitude flights above Mediterranean Sea), and Strateole (long duration flights in the tropical stratosphere).

The scientific flights were performed by the French Space Agency (CNES). Commercial flights under meteorological balloons (coupled with meteorological measurements) can be conducted using the telemetry system of the MeteoMODEM Company.

Aerosol detection with induced currents

M. Fierz[1,2], D.Meier[2], P.Steigmeier[1] and H. Burtscher[1]

[1]Institute for Aerosol and Sensor Technology, University of Applied Sciences Northwestern Switzerland, Windisch, 5210 Switzerland

Presenting author email: martin.fierz@fhnw.ch

Many aerosol instruments are based on unipolar charging followed by the detection of charged particles with electrometers. In instruments with multiple detection stages, charged particles can induce currents when passing through the initial stages of the instruments – this has been reported for example for the Dekati ELPI, the Cambustion fast particle analyser and for an electrical diffusion battery, leading to measurement artefacts (Fierz et al. 2009). These artefacts can be minimized or at least reduced through various techniques, such as guarding electrodes, dummy stages or data correction in software. In all these cases, however, the induced currents are a nuisance.

Here, we propose a new measurement technique which makes use of such induced currents to measure aerosols: We deliberately generate induced currents by switching the unipolar charger on and off at a well-defined frequency, thereby producing clouds of charged particles, which will induce currents in the instrument. The basic setup is shown in figure 1:

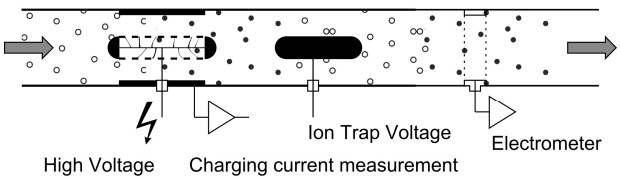

Figure 1: Scheme of an induced-current aerosol sensor; open circles represent uncharged particles, full circles represent charged particles.

The uncharged aerosol enters the sensor, and is charged in a unipolar charger whose high voltage is pulsed. Excess ions are removed after the charging zone in an ion trap, and thus, clouds of charged and uncharged particles are generated that flow through an empty Faraday cage, which can be either a real cage or simply an open tube. The electrometer amplifier will attempt to keep the Faraday cage at zero potential, and for any net charge Q inside the cage, it will thus produce a charge of equal magnitude but opposite sign, thus -Q, on the Faraday cage. The advantages of this principle compared to the traditional detection in particle filters are that (1) the charged particles are measured without contact, i.e. there is no (or much less) need for cleaning and filter exchanges, (2) the charged particles are still available after the measurement for further purposes and (3) there is practically no pressure drop over this type of measurement. This basic principle of operation allows multiple types of instruments to be constructed that make use of these advantages, for example:

1. Aerosol dosimeter: An instrument based on the principle shown in figure 1 is built in the smallest possible package (see figure 2), measuring a signal which is proportional to the lung-deposited surface area of the aerosol (Wilson, 2007).

Figure 2: dosimeter prototype with a volume of just 300cm^3.

2. Extended dosimeter with size and number determination: In this embodiment, two Faraday cages are used in succession, with a size-selective particle trap between them. The second Faraday cage then measures only the particles that passed the trap; and the comparison of the two signals allows a determination of particle size and number, similar to the algorithms used in the Matter Aerosol DiSC, or the Grimm nanoCheck.

3. Electron microscopy sampler with automatic determination of the necessary sampling time: in this embodiment, the charged particle stream leaving the Faraday cage is deposited in an electric field on a TEM grid. Because the amount of charge flowing to the grid is continually measured, the sampling time necessary for a sensible coverage of the grid can be determined

We have constructed the embodiments (1) and (3) described above, and will show results obtained with these devices in our presentation.

Remote sensing of atmospheric aerosols with the spectropolarimeter SPEX

J. de Boer[1], G. van Harten[1], F. Snik[1], O. P. Hasekamp[2], H. Volten[3], A. Apituley[4], C. U. Keller[1], J. H. H. Rietjens[2], J. M. Smit[2], D. M. Stam[2], and P. Stammes[4]

Presenting author email: jozuadeboer@iSPEX.nl

Remote sensing of atmospheric aerosols is still an underdeveloped technique, despite the significant influence of aerosols on public health, climate and economy. Current methods are local, time consuming, expensive, and cannot determine macro- and microphysical aerosol properties simultaneously. Spectropolarimetry is a promising remote sensing method for the detection and characterization of aerosols. It is unique in its capability to unambiguously retrieve microphysical aerosol parameters such as size distribution, chemical composition and shape. Existing polarimetric instrumentation either uses a few broad spectral bands, a limited number of viewing angles, or is not accurate enough to fully exploit the polarization measurements.

SPEX, the Spectropolarimeter for Planetary EXploration, is designed to characterize aerosol and cloud particles in the atmospheres of Solar System planets from orbiting satellites, by measuring both the flux and the degree and direction of linear polarization across the visible spectrum with a spectral resolution of 2 nm (flux) to 20 nm (polarization). SPEX measures the polarization using the spectral modulation technique by Snik et al. (2009), which allows both the flux and the full linear polarization information to be measured simultaneously, across all wavelengths. Thanks to this technique, SPEX has no moving components, except for pointing purposes, is very robust and small, and also accurate.

This study aims at testing whether a ground-based version of SPEX is able to characterize aerosols by reaching a high polarimetric accuracy. It furthermore aims at assessing how SPEX would function autonomously within an air quality network. The ground-based SPEX instrument measures the polarized spectrum of the sky across the visible at a range of scattering angles.

The wavelength dependent intensity and degree of linear polarization for different scattering angles offer a large data dimensionality in a SPEX measurement, which is needed to retrieve all free parameters of our atmospheric aerosol models. The algorithm we use for retrieval of the aerosol properties is based on the POLDER retrieval code of Hasekamp et al. (2011). This algorithm fits intensity and polarization spectra computed with a radiative transfer model for an atmosphere containing gas molecules and aerosols to measured spectra, using a range of aerosol properties (e.g. size distribution, aerosol optical depth, refractive index).

The instrument is stationed at CESAR, the Cabauw Experimental Site for Atmospheric Research. Measuring at this location allows us to compare our measurements with the aerosol optical depth provided by the AERONET sun photometer, and our size distributions with the in-situ aerosol measurements performed at CESAR. Aerosol height distributions are provided by (Raman) lidar measurements.

We will present the concept and design of SPEX, the first blue sky observations, the retrieved aerosol properties and a comparison with aerosol properties derived from simultaneous measurements by other instruments.

Evaluation of the Cavity Attenuated Phase Shift (CAPS) Extinction Monitor

A.Petzold[1], T. Onasch[2], P. Kebabian[2], A. Freedman[2]
[1] Institut für Physik der Atmosphäre, DLR, 82234 Oberpfaffenhofen, Germany

The measurement of the complete set of aerosol optical properties by means of closure studies is still demanding because it requires the simultaneous measurement of aerosol extinction, scattering and absorption coefficients. Particularly the in-situ measurement of the aerosol single-scattering albedo (= ratio of aerosol scattering to aerosol extinction) is identified as a key challenge in atmospheric sciences.

Among new methods for the measurement of aerosol extinction the Cavity Ring-Down (CRD) method yields the aerosol extinction coefficient by measuring the time constant for light decay in a high-finesse cavity containing the absorbing and scattering particles. A detailed introduction to the CRD technique for aerosol extinction measurement is given by Strawa et al. (2003) whereas Moosmüller et al. (2005) provide an overview over the various CRD approaches.

The Cavity Attenuated Phase Shift (CAPS) technique, similar in its basic principle to cavity ring-down, relies on the use of a sample cell employing high reflectivity mirrors (Kebabian, et al., 2007). Square-wave modulated light emitted from a light emitting diode (LED) at a wavelength $\lambda \cong 630$ nm is directed through one mirror into the sample cell. The distortion in the square wave caused by the effective optical path length within the cavity (approx. 1 km light path) is measured as a phase shift in the signal as detected by a vacuum photodiode which is located behind the second mirror. A detailed description of the method including first results from laboratory characterization and field deployment is given by Massoli et al. (2010).

Our study characterizes the CAPS instrument for both laboratory test aerosols and ambient aerosol. The CAPS instrument was evaluated against a combination of the 3-wavelength Integrating Nephelometer (TSI Model 3563), and the 3-wavelength PSAP (Virkkula, et al., 2005). Triggered by successful direct measurements of the single-scattering albedo (Massoli, et al., 2010) using CAPS-based extinction coefficients and absorption coefficients measured by a Multi-Angle Absorption Photometer (MAAP) (Petzold and Schönlinner, 2004) we included a MAAP instrument in our studies.

We used spherical polystyrene latex particles for instrument calibration, and black carbon, ammonium sulfate and mixtures of both components for the instrument evaluation. Aerosol light absorption was measured by a 3-wavelength particle soot absorption photometer (PSAP) and a Multi-Angle Absorption Photometer (MAAP), aerosol light scattering was measured by a 3-wavelength integrating nephelometer. Instrument calibration and evaluation was then tested by an instrument intercomparison for ambient aerosol.

The calibration studies yielded a linear instrument response over the investigated dynamical range from 20 to 450×10^{-6} m^{-1} (Mm^{-1}) with a linear correlation coefficient of $R^2 > 0.98$. Correlating CAPS extinction to extinction measured by the Integrating Nephelometer – PSAP combination provided a linear regression line with slope m = 0.986 ($R^2 = 0.996$) for single-scattering albedo values (λ = 660 nm) ranging from 0.35 (black carbon, BC) to 1.00 (ammonium sulfate, AS); see Fig.1 for details. For ambient aerosol, light extinction measured by CAPS was highly correlated ($R^2 = 0.995$) to extinction measured by Integrating Nephelometer – PSAP with slope m = 0.95.

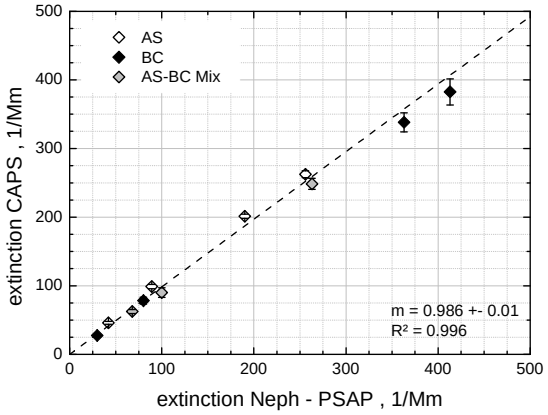

Figure 1. Intercomparison of extinction measured by CAPS and extinction obtained from the combined Neph – PSAP analysis for polydisperse laboratory aerosols; all data are adjusted to λ = 660 nm. The dashed line represents the 1:1 ratio.

This study was conducted during a DLR-sponsored research stay of A. Petzold at Aerodyne Research Inc.

Improvement of the nanoparticle charging efficiency by using sheath air flow in a single-wire corona unipolar charger

C.L. Chien[1], C.J. Tsai[1], V. Wattanmekhinkul[1]

[1] Institute of Environmental Engineering, National Chiao Tung University, Hsinchu, 300, Taiwan.
Keywords: unipolar aerosol charger, charging efficiency, nanoparticles, aerosol instrumentation.
Presenting author email: clchien.ev91g@nctu.edu.tw

The extrinsic charging efficiency of the unipolar aerosol charger designed with a sheath air by Chien et al. (2011) was shown to be higher than those of other corona-based unipolar chargers, except lower than those of Kimoto et al. (2010) for particles smaller than 10 nm in diameter. To improve the design of the previous charger, a single-wire corona unipolar charger was developed to enhance the extrinsic charging efficiency of nanoparticles by using radial sheath air through the grounded porous wall to avoid charged particle losses. The charger has a stainless steel porous tube (Mott Corp., MA, USA) of 6.35 mm in inner diameter in which a gold wire of 50 μm in diameter and 6 mm in length is used as the discharge electrode. A filtered sheath airflow with the flow rate (Q_{sh}) of 0.7–2.1 L/min was introduced through the porous wall while the aerosol flow (Q_a) was varied from 0.3 to 1 L/min. Currently, the performance of the present charger is being experimentally evaluated to determine an optimum operation condition.

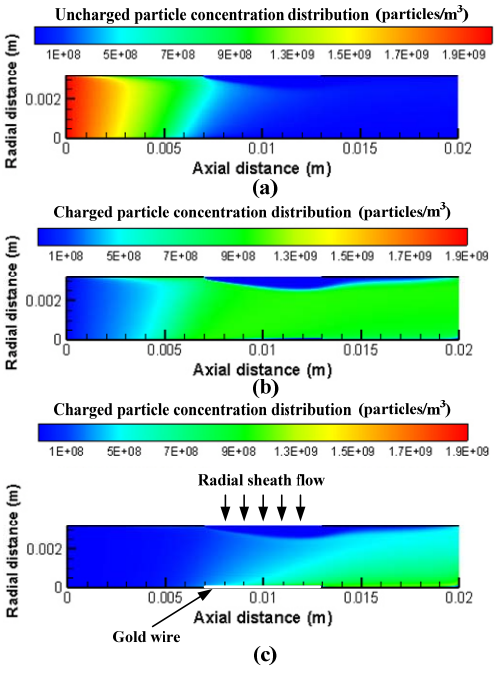

Figure 1. Number concentration field of 20 nm particles carrying 0–2 charges at the applied voltage of +2.9 kV at Q_a = 1 L/min at Q_{sh} = 0.7 L/min. (a) 0 charge, (b) 1 charge, (c) 2 charges.

A 2-D numerical model developed by Chien (2011) was first used to predict the charging efficiency of the present charger by simulating the simplified calculation domain. The analytical solution for the equation of unipolar diffusion charging incorporating the wire-in-tube electrostatic precipitator theory was calculated to examine the relationship between the fraction of charged particles and charging parameter, $\alpha_0 N_i t$ (α_0: combination coefficient between ion and uncharged particle, N_i: ion concentration, t: charging time). An example is shown for 20 nm particles carrying 0–2 charges at the applied voltage of +2.9 kV at Q_a = 1 L/min at Q_{sh} = 0.7 L/min in Figure 1. It shows that using the radial sheath air the charged particles migrating toward the wall are forced to move toward the core of the tube and the electrostatic loss is reduced. Major charged particle loss is seen to occur on the wall surface on the left-hand-side in the charging zone. Numerical results showed the advantage of using the radial sheath air to minimize charged particle loss. At the applied voltage of +2.9 kV, the predicted extrinsic charging efficiency of the present charger was 7.2%–71.1% for particles ranging from 2.5 to 20 nm, as shown in Figure 2. Using the current design, both aerosol and sheath air flow rate can be adjusted further to maximize the extrinsic charging efficiency.

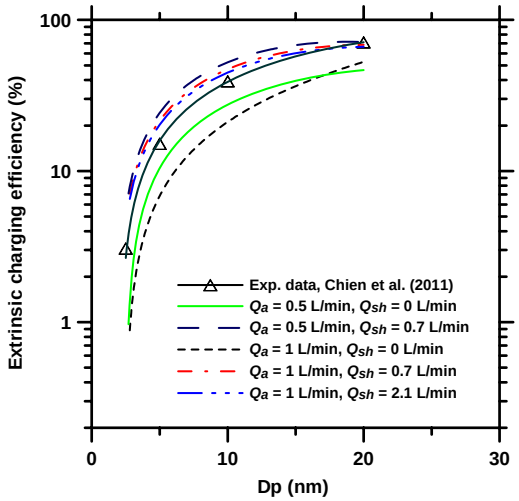

Figure 2. Predicted extrinsic charging efficiencies of the present charger.

Carbonaceous aerosol is a major component of urban particulate matter (PM), in particular of its finer fractions (PM2.5, PM1). The elemental part, often referred to as EC, is strongly light absorbing: when determined by optical methods it is usually called "black carbon" (BC). The two quantities, EC and BC, do not exactly define the same PM component.

PM samples are routinely collected in urban areas to monitor PM10 and PM2.5 levels. Low volume sequential samplers (LVS) are often equipped with 47 mm filters and operated on a daily basis. PTFE (Teflon®) membranes are very appropriate for gravimetric and compositional analyses of PM and currently 47 mm filters with 2 μm pores are often used to collect PM samples on daily basis (LVS). We have developed a simple, fully automatic and non-destructive new optical system to measure off-line the light absorption and hence the BC content in the PM on the PTFE filters routinely used for PM studies and on other collecting substrates. This gives the opportunity to measure in each sample the concentration of total PM by gravimetric analysis, BC, metals by, for instance, X Ray Fluorescence, and ions by Ion Chromatography. All these pieces of information can be obtained with just one filter being sure to analyze the same PM. The set-up we realized is composed by a collimated laser source and three low-noise photodiodes (PD) placed at 0, 125 and 160 degrees with respect to the laser beam direction. The PDs active surface is about 65 mm^2 and a large fraction of the forward scattered radiation is collected by the 0-degree PD positioned just behind the sample. Samples can be analyzed in sequence and in an automatic and controlled way in about 15 minutes thanks to a wheel which can host up to 16 47-mm filters. The wheel is connected to a stepping motor to change the filter under analysis and to two linear translator which allow the scanning of the whole deposition area. All the movements and the acquisition of the photodiode signals are controlled by a PC using a Labview 8.5 home-made software. The set-up is completed by three different interchangeable laser sources: 4 mW - red (λ = 635nm), 4 mW - blue (λ = 405nm) and 20 mW - IR (λ = 850nm). For the calculation of BC we have adopted and extended the method, based on the radiative transfer scheme proposed by Hänel (Hänel, 1987 and 1994), used by the MAAP (Petzold and Schönlinner, 2004). Furthermore, thanks to the computer control, the analysis of non-homogeneous PM samples, as those collected by multi-stage cascade impactors, is also possible.

Our new instrument has been validated in different campaigns and, for the first time, has been employed in a long campaign realized in the frame of the MED – APICE program (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions, http://www.apice-project.eu/). In this case, a 6-month PM2.5 sampling campaign was organized between spring and summer 2011, at three sites in the urban area of Genoa (Italy). A LVS (TRC-Tecora, Italy) was used to collect daily PM2.5 alternatively on quartz fiber and on PTFE filters. All the samples (about 250 per each medium) were first analyzed with the optical set-up and quartz fiber filters only were subsequently analyzed by a SUNSET EC/OC thermal-optical instrument adopting the EUSAAR_2 protocol in order to obtain the EC load on each sample. Comparing the results obtained from the two different techniques it is possible to find the aerosol light absorption cross-section σ_{abs} for the different sites (in Figure 1 the results for one of the three sites). In this way we are able to calculate the BC concentration also for the days in which PTFE filters were used.

We will briefly describe the optical method providing details on the set-up and on its components. Results of the analysis on different set of samples will be also presented, with particular attention to the results obtained from measurements at the three different wavelengths with the two different kinds of filters.

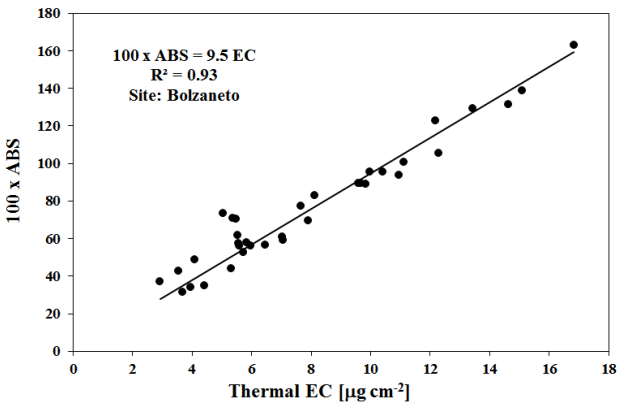

Figure 1. Regression study between ABS values given by the optical analysis and the EC concentration on quartz fiber filters measured by SUNSET using the EUSAAR_2 protocol.

A new expansion chamber CPC applicable to atmospheric measurements

T. Pinterich[1], P.M. Winkler[1,2], P.E. Wagner[1] and A. Vrtala[1]

Presenting author email: tamara.pinterich@univie.ac.at

In the past few years the influence of atmospheric aerosols on the evolution of the global climate has received considerable attention. In this connection the formation of nanoparticles in the atmosphere is a major though not well understood process. Thus accurate determination of aerosol properties particularly in the size range above ~1nm diameter is of great importance.

Therefore we developed a new expansion chamber CPC – the versatile Size Analysing Nuclei Counter (vSANC). Using this device experiments on nucleation and condensational growth of nanoparticles in supersaturated vapours can be performed under well defined conditions. The measuring principle was adopted from the Size Analyzing Nulcei Counter and can be found elsewhere (see P. E. Wagner *et al* (2003)). During the development of the vSANC, care was taken to ensure its applicability to atmospheric conditions.

It is well known that sulphuric acid plays an important role in atmospheric nucleation (see e.g. M. Sipilä *et al* (2010)). Therefore great care was taken to ensure the chemical inertness of all parts in contact with the aerosol. The expansion chamber, for example, consists of stainless steel with black bronzed surface, a coated glass ring and FEP (fluorinated ethylene propylene) coated O-rings. Moreover the usage of any adhesives was avoided for all parts with aerosol contact.

So far a drawback of common CPCs was the limitation to positive temperatures only (see e.g. Kirkby *et al* (2011)). However the vSANC can operate at temperatures ranging from -20°C to +40°C. In order to prevent evaporation losses or changes of the aerosol during sampling the connection between inlet and expansion chamber is temperature controlled. The wide variability in temperatures is implemented by means of Peltier elements and an associated thermostating liquid. The thermoelectric modules control aerosol temperature in the aerosol pre-thermostating unit (APT, connection between sample inlet and expansion chamber), both humidifiers and the expansion chamber. The associated thermal fluid is used to increase the efficiency of the Peltier elements. This special temperature regulation permits fast changes and precise settings of any temperature within the range noted.

Another typical difficulty of expansion type CPCs is the detection of particles at comparatively low number concentrations as encountered, e.g., in atmospheric background measurements. Thus another focus in development was on decreasing the lower concentration limit to ~50/cc.

Therefore diffusion losses were minimized by designing the connection between inlet and expansion chamber short and straight. In this context hydraulically operated pinch valves with a complete and true full bore are applied. In other words, the inside diameter of the sampling line stays constant for aerosols flowing towards the expansion chamber.

Additionally the optical arrangement and the observed scattering light volume are optimized to obtain better data statistics even at comparatively low number concentrations.

A further, and decisive, point when performing field measurements are fast and unexpected changes in aerosol properties. Accordingly, it is necessary to have an instrument with high time resolution. Therefore the vSANC has a special designed flow shaper installed at the outlet of the expansion chamber. Its application guarantees fast and complete flushing of the measuring chamber after expansion. Thus the measuring frequency can be decreased down to a minimum of 6 seconds per expansion.

However, for the characterisation of atmospheric aerosols not only short-term changes but also long-lasting processes must be taken into account. Thus for future long term measuring campaigns all consumables such as filters, driers etc. were implemented redundantly. Thus they can be exchanged without stopping the experimental cycle.

By its special design we expect that the vSANC will bring new findings on the role of nanoparticles in atmospheric processes. With this aim the instrument will likely participate at the CLOUD campaigns at CERN.

Keywords: nucleation events, number size distribution, SMPS, classification

Thessaloniki is a densely populated coastal city of northern Greece with high concentrations of atmospheric particulate matter (PM) frequently observed in the city centre. Several studies have investigated the concentration levels, the chemical composition of PM, as well as the size distribution of particle mass concentrations over the city (Voutsa *et al*., 2002; Petrakakis *et al*., 2007; Terzi *et al*., 2010;). Preliminary measurements of the size distribution of aerosol number concentration in Thessaloniki were conducted during winter-time at a kerbside site and an urban background site (Terzi et al., 2007). The size distribution of aerosol number concentration during the summer-time and the relationships with PM mass, photochemical pollutants and meteorological parameters was investigated in Siakavaras et al., (2008), while a classification of the nucleation events during the same period was recently reported (Siakavaras et al., 2011).

In this paper we analyse the differences between particle nucleation and growth events observed during the summer period at two monitoring stations (Venizelou – kerbside site, and Eptapyrgio – urban background site). Two identical Scanning Mobility Particle Sizers (TSI Model 3034) have been employed to measure simultaneously the size distributions of the particles having diameters in the range 10-487 nm at the two sites. Gaseous pollutants (CO, NO_x, SO_2 and O_3) and meteorological parameters (wind speed, wind direction, temperature and relative humidity) were also recorded during the measurements. The experiments were conducted during June to October 2009.

Nucleation events were classified in 5 categories based on their intensity. At Venizelou (kerbside site), 6% of the days were classified as class Ia events, 3% as class Ib, 10% as class II, 14% of the days exhibited no clear particle formation patterns and were considered as undefined and 67% of the days showed no event. At Eptapyrgio (urban background site) 8% of the days were class Ia events, 7% class Ib, 5% class II, 5% were undefined and 75% of the days showed no nucleation.

Characteristic differences between the classes can be seen in Fig. 1. For Class Ia the diurnal variation of the particle number concentration shows a significant increase starting at 07:00 at Venizelou and at 12:00 at Eptapyrgio, whereas for the non-event days, the diurnal variation is less pronounced for both stations. Nucleation events were more frequent during July, and for both stations correlated well with high concentrations of SO_2 and NO_x.

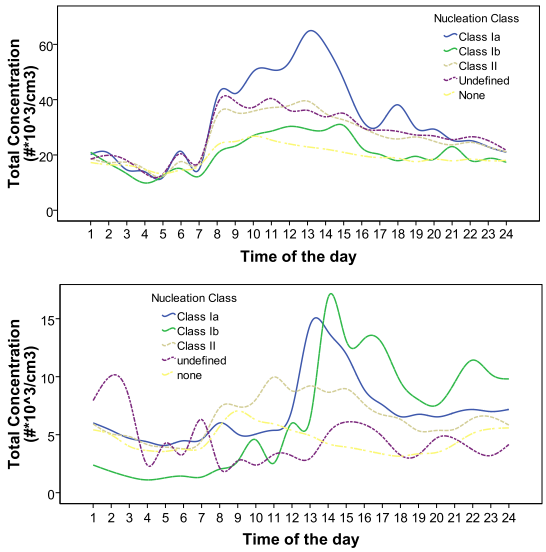

Figure 1. Average diurnal variation of particle number concentrations during nucleation event days of all classes at Venizelou (upper part) and Eptapyrgio (lower part)

The role of marine microcolloids in new particle formation over the Arctic Ocean

M. Karl[1], E. Coz[2] and C. Leck[3]

The High Arctic summer atmosphere is of particular interest for the study of aerosol-cloud-climate interactions, since it is characterized by relatively few aerosol particles, usually less than 200 per cubic centimetre, available to form cloud droplets. The frequent occurrence of new particle formation events in the marine boundary layer (MBL) over the central Arctic Ocean is however difficult to explain because of the limited availability of low-volatile vapours, such as sulphuric acid (H_2SO_4), which can act as nucleating agents (Karl et al., 2012).

Spherical nanometre sized (~2-10 nm diameter) granules, hereafter termed nano-granules, have been discovered in surface micro layer (SML) samples of the open leads (openings in pack ice, 1-100 m wide and km long) in the High Arctic. These nano-granules form colloidal aggregates, classified as polymeric microgels, which are known to be exopolymer secretions (EPS) produced by phytoplankton and marine algae. Leck and Bigg (2010) recognized the significance of the very large numbers of airborne biogenic nano-granules and related their appearance to observed new particle formation events. Orellana et al. (2011) demonstrated that microgels found in cloud, fog and airborne aerosol sampled at 87°N during the Arctic Summer Cloud Ocean Study (ASCOS, www.ascos.se) cruise were material originating from the SML of the open leads.

An important observation is that the onset of inner Arctic nucleation events often occurred shortly after dissipation of fogs (Leck and Bigg, 1999; 2010; Karl et al., 2012). Fog droplets are proposed here to be a medium facilitating the collapse of the marine gels which enclosed the nano-granules. We postulate a novel pathway to new particle formation (illustrated in Fig. 1) which includes the following steps: 1) release of nano-granules from evaporating fog droplets, 2) nucleation of H_2SO_4 molecules to form stable clusters, 3) secondary production of condensing organic vapour (COV), 4) condensation of vapours onto nano-granules and H_2SO_4 clusters, 5) coagulation of nano-granules and H_2SO_4 clusters to form >3 nm diameter particles.

The novel pathway is supported by observational evidence from electron microscopy analysis and by model predictions obtained using the sectional multicomponent aerosol model MAFOR. The resolution of the field emission scanning electron microscopy (FESEM) allowed the quantification of native gels with sizes below 10 nm diameter. The morphology and structure of the microgels in cloud and fog samples from ASCOS showed high numbers of building blocks of the microgels, confirming that airborne nano-granules could in fact have been released from evaporating droplets.

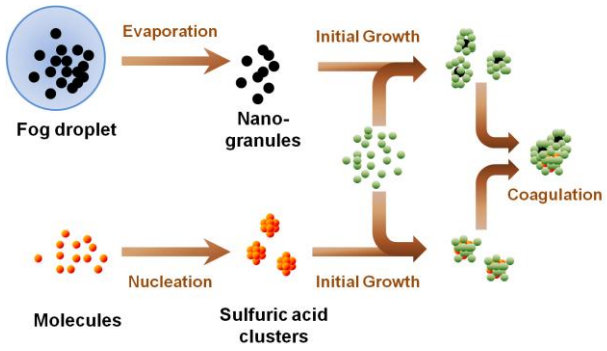

Figure 1. Schematic outline of the new nucleation route involving sulphuric acid (orange), organic vapour (green), and marine nano-granules (black).

Model simulations with MAFOR initialized with a pre-existing population of nm-sized clusters, representative for the novel pathway, showed much better agreement with the observed number enhancement of nucleation mode particles during selected new particle formation events than simulations that did not consider the presence of nano-granules.

The evident presence of nm-sized building blocks of microgels in surface waters of the Atlantic, Pacific, and central Arctic Ocean suggests that the proposed pathway, operative after the evaporation of cloud or fog, might be relevant worldwide and able to explain new particle formation events in the MBL of remote oceans.

Response of Cloud Condensation Nuclei (> 50 nm) to changes in ion-nucleation

M. B. Enghoff,[1] H. Svensmark,[1] and J. O. P. Pedersen[1]

[1]National Space Institute, Technical University of Denmark, Copenhagen OE, dk-2100, Denmark
Keywords: Ion induced nucleation, Cloud condensation nuclei
Presenting author email: enghoff@space.dtu.dk

The role of ionisation in the formation of clouds and aerosols has been debated and investigated for many years. A substantial body of evidence exists that correlates cloud properties to galactic cosmic ray ionisation (e.g. Svensmark and Friis-Christensen 1997, Harrison and Stephenson 2006), however these results are still contested (e.g. Sloan and Wolfendale 2008). In recent years clear experimental evidence has also been produced showing that ionisation can promote the nucleation of small aerosols (1-3 nm) at atmospheric conditions (Svensmark *et al* 2007, Kirkby *et al* 2011).

The experiments initially showed that an increase in ionisation leads to an increase in the formation of ultrafine aerosols (~3 nm), but in the real atmosphere such small particles have to grow by coagulation and intake of condensable gases to become cloud condensation nuclei (CCN) (> 50 nm) in order to have an effect on clouds.

Theoretical doubts about the likelihood of such particle growth into CCN have arisen from consideration of (1) the competition between the additional ultra-fine aerosols for the limited supply of condensable gases leading to a slower growth and (2) the larger losses of the additional particles during the longer growth-time to larger particles by coagulation and by other loss mechanisms. Numerical studies using the current knowledge of aerosol dynamics predict that variations in the count of ultra-fine aerosols will lead only to an insignificant change in the count of CCN (Pierce and Adams 2009). It is even suggested that an increased production of ultra-fine particles as a result of GCR ionization leads to a reduction in the CCN count.

In order to study the growth of aerosols to CCN sizes, measurements were performed in an 8 m^3 reaction chamber made from electro-polished stainless steel. One side was fitted with a Teflon foil to allow ultraviolet light (253.7 nm) to illuminate the chamber, which was continuously flushed with dry purified air. Variable concentrations of water vapor, ozone, and sulphur dioxide could be added to the chamber, where the pressure was held a few Pa above atmospheric pressure, and the temperature at around 296 K. UV-lamps initiated photochemistry producing sulphuric acid. Ions were produced in the chamber by the naturally occurring GCR and by background radiation from radon, and the ionization could be enhanced with two Cs-137 gamma sources (30 MBq), mounted on each side of the chamber.

Figure 1 shows the evolution of the aerosols, following a nucleation event induced by the gamma sources. Previous to the event the aerosols were in steady state. Each curve represents a size bin: 3-10 nm (dark purple), 10-20 nm (purple), 20-30 nm (blue), 30-40 nm (light blue), 40-50 nm (green), 50-60 nm (yellow), and 60-68 nm (red). Black curves show a ~1 hour smoothing. In this event the initial increase in small aerosols persists all the way to the largest size bin.

Similar experiments where the aerosol burst was produced with either the ionisation source or an aerosol generator (neutralised aerosols) were made and compared with each other and model runs. The runs using neutral aerosol bursts agree with the model predictions, where the initial burst is dampened by increased losses such that there is little or no change in the largest sizes. Thus there seem to be a fundamental difference between the bursts produced by ionisation and those produced by the aerosol generator. One possible explanation is that the ionisation assists the growth of the aerosols, by catalytically producing additional sulphuric acid for growth (Svensmark *et al* 2012).

Figure 1. Growth of aerosols, nucleated by ionisation.

Presenting author email: miikka.dal@helsinki.fi

Atmospheric aerosol formation has been studied intensively due to its significance in adding to the tropospheric aerosol loading (e.g. Kulmala et al. 2004). A major problem in quantitatively explain atmospheric particle formation is the current inability to identify and quantitatively measure the actual vapors participating in particle formation Several studies make use of estimations of the logarithm of the nanoparticle formation rate as a function of the logarithm of vapour concentration to gain insight into the formation mechanism. however, there are suggestions that such analysis is inaccurate and the effect of this on the power-law fits is unknown (Vuollekoski et al., 2010). To estimate the importance of various gas phase precursors, correlation analysis of measured gas phase parameters and measured and estimated nanoparticle formation rates have also been performed. These analyses often simplify the chemical kinetics the precursor oxidation chemistry and omit various sink processes of the participating compounds. The results of these analyses are used to draw conlusions of the vapors participating in the particle formation process.

In this study, we investigate the most frequently used conceptual models for particle formation, such as oxidation of plant volatiles and the subsequent participation of the oxidation products in nanoparticle formation, or formation of stable clusters from sulphuric acid and oxidised plant emissions. We investigate the predictions of for the dependence of the particile formation rate on commonly measurable parameters, such as sulphuric acid concentration, probable volatile organic aerosol precursors, hydroxyl radical concentration, and the sink of nanoparticles and non-volatile vapours caused by pre-existing aerosol.

In addition to theoretical predictions derived from gas-phase kinetics analysis, we use a model that simulates the early stages of growing atmospheric nanoparticles on a resolution of a single molecule, similarly to the model described in Lehtinen and Kulmala, (2003). In practise, the model is given a formation rate and size of a stable condensation nuclei (CN); these nuclei then grow by colliding with either vapour monomers or other CN. This results in a size distribution of small CN. The coagulation coefficient for CN collisions and CN-monomer -collisions are calculated using the Fuchs coagulation kernel for the wet aerosol sizes assuming spherical particles (Lehtinen et al., 2007).

There are several phenomena affecting the detection of atmospheric particle formation rates. One of them is the loss of fresh particles due to coagulation to background, and also apparent losses due to change in the size distribution shape. This has been extensively studied theoretically (Lehtinen et al., 2007, Anttila et al., 2010).

Another process affecting the determination of the apparent particle formation rate is the intermodal coagulation affecting the shape of the just-formed particle mode. Our model simulations show that the new particle population shape quickly changes shape, starting to resemble a log-normal size distribution due to collisions between young clusters. This, in turn, affects the time derivative of CN measured at larger sizes than the nucleation size, as the edge of the fresh mode passes the detection threshold of the measuring instrument. We discuss the effect of these processes as well as the effect of different temporal behaviour of the temporal profile of the condensing vapour production rate.

We compare our measurements to real-world situations of actual measurements in field conditions and chamber experiments, and discuss the relevance of the studied processes for each.

We found that the magnitude of the reaction pathways leading to aerosol formation in comparison to non-aerosol forming pathways is a key factor determining the functional dependence of the observed formation rate on measurable parameters. In addition, nano-size aerosol dynamics add another layer of complexity to the analysis. We discuss these effects for various scenarios, including OH- or ozone-dominated environments, the presence of high sulphuric acid loading, and environments with either high or low background aerosol loadings.

The role of amines in atmospheric nucleation

Almeida-Simões, João[1,2], Curtius, Joachim[1], Kirkby, Jasper[2], and the CLOUD collaboration

[1] Goethe-University of Frankfurt am Main, 60438 Frankfurt am Main, Germany
[2] Physics Department, CERN, CH1211, Geneva, Switzerland

Keywords: CLOUD experiment, cosmic rays, atmospheric nucleation, nucleation rate, amines.

Atmospheric sulphuric acid and water, together with other trace gases, can condense to form molecular clusters. These nucleated aerosol can grow to sufficient size to become cloud condensation nuclei. Thus understanding how aerosol form and what vapours participate is important to understanding climate and climate change. In the CLOUD experiment we have studied aerosol nucleation and early stages of growth from dimethylamine, sulphuric acid and water vapours at atmospheric concentrations.

The CLOUD experiment involves a 3m stainless steel aerosol chamber exposed to a pion beam from the CERN Proton Synchrotron. A suite of instruments continuously analyse the contents of the chamber via sampling probes. Each instrument has its own data acquisition system which delivers data in real-time to the CLOUD server. The CLOUD chamber is able to reproduce a wide range of well-controlled atmospheric conditions, including temperatures -90ºC to 100ºC, ion-pair concentrations 1-4000 cm^{-3} and relative humidities, RH, 0-100%.

The analysing instruments include the following: a Chemical Ionisation Mass Spectrometer (CIMS) for H_2SO_4 concentration, Atmospheric Pressure Interface Time Of Flight (APi-TOF) mass spectrometer for molecular composition of positive and negative ions, several particle counters with thresholds in the range 1.3–2.5 nm (2 Particle Size Magnifiers, PSM, of which one operated in a continuous scanning mode, 2 Di-Ethylene Glycol CPCs, DEG-CPC, and a TSI 3776), Neutral cluster and Air Ion Spectrometer (NAIS) and two instruments dedicated to NH_3 and DMA measurements (Ion Chromatograph, IC , and Proton Transfer Reaction Mass Spectrometer, PTR-MS).

A series of experiments have been performed in the CLOUD chamber with H2SO4 in the range 10^6-10^7 cm^{-3} at 278 K and 38% relative humidity. The experiments separate the contribution of neutral nucleation from ion-induced nulceation using the internal electric field of the CLOUD chamber (for neutral nucleation) and the CERN pion beam (for charged nucleation). To investigate the influence of amines, dimethylamine was added at mixing ratios between 1 and 65 pptv. Large enhancements were observed after adding dimethlamine. The results will be presented in this paper, including a comparison of amine-ternary with ammonia-ternary (reported in Nature Kirkby 2012) nucleation and with atmospheric boundary layer observations.

These data represent the first to measure amine-ternary nucleation at atmospheric conditions and the first to measure the molecular composition and nucleating mechanism of the amine-containing molecular clusters.

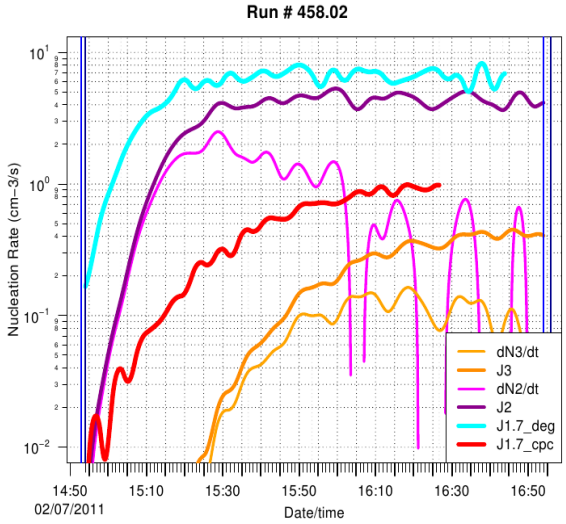

Figure 1. Typical nucleation rates in a CLOUD run with added DMA. The various lines represent observed rates provided by two independent counters with different cut-offs, with and without corrections applied. The corrected lines should plateau during the run if the loss mechanism is well known. Both counters are also scaled to the same small diameter of 1.7nm, which is taken as the critical stable cluster size.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC Seventh Framework Programme (Marie Curie Initial Training Network "CLOUD-ITN" grant no. 215072, and ERC-Advanced "ATMNUCLE" grant no. 227463), the German Federal Ministry of Education and Research (project no. 01LK0902A), the Swiss National Science Foundation (project nos. 206621_125025 and 206620_130527), the Academy of Finland Center of Excellence program (project no. 1118615), the Austrian Science Fund (FWF; project no. P19546 and L593), the Portuguese Foundation for Science and Technology (project no. CERN/FP/116387/2010), and the Russian Foundation for Basic Research (grant N08-02-91006-CERN)

Atmospheric amine measurements with CI-APi-TOF

Nucleation of new particles is one of the main sources of cloud condensation nuclei (CCN) in the atmosphere contributing even up to 50% to the global CCN budget. The initial steps of nucleation require the presence of sulphuric acid (SA) (e.g. Sipilä *et al*. 2010) but additional vapours are needed because SA does not nucleate itself at typical atmospheric conditions. Kirkby *et al*. (2011) found ammonia and dimethylamine (DMA) from charged clusters formed by ion induced nucleation and concluded that amines are plausible candidates for stabilizing neutral clusters at lower atmospheric conditions. The enhancing effect of amines on new particle formation was observed also in laboratory studies by Berndt et al, (2010). Amines can bind the cluster much more strongly than ammonia and even ppt levels of amines can be enough to account for atmospheric nucleation rates (Petäjä *et al*., 2011).

In here we present the first ambient amine measurements using an acetone based Chemical Ionization Atmospheric Pressure interface Time-Of-Flight mass spectrometer (CI-APi-TOF). We previously used the exact same inlet for sulphuric acid measurements (Jokinen *et al*, 2011) but this time we used acetone for the proton transfer reaction and ran the APi-TOF in the positive polarity mode. In this experiment acetone + water in clean air was ionized using a ^{241}Am bipolar charger to create positively charged acetone ions and clusters. In the proton transfer reaction only compounds that have higher proton affinity than the reagent ions will get charged and detected by the APi-TOF.

The data analysis is still ongoing and these results must be considered preliminary. We identified amine clusters by their exact masses and isotopic patterns. So far two signals have been identified to correspond to the same chemical composition and exact mass as common aliphatic amines. These signals are $C_4H_{12}N^+$ (diethyl amine) and $C_6H_{16}N^+$ (triethylamine). Time series of these signals are shown in figure 1. Figure 1 also demonstrates SA concentration (divided by 10 000) and it's seen that during a nucleation event, when SA concentration reaches its maximum, we only see a minimum amine signal. This may indicate the role of surface source and boundary layer dynamics as factors controlling the concentrations or that amines are reacting and/or clustering with freshly forming SA molecules.

This setup has a few disadvantages that need to be further developed. First, one of the most interesting amine signals, trimethylamine (TMA), is overlapped with the acetone isotope signal and it is almost impossible to separate from the spectrum. Second, this instrument consumes high amounts of acetone. Also the purity of the air entering the ion source is crucial. The design of the inlet will be improved to consume less chemicals and the reagent ion may have to be changed before quantitative analysis of atmospheric amines can be done using the CI-APi-TOF.

Presenting author email: theo.kurten@helsinki.fi

Sulfuric acid is believed to be the main compound driving atmospheric new-particle formation. However, sulfuric acid (or sulfuric acid and water) alone cannot account for observed nucleation rates in the boundary layer. Three major groups of compounds have been proposed as ternary nucleation enhancing agents for H_2SO_4 or H_2SO_4- H_2O nucleation: ions (particularly anions), nitrogen-containing base molecules such as ammonia or amines, and non-basic oxygenated organic molecules such as diacids. Using the concept of Lewis acidity, the two first cases are actually examples of the same fundamental mechanism: enhancement of acid clustering by Lewis bases.

The textbook definition of a Lewis base is an electron pair donor. Ammonia and amines are moderately strong Lewis bases due to the lone electron pairs of the nitrogen atoms, which readily participate in hydrogen bonding. Anions such as HSO_4^- or NO_3^- are strong Lewis bases due to their excess electron. The different Lewis bases thus compete for the available sulfuric acid molecules, and the relative role of each base in enhancing nucleation depends both on the strength of its interaction with H_2SO_4, and on its concentration: typically around $10^{2,,4}$ cm^{-3} for anions, $10^{6...9}$ cm^{-3} for amines and $10^{8...11}$ cm^{-3} for NH_3. Anions interact much more strongly with the first few acid molecules in a nucleating cluster, but the differences between the Lewis bases with respect to acid addition free energies, and thus the acid saturation vapor pressures and evaporation rates, essentially disappear once the cluster contains more than two or three H_2SO_4 molecules (see Figure 1).

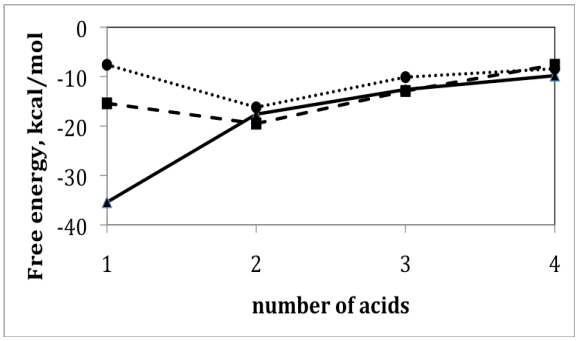

Figure 1. Free energies (kcal/mol) for the reactions $X•(H_2SO_4)_{n-1} + H_2SO_4 \Rightarrow X•(H_2SO_4)_n$, for n = 1…4 and $X = HSO_4^-$ (solid line), $(CH_3)_2NH$ (dashed line) and NH_3 (dotted line). Values correspond to 298 K and 1 atm, see Ortega et al. (2012).

There are two crucial differences between anions and other Lewis bases with respect to the growth dynamics of the base-stabilized sulfuric acid clusters. First, while self-coagulation of neutral acid-base clusters may efficiently promote cluster growth (while reducing total number concentrations), charged clusters cannot self-coagulate due to electrical repulsion. Second, the condensational growth rate of charged clusters is enhanced due to the attractive charge-dipole interaction with condensing molecules, which decays much more slowly with distance than the dipole-dipole interaction (see Figure 2 for representative numerical values).

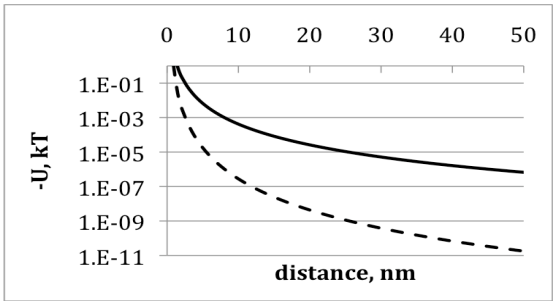

Figure 2. Potential energy (in units of k_bT) of H_2SO_4 interacting with a $X•H_2SO_4$ cluster, for $X = HSO_4^-$ (solid line), or $X = (CH_3)_2NH$ (dashed line). Computed using B3LYP/CBSB7 dipole moments on Gaussian 09 (Frisch et al, 2009), classical electrostatics and 298 K Boltzmann thermal averaging of interaction angles.

Using the concept of Lewis basicity, ternary neutral and binary ion-induced sulfuric acid nucleation are shown to be examples of the same fundamental process. The difference between the stabilizing effect of anions and neutral bases on the sulfuric acid clusters disappears rapidly with cluster size. Cluster growth is further enhanced by self-coagulation for the neutral base-containing clusters or by condensation enhancement for the anion clusters. Kinetic models (McGrath et al., 2011) will be used to determine the concentrations regimes at which the various bases are important for nucleation.

Presenting author email: javier.andrey@gmail.com

Saharan dust is the major source of aerosols emitted yearly to the atmosphere. The Iberian Peninsula, located at the North of the Sahara desert, is frequently affected by Saharan dust intrusions, especially during the summer period (Toledano et al., 2007; Bennouna et al., 2011; Guerrero-Rascado et al., 2009).

In June 2011, an airborne campaign was conducted by INTA in collaboration with Granada University intended to study Saharan dust aerosols properties. Flights were carried out over INTA "El Arenosillo" sounding station (ARN, 37.1N 6.7W) and Granada (GRA, 37.2N, 3.6W) under dust (D) and non-dust (ND) conditions. The data under ND condition were used as a "clean" reference for the D measurements. Four flights were carried out during the airborne campaign, two of them over each station.

The INTA atmospheric research aircraft was equipped with two optical particle counters designed by Droplet Measurement Technologies (DMT): PCASP-100X (15 bins, 0.1-3.0 μm) and CAPS (30 bins, 0.51-50 μm). The CAPS was equipped with optional depolarization module allowing determinations of refractive index and particle shape of the sampled aerosols. The algorithm to determine both refractive index and particle shape are based on the Mie theory.

Several particle counters and two CIMEL sun-photometers were deployed at both stations or in the vicinity of them. The size distributions retrieved by the airborne instrumentation are compared with in-situ measurements of particle counters and AERONET retrievals from the particle counters and CIMEL sun-photometers respectively. Data from CIMEL stations within the studied area have been used to provide a global image of the Saharan dust episode. Refractive index retrieved by the optional depolarization module is also presented and compared with CIMEL retrievals in this work.

The AOD at 440 nm during the flight for D conditions reached values of 0.48 and 0.30 over ARN and GRA, while under ND conditions the AOD reached 0.10 and 0.11 respectively. The ceiling of the Saharan dust intrusions detected by the aircraft was located at 6 and 5 km asl over ARN and GRA respectively. In both cases the concentration of particles in the coarse mode was higher at lower levels (2-3 km asl) than in the intrusion top height.

An oversampling issue in the coarse mode was noted for the PCASP measurements during ND days. This may be related with the low particle concentration found in this range.

The importance of Nocturnal Low-level Jets for simulating mineral dust emission

S. Fiedler[1], K. Schepanski[1], B. Heinold[1], P. Knippertz[1] and I. Tegen[2]

[1]The University of Leeds, School of Earth and Environment, Leeds, LS2 9JT, United Kingdom

Keywords: Aerosol emission, Modelling, Saharan/mineral dust
Presenting author email: eesfi@leeds.ac.uk

Mineral dust is important for the Earth system. The aerosols interact with short- and long-wave radiation, influence clouds and precipitation, and affect human health during atmospheric transport. Deposited desert dust fertilizes remote marine and terrestrial ecosystems. Modelling the atmospheric cycle and the impacts of dust depends on the accurate simulation of time, place and amount of mineral dust emission.

Dust emission in large scale atmospheric models is parametrised as a non-linear function of surface characteristics, and the momentum transfer of the wind to the ground. Particles are mobilised when the friction velocity exceeds the soil-specific threshold value. The nocturnal low-level jet (NLLJ) is one of the mechanisms that potentially generates a sufficient vertical momentum flux for dust emission. A NLLJ is a near-surface wind speed maximum developing over a surface-inversion at night. The air above the inversion-layer accelerates due to reduced dynamical friction. Momentum from the NLLJ is mixed towards the ground by both shear-induced turbulence at night and convection during the following morning. The latter, breakdown of NLLJs, has been suggested as important mechanism for dust emission based on observations covering weeks to a few years. However, a climatology of the NLLJ and its contribution to dust emission is missing.

This work presents the first statistical analysis of NLLJs and its importance for dust emission relative to other processes. A new and objective NLLJ detection algorithm for large-scale atmosphere models has been developed and is applied to 6-hourly data on 60 model levels from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-interim re-analysis for 1979-2011. Re-analysis data are considered as the best estimate of atmospheric conditions for North Africa, where the observation network is sparse. The offline dust model by Tegen *et al* (2002) with updates described in Schepanski *et al* (2007) is driven by near-surface wind speed and soil moisture from ECMWF to calculate mineral dust emissions.

The spatially-averaged NLLJ frequency over North Africa ranges from 22% of nights per season in Northern Hemisphere summer and 20% in autumn, to 26% in winter and spring. Typical spatial standard deviations are 13-20% of NLLJ nights dependent on the season, reflecting the spatial variance. The areal distribution of the NLLJ highlights their frequent occurrence along the margins of the heat-low in summer, and in regions affected by mountain channelling, e.g. the Bodélé Depression, Chad, where NLLJs characterise 40-80% of the nights between December and February (Figure 1). Most frequent heights of NLLJs are 300-400m and the median core speed is 10m/s. The results point towards a relative contribution of NLLJs to dust emission of 28+/-22% (mean +/- standard deviation) at 06 UTC and 42+/-18% at 00 UTC in the annual-mean over North Africa. The relative importance of NLLJs increases to annual-mean values around 70% NLLJ nights in some regions, where the phenomenon is more frequent.

In future work, this first NLLJ climatology for North Africa enables an evaluation of the representation of this phenomenon in state-of-the-art atmosphere models. It therefore holds the potential for improving the diurnal cycle of wind speed and dust emission in numerical weather prediction and climate models.

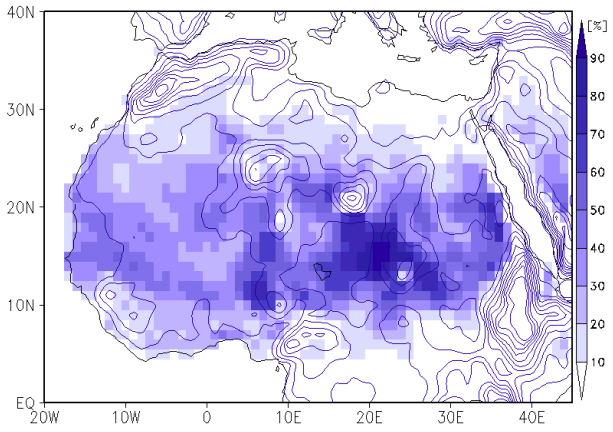

Figure 1. NLLJ frequency in % for north hemisphere winter (DJF) in North Africa. Contour lines show the topography in 200m steps (Fiedler *et al*)

Presenting author email: ja.garcia@umh.es

We present a summary of key results obtained in several field campaigns conducted from 2005 to 2012 mainly in the framework of two research projects. The RESUSPENSE project, 2005 – 2007, was aimed to quantify the contribution of resuspension to the airborne particulate levels in semi-arid Spain. The aerosol size distribution in the range 0.25 – 32 μm, PM10 concentration and chemical composition, as well as meteorological parameters, were studied at three measurement sites: a rural background location (R1), a rural site with influence of mineral industry (R2) and an urban background site (U). Another study was conducted from February to June 2008 in an agricultural plot previously cleared and leveled for future cultivation (R3). Aerosol size distribution was measured there at three heights above the ground. The field campaigns conducted since 2009 form part of the EroHondo project. *El Hondo* Nature Park is an area of ephemeral lakes that experiences cycles of flooding and desiccation with anthropic regulation. The sediments lying on the desiccated surface are susceptible to deflation. The objective of the project is studying the relationship between wind erosion and suspended particulate levels downwind, in relation to atmospheric and soil conditions. Two primary sampling sites (R4 and R5) were chosen for upwind – downwind measurement of suspended particulate concentrations (size distribution and PM10 levels). A number of sediment traps to collect saltating particles, as well as soil moisture and temperature sensors, were deployed. Top soil and saltating sediments were chemically analyzed, and granulometry was determined.

The crustal material in the PM10 fraction is elevated, 16.5, 12.5 and 9 μg m^{-3} at the U, R1 and R2 sites, respectively, which account for 54, 68 and 48% of the PM10 concentrations. Working days show a mean increase of the crustal material of 7 and 3.5 μg m^{-3} with respect to Sundays at R1 and R2, while days with African dust outbreaks increase that concentration by 9 μg m^{-3}. Daily PM10 concentrations, however, decrease with increasing wind speed at the typical situations of low to moderate winds. This holds also for the crustal component and any of the chemical elements in that fraction. Size-resolved measurements recorded with higher temporal resolution show, in turn, a net increase in the concentration of large particulates with higher wind speeds, while the smallest particles are dispersed by the wind action. Human activity in the surroundings may maintain moderate levels of particles lying in a broad intermediate size-range. These are dispersed with light winds although stronger winds increase their concentration due to resuspension.

The threshold wind speed from which particle concentration increases is higher for smaller particles. Results show that resuspension of the largest particles occurs just from very small wind speeds, convection being the facilitating mechanism.

The strong wind erosion episodes leading to dust storms in El Hondo Nature Park were associated to the passage of Atlantic frontal systems with no rainfall. Levanter (an easterly wind) promoted some moderate particle entrainment episodes. Winds larger than 9 m s^{-1} (at 2 m above the ground) and average friction velocity of 0.46 m s^{-1} triggered the erosion events. Such conditions were found in more than 40 occasions, but soil conditions limited deflation in some 80% of these situations by the existence of a large water sheet and near-surface water table, residual surface moisture or saline crusts.

As soil was getting drier, the concentrations of Na and Cl at the surface strongly increased and white saline crusts formed. The removal of the evaporite-rich top soil under erosion events led to a significant decrease in Na; correspondingly, both the saltating and the suspended particles were enriched in this element.

A clear indication of intense wind erosion is given by the concentration of suspended particles larger than 15 μm and by the relative abundance of sodium in the PM10 fraction. Streamwise fluxes of saltating particles in the range 0.5 to 85.5 kg through 1 m of field width and 0.35 m height have been registered in a single event. Suspended particulates, in turn, were lifted up to tens of meters while the dust plumes displaced over the eroding area, and the impact on a coastal village some 10 km downwind was registered.

Long-term observations of mineral dust deposition to the Northeast Atlantic Ocean and hygroscopic properties at the Cape Verde Islands.

Presenting author email: nicole.niedermeier@tropos.de

Mineral dust is one of the most important aerosol types under investigation. Their impact on clouds (e.g. serving as ice nuclei) and radiation can differ depending on their chemical composition and aging state. Furthermore, the understanding of the global dust cycle is still incomplete (Mahowald et al., 2005). The removal of mineral dust is essential for bioactivity in the ocean, since dust serves as a source of nutrients (e.g. iron) for oceanic microorganisms such as phytoplankton. Long-term observations of Saharan dust layers spreading over the Northeast Atlantic Ocean do however not exist so far.

Within the project SOPRAN (Surface Ocean PRocesses in the ANthropocene), microphysical aerosol measurements at the Cape Verde Island Sao Vicente in the tropical North Atlantic Ocean are carried out since May 2007. Particle number size distributions (PNSD) using the combination of SMPS and APS and absorption measurements (MAAP) are available. Several intensive field experiments were performed to characterize optical and hygroscopic properties of mineral dust and sea salt particles. Together with micrometeorological measurements, dust mass deposition fluxes can be calculated. Since December 2011 mineral dust mass concentrations (Aethalometer) and high time resolved 3D wind velocities (sonic) are measured. Furthermore, number fractions (nf) and growth factors (GF) at a relative humidity of 90% of a mixture of mineral dust and sea salt at dry mobility diameters of 600, 800, 1000 and 1200 nm (H-DMA-APS, Leinert and Wiedensohler, 2008) are investigated.

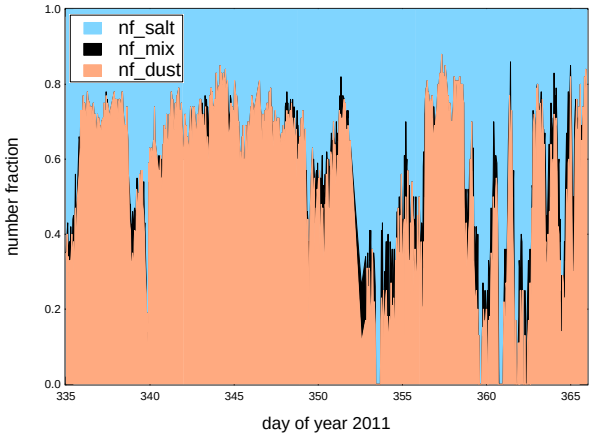

Figure 1: Number fractions of dust (brown), sea salt (blue) and a mixture of both (black) by hygroscopic growth measurements with an H-DMA-APS.

Hygroscopic growth measurements show an external mixing of dust and sea salt in most cases. However, in some cases, also an internal-external-mixture of both particle types is observed. This mixture was also detected by Kandler et al. (2012) at the same location by electron-microscopical single particle analysis of passive sedimentation samples. Figure 1 shows the number fractions of dust and sea salt at a dry mobility diameter of 800 nm for December 2011. Dust dominates the whole period with some exceptions having a mean value of 53%. In most cases nf_mix is lower than 10% and does not exceed 30%. Dust number size distributions and dust mass size distributions can be calculated from nf_dust at different diameters, the PNSD, and the particle density. Turbulence parameters obtained by the sonic measurements are used to calculate size-resolved particle deposition velocities. This data was combined to obtain the dust mass deposition fluxes (Held et al., 2006).

First calculations of the GF of mineral dust showed values below 1.1. This leads to the assumption that no or less aging occurs on mineral dust particles from the Saharan Desert to the Cape Verde Islands. Investigations of the GF of sea salt varied much more with values between 1.5 and 2.2. The highest values are consistent with that of pure sea salt. The lower values raise the question, whether organics and other insoluble material exist in internal mixture within the particles.

Sahara desert is the most important source of mineral dust, contributing as much as 1900 million tons per year. Due to its localization, Cape Verde is ideal to quantify and to characterize the dust transported from Sahara desert. Cape Verde is an archipelago composed by 10 islands, localized in Atlantic Ocean, near African coast. Santiago's island is the biggest island of Cape Verde, with an area of 991 km^2 and it was the selected island to perform this study (Fig. 1), which was done within the project *Atmospheric aerosol in Cape Verde region: seasonal evaluation of composition, sources and transport* (*CV-Dust*) - that aims to assess the transport of dust from Sahara by using an integration of measuring and modelling tools.

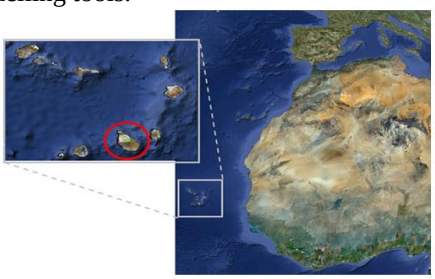

Figure 1 - Localization of the Cape Verde Islands

PM_{10} was collected in Praia city (14º94'N; 23º49'W) with a Tecora® sampler in order to characterize the chemical composition. The collected filters were weighted by gravimetry using a Mettler® Toledo balance with 0.1 µg readability, placed in a controlled clean room (class 10,000). All samples were irradiated at the Portuguese Research Reactor (RPI-ITN; nominal power: 1MW) during 5 h, and measured for 5-7 h after 2-5 days and 4 weeks of decay, in high-purity and high-resolution germanium detectors. A comparator – Al-0.1% Au alloy disk – was also irradiated and measured for application of the k_0-INAA methodology.

Fig. 2 shows the average element mass concentration in PM_{10}. The elements As, Sm, Co, Fe, Sc, K, Cr, Ce and Ba presented a similar behaviour throughout the sampling period, indicating a common source. Fig. 3 presents the relation between all the measured elements with Fe. Ratios for soil composition are presented and confirm a soil origin for these elements. Two periods with higher concentrations were achieved. Hysplit model indicated that these periods were associated with Sahara dust events. All these elements presented significantly higher concentrations in Cape Verde comparing with other studies performed in Lisbon by our research groups. The elements Na, Sb and Zn presented a different behaviour indicating the existence of other emissions sources, probably the sea salt for Na and anthropogenic emissions for Sb and Zn.

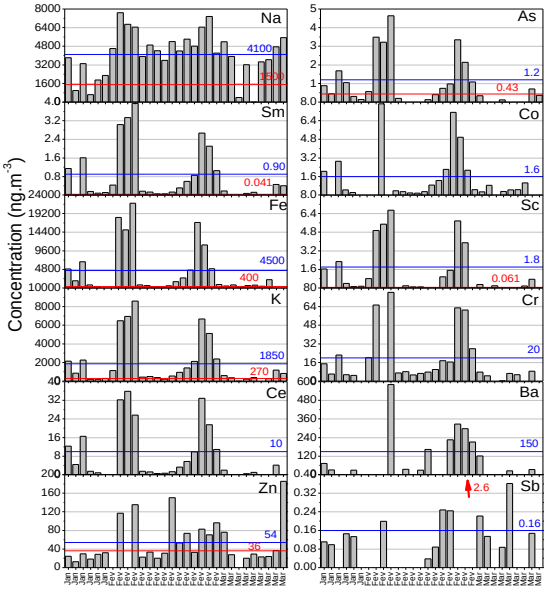

Figure 2 - Element mass concentration in PM_{10} sampled (average from CV-Dust and average from Lisbon)

The CV-Dust project is on-going which means that the results are being updated constantly.

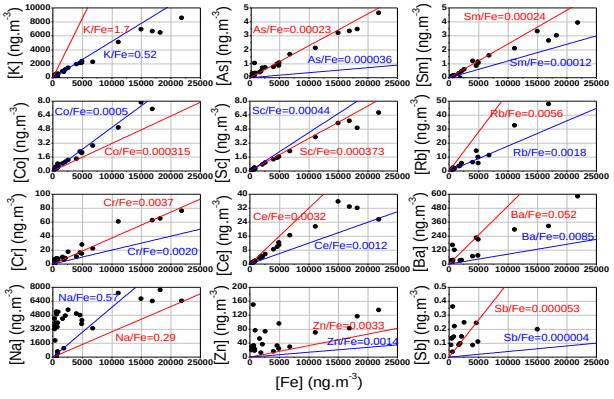

Figure 3 - Relation between composition of these particles and different types of soil (soil Mason composition[1] and Sahara desert soil[2])

We gratefully acknowledge FCT for funding the project PTDC/AAC-CLI/100331/2008 - Atmospheric aerosol in Cape Verde region: seasonal evaluation of composition, sources and transport (CV-Dust).

Optical behaviour of mineralogical composition. A laboratory study

T. Ajtai, Á. Filep, N. Utry, M. Pintér, Z. Bozóki, G. Szabó
Department of Optics and Quantum Electronics, University of Szeged, Hungary

Keywords: minerals, photoacoustic, optical absorption, Ångström exponent.
ajtai@titan.physx.u-szeged.hu

One of the major contributions in uncertainties on climate forcing is associated to aerosol. These uncertainties are mostly governed by absorbing particles. Aerosol light absorption in the solar spectral region is dominated by the inorganic (BC) and organic carbon (BrC) particles emitted by anthropogenic and natural combustion process as well as mineral dust (MD) aerosol. Although the mass absorption efficiency of MD is much smaller than that of BC, it significantly influences the climate due to its remarkable global emission rate. MD aerosol is a complicated mixture of various minerals having versatile spectral behaviour. Absorption feature of dust strongly depends not only on relative abundance of its composition but also on details of how the minerals are mixed, as well as chemical and physical transformation during its transport in the atmosphere. The common approach used in model calculation on segregated MD radiative forcing relies on optical constant determined from bulk samples collected at specific geographical location (Sokolik and Toon 1999). This approach has serious limitations: (i) poor data quality, mainly due to the limitation of applied method and instrumentation, (ii) sample artefact, so the sample experienced specific atmospheric conditions and transformations during its transport from the source to the sampling site, therefore the deduced optical constant is not adequate for modelling time- and space varying optical properties, (iii) nonlinearity of optical properties on refractive indices, so optical constant determined from bulk including mixture of minerals is not adequate for modelling specific mineral optical behaviour. Finally, the reliability of optical coefficient of particles deduced from bulk material is also questionable. Therefore the measurement of optical behaviour of single composite, especially its absorption, of MD is one of the major concerns in modelling the net radiative forcing by dust.

In this work we present first, in-situ measurement of minerals aerosols such as illite, kaolinite, quartz, limestone, rutile, bentonite and hematite in the solar spectral region. Optical absorption coefficient of minerals was measured by our novel photoacoustic instrument (4λ-PAS) operating at four discrete wavelengths in the UV, VIS, near IR spectral region. The instrument applies wavelength independent calibration and provides a unique possibility for in-situ characterization of absorption behaviour of aerosol with high reliability (Ajtai et al, 2010). Other microphysical parameters of minerals, which affect the optical absorption coefficient such as size distribution and shape, were also measured parallel. Measured absorption spectra were compared with absorption spectra modelled with Mie-theory and T-matrix method to decide whether the absorption coefficient deduced theoretically from bulk can be transferred to airborne mineral particles or not (Fig. 1).

We demonstrated measurement data of optical absorption, mass specific optical absorption and wavelength dependent absorption Ångström exponent of the measured minerals. We also demonstrated experimentally that the absorption feature of minerals is source specific parameter. Finally, we demonstrated that the selectivity of composition identification is continuously increasing towards the shorter wavelengths.

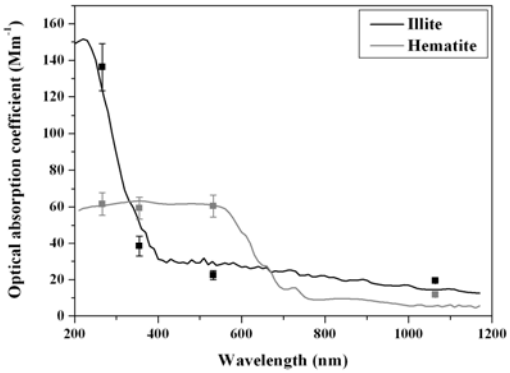

Figure 1: Optical absorption coefficient measured by the 4λ-PAS (symbols) and calculated with the Mie-theory (lines) of illite (labelled with black) and hematite (labelled with grey)

In the last few decades, the Amsterdam light scattering setup (Hovenier 2000) fulfilled a unique position in producing a significant amount of experimental scattering matrices as functions of the scattering angle of samples of small irregular particles relevant for astronomy, and studies of the atmosphere, as well as coastal and inland waters of the Earth (see e.g. Volten et al. 1998, 2001; Muñoz et al. 2001, 2004). The measurements of aerosols were performed at two different wavelengths (441.6 and 632.8 nm) in the scattering angle range from 3-5 degrees (depending on the sample) to 174 degrees. The hydrosol measurements were done at 632.8 nm in the scattering angle range from 20 to 160 degrees. These experimental data are a powerful tool for properly interpreting space- and ground-based observations or for testing different computational approaches devoted to obtain the scattering behavior of small irregular particles (see e.g. Nousiainen 2009 and references therein). In addition, the light scattering results may also be applicable in the paper and paint industry, or in the fields of chemistry and biology.

Since September 2003, the Dutch experimental data are freely available in digital form in the Amsterdam Light Scattering Database (Volten et al. 2006). Many different research groups around the world made use of the experimental data (see e.g. Bi et al. 2010, Valenzuela et al. 2012). After the closing down of the Dutch scattering apparatus in 2007, a modernized and improved descendant, the IAA Cosmic Dust Laboratory (CoDuLab), has been constructed at the Instituto de Astrofísica de Andalucía (IAA) in Granada, Spain (Muñoz et al. 2010). In the new apparatus the scattering angle range at which the measurements are performed is 3-177 degrees. The measurements can be performed at five different wavelengths namely, 483, 488, 520, 568, and 647 nm. The first results of this instrument for water droplets and for a sample of green clay particles, that had also been studied in Amsterdam, demonstrate the excellent performance of the Granadian instrument (Muñoz et al. 2011). We proceed to make these and future data also available for the community in tabular form by constructing a new light scattering database, the Amsterdam-Granada Light Scattering Database available at the website (www.iaa.es/scattering). The particle samples included in the database comprise a wide range in origin and composition, and have relevance for different subjects. The typical diameters (or volume-equivalent diameters) of the particles measured with the experimental setups in Amsterdam and Granada range from sub-micron to about 200 micron. By combining the data from the two instruments in this database we ensure the continued availability of the Amsterdam data, and we prevent fragmentation of important data over different databases.

The purpose of this work is to introduce the new Amsterdam-Granada Light Scattering Database giving examples of applications of database data.

Vehicles are a major source of particulate matter (PM) in urban areas. A large fraction of ambient PM consists of organic aerosol (OA), either primary (POA), from direct emissions, or secondary (SOA), formed via gas-phase reactions. Therefore any attempt to mitigate the effect of on-road vehicle emissions on public health and the environment should consider not only primary aerosol emissions but also secondary aerosol production potential (SAPP). However, only the primary aerosol from on-road vehicles is currently subject to direct legislation.

SOA formation from diesel exhaust has been reported, (e.g. Robinson *et al.*, 2007), but SOA formation from other common vehicles including gasoline vehicles has not. The effect of different conditions, such as fuel type, engine technology and ambient temperature on SOA formation remains unknown.

Here we determine emission factors (EFs) (g kg^{-1} fuel) for primary PM and for SOA, from two- and four-stroke scooters, a gasoline car and a truck, all complying with the latest European emissions standards. We also quantified the effect of using alkylated gasoline in scooters, liquid petroleum gas (dual fuel) in trucks and the effect of ambient temperature on SOA formation from gasoline cars and from trucks.

Vehicle exhaust was introduced into the new PSI mobile smog chamber during regulatory driving cycles on chassis dynamometers at the European Joint Research Centre Ispra, Italy. A high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) equipped with a $PM_{2.5}$ lens was used to quantify OA. Black carbon (BC) was measured using a multi angle absorption photometer (MAAP) and an Aethalometer (AE 33 prototype). A high resolution proton transfer time-of-flight mass spectrometer (PTR-ToF) was used to investigate volatile organic compounds and a suite of instruments was used to quantify CO, CO_2, CH_4, total hydrocarbon and other gases. EFs were calculated with a carbon mass balance applied to smog chamber data.

All gasoline vehicles showed significant SAPP. SOA/POA ratios were up to 27.1 for the gasoline car (Figure 1) vs. 1.4 from the truck. Average PM EFs, with the inclusion of SOA and BC, were higher from the gasoline car than from the diesel truck: 0.21 vs. 0.10 g kg^{-1} fuel, respectively. This large SOA formation is likely a consequence of higher gaseous hydrocarbon emissions from the gasoline car: 1.01 vs. 0.16 g kg^{-1} fuel for the truck.

OH exposure in smog chambers can be calculated from the decay rate of nine times deuterated butanol spiked into the chamber (Barmet *et al.*, 2011). Using this technique we show that SOA formation from gasoline exhaust would occur within 12-14 hours in the real atmosphere (colourscale, Figure 1).

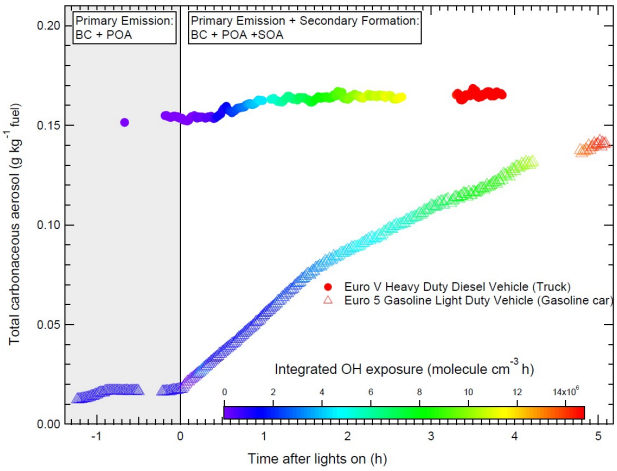

Figure 1: Carbonaceous aerosol and secondary aerosol formation emission factors from a gasoline car and a diesel truck vs. time in the PSI mobile smog chamber.

We demonstrate that aerosol emissions from gasoline vehicles can be significantly enhanced due to SOA formation and may match or even exceed those of diesel vehicles. This large SOA formation has substantial implications for emission controls which currently do not consider SAPP.

A source of oxygenated organic aerosol and oligomers from primary emitted gases

John Liggio[1], Shao-Meng Li[1] and Alexander Vlasenko[1]

[1]Atmospheric Science and Technology Directorate, Science and Technology Branch, Environment Canada, 4905 Dufferin Street, Toronto, Ontario M3H 5T4 Canada

It is well recognized that particulate organic matter (OM) often constitutes the largest fraction of the total particulate matter (PM) burden globally, and is an important factor with respect to climate change, and air quality issues. Despite its importance, the sources and formation mechanisms of OM remain poorly understood, due in part to the varied sources and complex mechanisms involved. Although SOA may comprise the largest OM fraction, a complete understanding of its formation mechanisms remains elusive, highlighted by the fact that traditional mechanisms involving the oxidation of precursors (via OH, O_3 and NO_3) are often unable to account for SOA observations. Recent evidence suggests that oligomer and high molecular weight (MW) species formed as a result of particle phase and heterogeneous chemistry mechanisms may also play an important role in SOA formation and potentially explain such discrepancies.

Although the relative importance of high MW compounds (via liquid phase reactions) and condensable species (via gas-particle partitioning) to the total SOA is not clear, both pathways are considered a result of the oxidation of biogenic or anthropogenic precursors on the time scale of hours in the atmosphere. As such, the degree of oxygenation in measured OM has been used as a metric to infer source types (POA vs SOA). Consequently, high OM oxygenation as represented by the atomic O:C ratio has been linked to varying degrees of aerosol aging and SOA formation, while conversely, POA is associated with a very low O:C.

In contrast, recent studies have suggested that the uptake of primary vehicle exhaust gases to pre-existing particles [Li et al., 2011] on very short timescales have the potential to increase OM mass in urban or suburban areas. In principle, this can lead to changes in the degree of aerosol oxygenation through the uptake of primary polar species to inorganic aerosol, or through subsequent particle phase reactions. From the standpoint of health impacts and atmospheric modeling, such a process occurring on a short time and spatial scale could lead to oxygenated OM and oligomers which will be indistinguishable from POA mass, and implies that POA in urban areas may be more oxygenated than previously considered.

In the present study the potential for primary hydrocarbon-like gases to partition and react on short timescales with inorganic seed particles is investigated by exposing urban ambient air influenced by vehicle emissions, to laboratory generated sulfuric acid particles and gas-phase ammonia in a smog chamber. The results demonstrate that the mixture and concentration of organic species in the ambient air is sufficient for a large organic uptake to particles to occur in less than 2 minutes. The resultant particulate organic mass spectra from the experiments were highly correlated to those of previous experiments exposing gasoline engine exhaust to neutral particles [Li et al., 2011], and concurrent with measured decreases in unsaturated hydrocarbons from the gas-phase. The initially added organics were considerably more oxygenated than that previously reported for primary organic aerosol, while the presence of numerous m/z fragments greater than 300 amu suggested that oligomer formation also occurred. Oligomerization was enhanced at high acidity but otherwise unaffected by subsequent particle neutralization. These results potentially represent a new source of oxygenated POA and high molecular weight species to the atmosphere, which may be similar or larger than the average POA (represented by HOA) measured in numerous regions worldwide. The results also suggest that a fraction of measured oxygenated OA, which correlate with secondary sulphate, may be of a primary source, formed prior to any gas-phase oxidation.

Presenting author email: miri.trainic@weizmann.ac.il

Constraining the optical properties of secondary organic aerosol (SOA) is a major challenge since they often consist of a mixture of several components with various internal structures, including homogeneous mixtures and core/shell structures. The importance in understanding the optical properties of aerosols is their effect on the magnitude and uncertainty of Earth's total radiative forcing and climate change. SOA form by the condensation of less-volatile gaseous compounds onto pre-existing aerosols, and by heterogeneous and multi-phase reactions.

The heterogeneous reaction between glyoxal gas and three atmospheric aerosol types; ammonium sulfate (AS), glycine and glycine-AS 1:100 was studied. The optical extinction cross section at λ=355nm and mobility size increased following the reaction under a broad range of RH values (30-90%), indicating that the reaction is relevant for a wide range of atmospheric conditions.

We propose that at low RH values, below the deliquescence point, the recations occur in interfacial monolayers of water, supporting previous findings about the importance of interfacial water in heterogeneous reactions.

The reactions exhibit a trend of increasing growth in physical and optical cross sections with decreasing seed aerosol size, as well as a clear dependence on ambient RH values (Figure 1). For small particles with near-zero extinction efficiency (Q_{ext}) values, the reaction induces the greatest increase in optical extinction cross section (up to 2 orders of magnitude enhancement) due to a combined effect of changes in optical properties and in size, resulting in a change in the location on the Mie curve.

AMS analyses of the reactions show that the main reaction products are glyoxal oligomers, and a small contribution from the formation of various C-N compounds, identified as imidazoles.

Our results suggest that unlike previously postulated, the reactions at RH values below deliquescence occur on interfacial water layers and their optical enhancement is mainly due to enhanced scattering and geometric cross section growth.

This study contributes to the understanding of the effect of the reactions on the optical properties of the aerosols in the atmosphere by demonstrating that the heterogeneous reactions between abundant atmospheric components may alter the aerosols' optical, physical and chemical properties on short timescales (~ 1 hour) and may have substantial implications on the radiative effects of these aerosols (Trainic et al. 2011; Trainic et al. 2012).

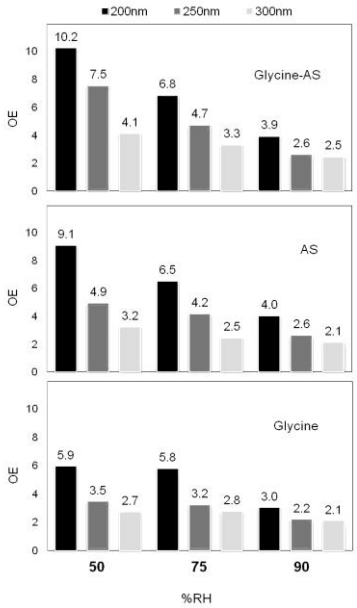

Figure 1: The optical enhancement (OE) of the extinction cross section due to reaction of glyoxal with pure glycine (bottom), AS (middle), and glycine-AS (top) at RH values of 50%, 75%, and 90% for initial sizes of 200nm (black columns), 250 nm (grey columns), and 300nm (light grey columns).

Conventional models for secondary organic aerosol (SOA) formation focus on the condensation of low-volatility products from gas-phase reactions. However, such models neglect aqueous-phase processing mechanisms, thereby excluding potentially important SOA formation pathways. These missing pathways may be an important factor in the inability of current models to fully explain SOA yields and oxidation states.

Glyoxal is an oxidation product of numerous organic gases and has recently been identified as an important SOA precursor (e.g. Ervens and Volkamer, 2010). Unlike traditional precursors, glyoxal partitions to the particle aqueous phase. Subsequent reactions can lead to low-volatility products that remain in the particle phase. Glyoxal partitioning and SOA formation have been observed to depend on numerous parameters, specifically aerosol water content, seed particle composition, and light exposure, which are explored in the present study.

Glyoxal SOA formation experiments were conducted in the PSI smog chamber. The chamber was filled by a mixture of seed particles (ammonium sulphate or internally-mixed ammonium sulphate/fulvic acid) with gas-phase HONO and acetylene (a glyoxal precursor) at controlled relative humidity (50 to 85%). Photochemistry was initiated by brief (i.e. a few minutes) exposure to UV light. Glyoxal was produced by the reaction of acetylene with OH radicals during brief (i.e. a few minutes) exposures to UV light. The reaction was then allowed to proceed undisturbed for several hours (under light or dark conditions), prior to another UV exposure. After several of these cycles, a dilution phase was initiated to investigate the reversibility of the produced SOA.

Gas-phase glyoxal was measured by a LED-CE-DOAS (Thalman and Volkamer, 2010), while additional gas-phase species were measured by ToF-PTR-MS. Aerosol composition was measured by an HR-ToF-AMS, thermal desorption PTR-MS, and offline filter measurements. Supporting measurements included gas-phase species (e.g. total hydrocarbons, CO, O_3, NO, NO_x), and particle number and size distributions.

The AMS organic mass spectral time series was analyzed by positive matrix factorization (PMF) to yield factors relating to reaction progress, including fulvic acid ("FA"), glyoxal ("GLY"), and glyoxal SOA ("GSOA"). Figure 1 shows a sample experiment, conducted at ~85% RH on a mixed ammonium sulphate/fulvic acid seed. All time series are normalized to SO_4 to correct for wall losses. Normalized GLY and GSOA both increase with each UV exposure. However, during the dilution phase there is a clear decrease in GLY while GSOA remains constant. This indicates that while GLY uptake is reversible, GSOA formation is irreversible. The GSOA factor mass spectrum has a strong contribution from mass fragments characteristic of imidazoles, which form irreversibly from reaction of hydrated glyoxal with several nitrogen-containing compounds (Ervens and Volkamer, 2010).

We will discuss glyoxal SOA yields and product distributions in terms of RH, seed composition, and visible light exposure. The effects of these parameters on glyoxal partitioning according to Henry's Law will also be explored.

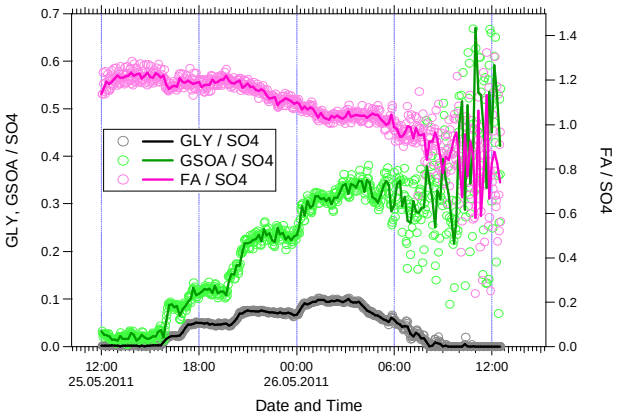

Figure 1. Sample time series of AMS PMF factors for glyoxal, glyoxal SOA, and fulvic acid, all normalized to particulate sulphate to account for wall losses.

The investigation of atmospheric aerosol chemical composition and its evolution during ageing is necessary to document particle impact on climate and health. Chemical composition of secondary organic aerosol (SOA) is particularly complex. Hence, its chemical properties are often addressed using macroscopic parameters such as volatility, hygroscopicity or oxidation state. However, to investigate mechanisms occurring during ageing or to identify markers for specific processes, SOA chemical composition has to be elucidated at a molecular level. Most previous studies, which present SOA composition at a molecular level, were based on simulation chamber experiments and provided a "fixed" picture of SOA. Only very few of them have reported on the molecular composition evolution during aerosol ageing (Alfarra *et al*, 2012; Claeys *et al*, 2012).

In this context, the molecular composition of SOA formed from α-pinene ozonolysis (selected here as reference reaction system) and its evolution with time was investigated. Experiments were performed in CESAM facility, which allows not only to work in realistic and controlled conditions, but also to study aerosol ageing (Wang *et al*, 2011). Indeed, aerosol lifetime in CESAM ranges from 10 h to 4 days depending on particle size distribution. Moreover, CESAM is equipped with three high pressure xenon arc lamps which provide a very realistic artificial solar irradiation. Finally, being evacuable, it is possible to generate clouds by fast expansion in this chamber.

In the present work, SOA ageing was studied under four experimental conditions: (1) excess of ozone, (2) excess of ozone + irradiation, (3) excess of ozone + cloud generation and (4) excess of ozone + pre-existing seeds (acidified ammonium sulfate), and for 2 initial α-pinene concentrations (50 ppb and 200ppb). Experiments lasted for up to 20 hours. Gaseous phase composition was monitored using Fourier Transform InfraRed spectrometry. Ozone was measured using a commercial monitor instrument. Particle size distributions (20 - 980 nm in diameter) were measured with a scanning mobility particle sizer coupled to a condensation particle counter. Once generated in the chamber, SOA was sampled using glass fibre filters. An active charcoal denuder was used to trap reactive gases and reduce positive sampling artefacts. Filters were then stored in glass jars at -18°C.

Aerosol analyses were performed using two complementary techniques. Supercritical Fluid Extraction coupled to Gas Chromatography and Mass spectrometry (SFE-GC-MS) with in situ derivatisation using BSTFA allowed to identify and quantify oxidised products such as aldehydes, ketones, carboxylic acids and di- or tri-functional species. Liquid Chromatography coupled to triple quadrupole Mass Spectrometry (LC-MS) with a preliminary extraction step in methanol using Pressurised Fluid Extraction was chosen to investigate more specifically the presence of dimers and of organo-sulfates.

More than 25 compounds and, amongst them, four dimers, could be identified in the particulate phase and were quantified, either properly using corresponding standards or tentatively using surrogate standards. Mechanisms will be proposed to explain the formation of these compounds. The evolution of their concentrations along the different ageing experiments will also be presented. These results provide valuable information about mechanisms occurring within the aerosol during ageing processes and their potential atmospheric implications.

Secondary aerosol formation, via gas-to-particle conversion, happens extensively and frequently in the boundary layer of our planet (Kulmala et al., 2004); a portion of the nucleated particles manages to grow to Cloud Condensation Nuclei (CCN) size and therefore influences climate both directly, changing the way sunlight is scattered and absorbed by the atmosphere and indirectly, changing lifetime and optical properties of clouds. The number of nucleated particles that reaches big enough size to become a CCN is strongly dependent on the Growth Rates (GR), especially on the rate of growth of the particle when it is very small, at the early stage, right after the aerosol is created, when the probability of attaching to a pre-existing particle is higher. Sulfuric acid has been identified as a one of the key components for triggering nucleation (Weber et al., 1996) but it has been shown not to be enough to explain the growth of particles to CCN size. In fact most of the mass in ambient aerosol is found to consist of organic compounds (Tunved et al., 2006).

During the CLOUD (Cosmics Leaving OUtdoor Droplets) experiments, more than 500 nucleation bursts were produced in an aerosol chamber, at different conditions. The first results (Kirkby et al., 2011) were focusing on the charge enhancement of nucleation rates in pure sulfuric acid conditions; in this study we carried out the analysis of the GRs, for each of the nucleation experiments, and we retrieved information of size-dependent GR studied as function of sulfuric acid, ammonia, dimethyl amine and pinanediol concentration (e.g. Fig.1). The range of concentrations of trace gases used in the experiments was within the atmospheric variability. The main instrument used for retrieving the GRs was a Neutral cluster and Air Ion Spectrometer, (Kulmala et al., 2007), able to measure air ion number size distributions in the mobility equivalent diameter range of 0.8 to 42 nm and correspondingly neutral particle number size distributions from 2 to 42 nm mobility diameter; in this study we focused mainly on the ion mode. A comparison between GRs of neutral and of charged particles taken at same conditions will also be carried out to investigate a possible charge enhancement. Size dependent GRs can be also calculated in small sizes (1.0 - 2.5 nm) for electrically neutral and charged environment from a scanning Particle Size Magnifier, Airmodus A09 (PSM, Vanhainen et al., 2011) which can be then compared to the GRs retrieved with the NAIS.

A comparison among the size dependence of GRs at different condensible vapour concentrations and mixing ratios will give an interesting insight on the physics and chemistry of a growing freshly formed nano-particle in the CLOUD chamber under precisely controlled conditions, going from a pure sulfuric acid environment to an environment enriched with organic compounds, as well as with ammonia and nitrogen containing organics, such as amines.

Nucleation is a significant source of atmospheric aerosol particles. In order to have a climatic effect these nanoparticles need to grow several tens of nanometers in diameter and the growth needs to be fast enough to compete with the coagulational losses. While sulphuric acid is found to be the key compound in atmospheric nucleation, its contribution to nanoparticle growth is estimated to be small in many environments. The observations on atmospheric nanoparticle growth suggest that a large fraction of the growth is due to condensation of organic vapors, although the exact identification of these vapors is still unknown. To condense on atmospheric nanoparticles organic vapors must have very low-volatility (e.g., Pierce et al. 2011). While reversible condensation requires a very low saturation vapor pressure, particle phase processes like salt formation may enable also more volatile compounds to contribute to particle growth. In fact, evidence for the presence of organic salts in atmospheric nanoparticles has been observed by Smith et al. (2010).

We study the potential contribution of particle phase formation of organic and inorganic salts on particle growth rates. This is done by using a single particle condensation model for an atmospherically relevant system consisting of two acids (sulfuric acid and an organic acid) and two bases (ammonia and trimethylamine, TMA). The net mass flux of each of the compounds to the particle is calculated dynamically based on the gas phase concentrations and the evaporative fluxes, in which the salt formation in the particle phase is taken into account.

Initially in the conceptual model for particle growth, we assumed that there was no water in the particle phase and that the bases could exist in the particle phase only if they had formed salts with one of the acids (while the acids were allowed to exist in the particle also in their molecular form). All the salts were formed from an acid and a base in 1:1 molecular ratio. In this approach the evaporative part of the mass fluxes of the acids from the particle were calculated based on their saturation vapor pressures (p_{sat}) assuming unity mass accommodation coefficients. For bases we assumed p_{sat} to be zero and the evaporative flux was treated using effective mass accommodation coefficients estimated based on cluster evaporation rates (0.001 for ammonia and 1.0 for TMA). Results from this model (Fig. 1) suggest that in typical ambient conditions a large fraction of total acids in the particle phase may have formed salts with basic compounds, thereby highlighting the need for understanding the effects of salt formation on growth in further detail.

In this work we will modify the growth model by adding detailed thermodynamics of acid/base dissociation and by including water as one of the condensing compounds. With the modified growth model we will study the potential effect of particle phase salt formation on the growth rates of particles in various ambient conditions as well as the relative contributions of chemically distinct acids and bases. The results will be discussed in the context of atmospheric particle growth rates and their observed size dependence.

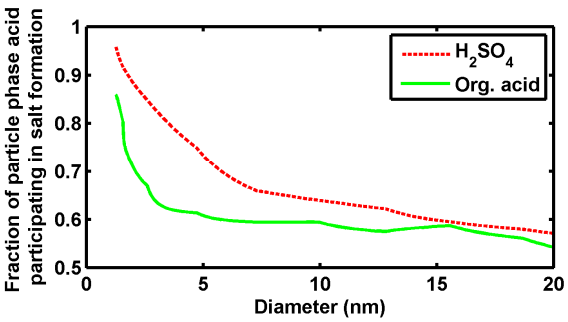

Figure 1. The fraction of the total mass of the acid in the particle phase that has formed salt with the bases as a function of particle size.

Presenting author email: c.vargas@unicas.it

Epidemiologic evidence indicates a relationship between particle pollution exposure and adverse respiratory and cardiovascular health effects, including decreased lung function, asthma, myocardial infarction and all-cause mortality (Brunekreef and Holgate, 2002). In general, the smaller the particle size, the greater its ability to penetrate into the lungs and thus to produce adverse effects on human health. For this reason, sub-micrometer particles and even more UFPs (diameter < 0.1 μm), show higher health care interest than other particle sizes. Anyway, while there is considerable toxicological evidence of potential harmful effect of UFPs on human health, epidemiological studies are still not sufficient for conclusions on the dose-response relationship concerning this aerosol fraction (WHO, 2005).

This study, which falls within the UPTECH international project, deals with the children's personal exposure assessment to UFPs and black carbon. BC was used as an indicator of exposure to diesel exhausts whose negative health effects (short and long-term cardiovascular, respiratory and neurodegenerative health effects) were reported in Baja et al., 2010; McCracken et al., 2010.

We considered children because they represent the most vulnerable group with regard to harmful effects of airborne particles exposure. This is due to: i) the higher dose of UFPs as function of the children lung size compared to adult one; ii) their developing organs and immunological system.

Air quality can be measured at four different spatial scales: i) “city scale”, the broadest and most common scale used to characterize air quality across several city blocks using remote measurements; ii) “outdoor scale”, representative of outside building grounds particle exposure; iii) “indoor scale”, within building rooms reflecting indoor-based exposure; iv) “personal scale”, using hand-held instruments carried as a personal monitor in order to assess their actual exposure.

The daily overall children exposure is dominated by particle concentration levels in three main microenvironments: home, school, and transport mode. Therefore, children attending the same school, can receive different doses.

In the present work personal exposure measurements were performed on a sample of about one hundred children aged 8 to 11 years who attend three schools (S_1, S_2, S_3) in Cassino (Italy). S_1 is a primary school located on traffic urban street; S_2 is a secondary school close to intersection of moderate and heavily trafficked urban street; S_3 is a primary school located in a rural area far away from urban traffic.

The personal exposure was monitored through: two hand-held particle counters (NanoTracer, Philips) and one BC monitor (Aethalometer-microAeth Model AE51, MageeScientific). These monitors have a high temporal resolution (1÷16 s for NanoTracer, 1 s ÷ 5 min for Aethalometer), are small and portable (750 g and 250 g, respectively) and do not require special training to use.

NanoTracer, which works by diffusion charging, is able to provide number concentration (in the range 10-300 nm), average particle diameter, and lung deposited surface area concentration measurements. An electrometer measures the current induced by previously charged particles collected on a filter inside a Faraday cage. The device is also able to evaluate the different fractions of the lung deposited surface area through a semi-empiric algorithm implemented by Marra *et al*., 2010.

The Aethalometer detects the changing optical absorption of light transmitted through an internal small teflon-coated borosilicated glass fiber filter where BC-particles are captured.

We monitored children for 24-h, they also filled in a diary reporting the main indoor and outdoor activities (such as studying, eating, transportation, sleeping), also indicating the length of each activity.

From data collected by NanoTracers it was found that school contribution on daily exposure to UFPs is about 15%-20%, with an average particle number concentration in the range $1.5\times10^4 – 5.3\times10^4$ part. cm^{-3}. The highest exposure intensity was measured during lunch time with a contribution of about 20% and particle number concentrations in the range 4.2×10^4-1.9×10^5 part. cm^{-3}.

For BC, as expected, the most contributing activity to personal exposure is transport with an average exposure of 12.4 μg m^{-3}, while lowest average exposure was found at home (4.4 μg m^{-3}).

Determining the regional deposition of tobacco smoke in the human respiratory system

C.J. Dickens[1], C.M. McGrath[1], J. Perkins[1], P. Biggs[1], R.A. Cabot[1], J.J. McAughey[1]

[1]British American Tobacco, Group R&D, Southampton SO15 8TL, UK

Keywords: Aerosol modelling, lung deposition, particle deposition

A study was conducted to determine the regional deposition of tobacco smoke aerosol in the respiratory system of volunteer smokers, using real-time measurement of respiration and puffed/exhaled smoke particulate, and a compartment model for particle deposition in the human respiratory system.

Nine current regular cigarette smokers were recruited for this study. The volunteers smoked a commercial King-Size cigarette with 7mg tar yield, as measured by machine smoking at the ISO smoking regime. Each volunteer smoked 3 cigarettes with no constraints on how they smoked them (free smoking). Additional measurements were made to help optimise the model where volunteers smoked at the self-perceived inhalation regimes of mouth hold only and shallow inhalation. Real time puffing behaviour and puffed optical tar (smoke mass concentration) were measured by a smoking analyser (SA7), and real time respiratory behaviour and exhaled optical tar were measured using a Breathe in Breathe out system (BIBO). Both devices recorded data at 25Hz, with smoke concentration determined using light obscuration.

Exhaled smoke was captured by a sampling system operating at a constant flow of 217 $l.min^{-1}$. A sub-sample was taken from the sampling system for analysis by a real-time particulate spectrometer, DMS-500 (Cambustion, UK) which measures particle size and concentration over a size range of 5 – 1000 nm at 10Hz resolution. Puffed smoke was characterised by replaying the recorded human puffing profiles, as measured by the SA7, on a Smoking Cycle Simulator/DMS-500 (Cambustion, UK). Assuming spherical particles of unit density allowed a calculation of aerosol mass. Puffed and exhaled smoke was also characterised by measuring solanesol, a tobacco-specific high boiling point alcohol (C45H74O : MW = 630) which is a good marker for the particulate phase of tobacco smoke

The ratio between solanesol and aerosol mass was constant for all tests and similar between puffed and exhaled smoke. The ratios of optical tar to both solanesol and aerosol mass were higher for exhaled smoke than for puffed smoke, implying that the exhaled smoke aerosol was different to the puffed smoke aerosol. The assumption was made that this difference is due to hygroscopic growth of the particles in the lungs, which would affect the optical signal, but not the solanesol content, and not the aerosol measurement as the DMS operates at a pressure of 0.1atm which may dry particles before measurement. This gave an estimated hygroscopic growth factor of 4.0 for smoke particles in the lungs.

The model split the respiratory system into 200 compartments of equal volume representing progressively deeper depths into the respiratory system from the mouth down to the alveoli. The sum of the compartments represents the vital capacity of the lungs. Equations allowed the movement of particles between each compartment due to diffusion and under the influence of respiratory airflow, and the deposition of particles due to sedimentation. Coagulation was assumed to occur instantly once the smoke entered the mouth, and hygroscopic growth was assumed to occur instantly and uniformly once the particles reached the bronchi. The model ran in incremental time steps of 0.04s.

The model was run for each test using puffing data (flow and optical tar) and respiratory data as input. Model parameters for deposition rate in compartments representing five main anatomical regions of the respiratory system were set to provide the best fit between measured and model predictions of exhaled optical tar across all tests, including mouth hold only and shallow inhalation tests.

There were good correlations between the measurements and the model predictions of exhaled optical tar for all tests (R^2=0.90) and for the free smoking tests only (R^2=0.95) (Figure 1). This good correlation gives confidence in the regional deposition predictions of the model.

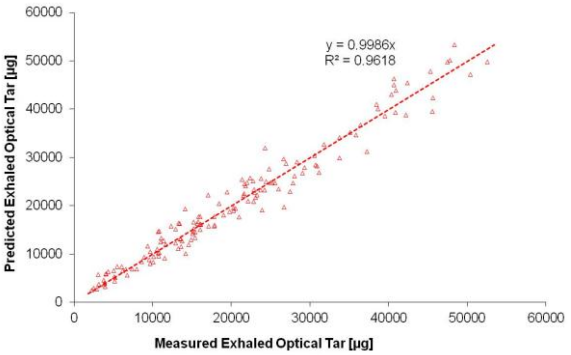

Figure 1. Predicted versus measured exhaled optical tar

It is hypothesised that the hygroscopic growth of the particles has a major effect on the deposition rate of the particles in the lungs. Future work will look to measure hygroscopic growth directly by measuring the particle size of exhaled smoke.

Phase transition of inhaled particles within the human respiratory system

L. Pichelstorfer and W. Hofmann

Department of Materials Research and Physics, University of Salzburg, 5020 Salzburg, Austria
Keywords: Condensation, relative humidity, lung deposition
Presenting author email: Lukas.Pichelstorfer@sbg.ac.at

To assess health risks due to airborne particle exposure, it is necessary to obtain information on regional and local deposition. Since the particle diameter is a key parameter of physical deposition mechanisms, the size distribution of an aerosol within the human respiratory tract is an important determinant of particle deposition.

During inhalation, particle size and composition may vary significantly due to various mechanisms such as deposition, coagulation or phase transition (i.e. condensation or evaporation). The latter also includes hygroscopic growth. Since relative humidity reaches nearly 100% within the human lung, growth due to condensation of water vapor has a considerable effect on hygroscopic particles. However, to describe the evolution of soluble particles within a vapor phase, the interaction of the constituents of the particles has to be taken into account. Thus, the objective of this work is to develop a numerical model for multi-component growth of a polydisperse aerosol within the human respiratory system which is independent of particle size.

The present model takes into account the interaction of various vapors (the case of unary growth may be considered as a limiting case). The condensation is assumed to be quasi-stationary. As a result, the temperature difference between the droplet and the ambient vapor phase adopts a constant value at each point in time. The same applies to the droplet composition. The present model is based on the work of Mattila et. al. (1997). Initially inhaled and newly formed particles are assumed to be spherical.

The inhalation of a “dry“, i.e. the particle does not contain substances from the vapor phase, cigarette smoke particle with a diameter of 150 nm was simulated with the model. Two cases were observed:

1) Water vapor as the only condensable vapor in the system
2) Water vapor and a constant 0.115% (of total vapor phase) nicotine fraction

Relative humidity of water and nicotine were adopted from Ferron (1987) and Lipowitz and Piadé (2004). According to Ferron, the initial relative humidity of water is 50% in the oral region. It increases to about 85% in the pharyngeal region and reaches its final value of 99.5% in the trachebronchial region. For the calculation we assumed a 1 s residence time of the particle in the mouth before it is inhaled.

Results from the calculation are plotted in Figure 1. The droplet growth can be segmented in four stages: In the first stage, in the case of pure water vapor the droplet does not grow since the saturation ratio of water is too low. The droplet situated in the binary vapor instantly starts to grow, though very slowly. In the second stage, which begins at about 0.75 s, the particle starts to grow faster until the soluble part of the cigarette smoke particle is totally dissolved. This stage lasts for about 0.1 s. In the next stage, which extends from 0.85 s to 1.25 s, particle growth is driven by the continuously rising relative water humidity. In the fourth stage of particle growth the relative water humidity reaches its final value. While the particle in the unary vapor reaches the equilibrium diameter rapidly, the particle in the binary vapor surrounding still grows, but very slowly.

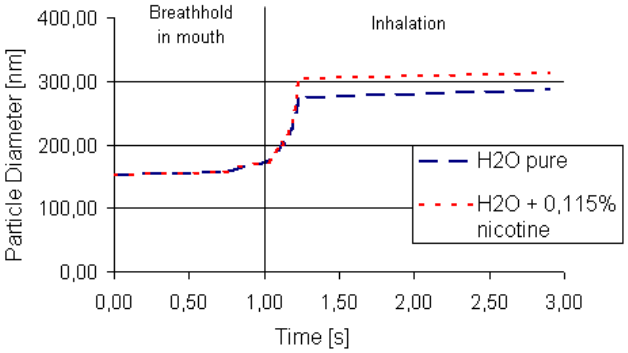

Figure 1. Particle diameter as a function of inspiratory time.

The time dependence of particle growth due to phase transition of the condensable vapors in the system is depicted in Figure 1. In case of an additional nicotine vapor in the system, very slow particle growth sets in immediately. However, the growth of the particles is quite similar. Interestingly, there is a significant difference in the final diameter of the droplet. In the case of binary growth, the particle reaches a diameter which is 8% greater than that in the vapor environment without nicotine. Note, that the mole ratio of nicotine to water is less than 1.9%.

This condensation/evaporation model will eventually be implemented into the stochastic deposition model IDEAL (Koblinger and Hofmann, 1990), considering dilution, deposition, coagulation and phase transition.

Particle deposition under transient high frequency ventilation air flow in a physiologically realistic bifurcation

E. Makris[1,2], M. Pilou[1,2] ,P. Neofytou[2],S. Tsangaris[1] and C.Housiadas[2].

Presenting author email: vagmakr@ipta.demokritos.gr

The simulation of complex respiratory airflow fields coupled with particle dynamics may be a highly important tool for respiratory medical applications in terms of targeted drug delivery and inhalation toxicology.

High Frequency Ventilation (HFV) is a technique of mechanical ventilation assisting or replacing spontaneous breathing, with major application the adequate ventilation of neonates. High frequency ventilation is characterized by high flow oscillation frequency (5 – 50 hz) and small tidal volumes.

Alveolar delivery of inhaled aerosol drugs in critically ill neonates undergoing HFV is a highly interesting subject. However, pulmonary delivery of aerosol drugs during HFV has been rarely studied in - vivo due to the difficulty of in – vivo measurements and ethical concerns in conducting studies in neonates (Sood et al 2010).

The current study is a computational simulation of transport and deposition of inertial particles, under HFV flow field, inside a physiologically realistic bifurcation, modelling the third and fourth lung generation (G3 – G4).The simulation is a fully Eulerian approach, for both air and particle flow. Due to the small size of the particles, the influence of the particulate phase on the air flow field is considered negligible (one-way coupling).

The numerical simulation of the air HFV flow field is carried out by the commercial software Ansys CFX® .The inlet profile is assumed to be a sinusoidal velocity profile with frequency equal to 23 Hz and peak Reynolds number equal to 1250.

The aerosol particle dynamics simulation is carried out, also, using an in-house particle dynamics code developed for studying particle transport and deposition during internal flows (Pilou et al. 2011). The code is based on an Eulerian description of the particles General Dynamic Equation .The Eulerian approach offers significant advantages over the frequently chosen Lagrangian approach (Zhang Z. et al. 2002). Initially, it may be used for small particle diameters where the Lagrangian approach becomes highly demanding in terms of numerical implementation. Furthermore the Eulerian model is more accurate than passive tracer (Lagrangian) models as it can take into account simultaneous diffusive and inertial particle transport. The code is based on an Eulerian description of the particles General Dynamic Equation, and the particle velocity $\vec{v}_p$ is written as :

$$\vec{v}_p = \vec{u}_{fluid} + \tau_p(\vec{g} - \vec{u}_{fluid} \cdot \nabla \vec{u}_{fluid}) - D\nabla \ln c \quad (1)$$

Where τ_p is the particle relaxation time and D the Stokes – Einstein diffusion coefficient. The aerosol particles are assumed to be spherical with Stokes number ranging from 0.02 to 0.12. The particles are jetted at the beginning of the HFV operation and the particle concentration and deposition, inside the bifurcation, is calculated during several time periods.

The geometry of the study is a physiologically realistic bifurcation based on the geometrical characteristics of the bifurcation created by the third and fourth lung generation (G3 – G4). These generations are selected due to the peak particle deposition in this region that previous experimental studies have recorded.The computational grid of the study is created by an in - house structured grid generation code (Makris et al. 2012). The result is a multi-block high quality structured grid with the adoption of the "butterfly" topology.

In conclusion the study presents an application of aerosol particles deposition under HFV in a physiologically realistic bifurcation of the human lung. The Eulerian approach for the particles combined with a transient and strongly oscillating flow field, such as the HFV velocity profile, provides a valuable tool for the simulation of aerosols drug delivery under mechanical ventilation assistance.

Aerosols are emitted from the respiratory tract during various activities such as coughing, speaking or sneezing. These aerosols play an important role in the transmission of airborne diseases such as influenza, tuberculosis and others. After evaporation droplets can form droplet nuclei which, in turn, can remain suspended for prolonged periods and constitute a health hazard.

The dynamics of droplets exhaled from the respiratory system during coughing or talking is addressed. A mathematical model is presented accounting for the motion of a droplet in conjunction with its evaporation. Droplet evaporation and motion are accounted for under two scenarios: (1) a well mixed droplet and (2) a droplet with inner composition variation. A multiple shells model was implemented to account for internal mass and heat transfer and for concentration and temperature gradients inside the droplet. The trajectories of the droplets are computed for a range of conditions and the spatial distribution and residence times of such droplets are evaluated.

Exhaled respiratory droplets, composing of saliva, mucus and several chemical species, are emitted during cough, sneeze or speak (Morawska et al., 2009). Small droplets can remain suspended in air for several minutes. Larger droplets can evaporate and form droplet nuclei that can remain suspended for a similar period of time. Droplet nuclei are composed of the non-volatile components (such as inorganic salts and glycoproteins) and a small amount of water. The size of the nuclei is determined by internal parameters such as initial droplet size and composition and environmental conditions such as temperature and relative humidity. Recent studies have also shown that relative humidity has an effect on the viability of viruses (Morawska, 2006).

In a recent study, Chao et al. (2009) conducted a series of experiments for measuring the size distribution and air velocity immediately at the mouth opening before evaporation occurs. Droplet size was determined using IMI (Interferometric Mie imaging) and the droplet velocity was determined using PIV (Particle Image Velocimetry). Measurements were taken at distances of 10mm and 60mm from the mouth. The estimated total number of droplets expelled ranged from about 1000 to 2000 per cough. The average expiration air jet velocity was about 12 m/s for coughing and 3 m/s for speaking. The velocity of air was found to be approximately constant at a distance of 100mm. The present calculations make use of data obtained in that study.

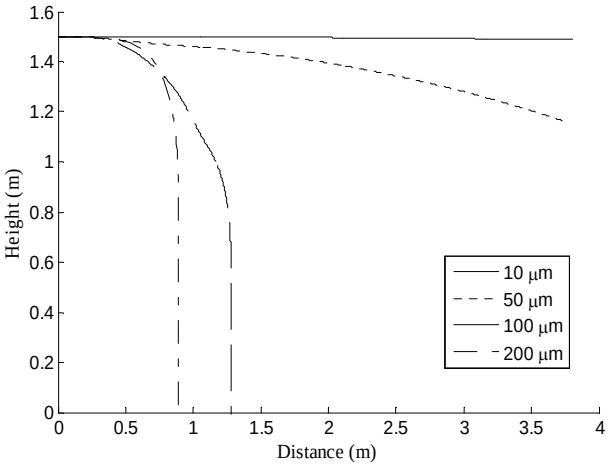

Fig. 1. Calculated trajectories of exhaled droplets during coughing, as a function of droplet size.

Fig. 1 presents examples of trajectories of droplets of various sizes. Smaller droplets are carried more effectively by the exhaled jet stream than larger ones. These trajectories are calculated as coupled with the change of composition and size of the droplets.

The model and results that will be elucidated, can serve together with the corresponding reported measurements in assessing the risk associated with the transmission of airborne diseases and assist in designing solutions to minimize this risk in controlled environments.

Introduction

Deposition pattern of inhaled particles is a main parameter controlling target tissue, future clearance and potential adverse health effect. In this context the characterization and the estimation of risks to children from inhaled particles is complicated by the lack of reliable experimental data. Especially, a main challenge consists in measuring *in vivo* regional deposition within a child-like respiratory model of size-resolved particles in the submicron range. As a result, this work proposed to study the *in vivo* regional deposition of size-resolved radioactive particles in the 230nm-2.8µm range of AMAD within a baboon model (*i.e.* a child-like respiratory model).

Methods

Jet medical nebulizers were used to generate aerosols: an Atomisor NL11 (DTF Medical, France), a modified Sidestream (Philips Respironics, Ref 12NEB400, England), and a Nanoneb (DTF Medical, France). Nebulizers were loaded with 2 mL of DTPA solution containing 74 MBq Technetium 99m.. Particle size distributions and aerosol output of the analyzed radioactive aerosols were determined using gamma-camera detection coupled to an Electrical Low Pressure Impactor. *In vivo* experiments were realized with three healthy baboons weighing 10 kg to 14 kg. They were then kept awake while aerosol was administered through a tight-fitting face mask specifically designed for baboons. Each baboon inhaled twice an aerosol produced by the three different types of nebulizer selected for this study. The order of the nebulizers tested was randomized for each baboon, resulting in six inhalations per nebulizer.

Results

Particle size distributions are summarized in Table 1. Almost the totality of particles produced by the 230nm AMAD aerosol (98.6%) and the 550nm AMAD aerosol (98.3%) were smaller than 2.5µm. In contrast, less than a half (47%) of fines particles (FPs) were observed in the 2.8µm AMAD aerosol.

Table 1. Features of the aerosols inhaled by the baboons to assess the *in vivo* regional distribution.

AMAD	GSD	Aerosol output	FPs	UFPs
2.80µm	3.2	44.5 ± 1.5%	47.0%	0.4%
550nm	2.1	9.3 ± 3%	98.6%	1.7%
230nm	1.6	4.2 ± 1%	98.3%	7.3%

In the studied submicron-size range, results doubtless demonstrate that the total lung deposition decreases as the particles size increase (Figure 1). A huge deposition in the extrathoracic (ET) region was found for the 2.8µm AMAD aerosol (72 ± 17% of the total aerosol fraction deposited) whereas the 230nm AMAD aerosol showed the smallest ET deposition (only 16 ± 4% of the total aerosol fraction deposited). As a result, aerosols with smaller AMAD (*i.e.* 230nm) can be associated to an almost exclusively thoracic deposition (84 ± 4% of the total aerosol fraction deposited). Finally, airborne particles with an AMAD of 550nm showed an intermediate behaviour (49 ± 8% of the total aerosol deposition in ET region and 51 ± 8% of the total aerosol deposition in TH region).

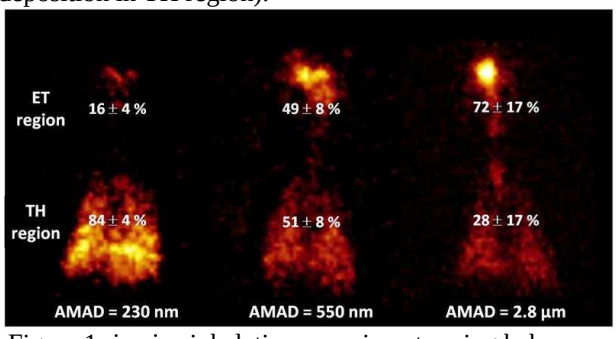

Figure 1. *in vivo* inhalation experiments using baboons.

Conclusion

We established that a diminution of the inter-subject variability and a targeted deposition in the thoracic region can be achieved by reducing the medium activity diameter (AMAD) of airborne particles around 230 nm.

Not only Asbestos exposure, but also inherited susceptibility, is responsible for the occurrence of mesothelioma in humans

Presenting author email: cetta_francesco@libero.it

Mesothelioma is a neoplasm with invariably dismal prognosis, which is strictly related with asbestos exposure and usually occurs 30-40 years after occupational or non occupational exposure. Recent reports have suggested that, although the incidence of mesothelioma (MM) is anticipated to decline in the coming decade, it may not decrease to background risk levels, because secondary asbestos exposure from the environmental will continue, Tse *et al* (2010).

During a 13 year- interval, a consecutive series of 80 subjects with MM was observed at the University of Siena. There were: 56 M, 24F , mean age 65 y, range 43-86 y. In particular, there were 66 pleural MM, 11 peritoneal MM, 1 MM of the pericardium and 2 MM of the tunica vaginalis testis. In particular, a genome wide analysis (array CGH analysis) performed in a small subset of these couples (husband occupationally exposed, but unaffected, and wife unexposed but affected), showed a panel of differently expressed genes, which were partly common and partly different from couple to couple.

Interestingly, common genes with diverse copy numbers included major histocompatibility genes, genes involved in the metabolism of xenobiotics and genes involved in the inflammatory response, Cetta (2011). It was shown that, analogously to what occurs for pollution related diseases, also concerning asbestos related diseases, clinical outcomes occur as the final result of host-fiber interaction. In particular, we showed that asbestos related MM occurred in the tonaca vaginalis testis (as primary site), i.e. in a distant site from the portal of entrance of asbestos fibers, and that asbestos fibers have been documented at this level (in other patients). In addition, we observed subjects developing MM more than 45 years after short-term exposure to asbestos (service in the Navy at age 18-20) without any additional occupational exposure. Finally, we observed some couples (husband-long-term occupationally exposed to asbestos and wife non occupationally exposed) with the interesting finding that the non exposed wife developed pleural MM (with asbestos fibers documented in the operative specimen), whereas the exposed husband had neither MM, nor lung cancer, or even overt asbestosis. This points dramatically to the crucial role of individual susceptibility in the occurrence of asbestos related diseases. In particular, after genome wide analysis of blood samples of these couples, we showed that they differed for a diverse expression of a panel of genes, including some of those responsible for major hystocompatibility system, drug metabolizing enzymes and host immune response, Cetta (2011). These findings dramatically suggest that, whereas most individuals do not develop MM or lung cancer even after a 30-year-occupational exposure to chrysotile, which is the most toxic variant of asbestos, other apparently normal, but highly susceptible people can develop pleural MM after indirect exposure to small quantities of asbestos of whatever structure and composition, or show a mesothelial tumor in a distant, but susceptible site, such as tonaca vaginalis testis. Further ecologic studies and analytical studies, but also pathophysiological and genetic studies are obviously required, before stating which is which, i.e. what is the relative potency of the various asbestos variants and what's the relative role of intrinsic toxicity fibers and of host susceptibility.

However, it is likely that, once that a powerful toxic agent as asbestos has been disseminated in a given community, the decrease to background risk levels is highly improbable, not only because of continuous asbestos use in other regions (imported as manufacts, even in small quantity), but also because secondary asbestos exposure from the environment will likely continue. In particular, this persistent exposure (after initial introduction) and the long-term persistency of asbestos fibers will be able, even at very low concentrations, to trigger the occurrence of MM. This evenience will be greater in predisposed people, as suggested by recent evidence that germ-line mutations in the gene encoding BRCA associated protein1 (BAP+1) are associated with an increased evidence of MM, Testa *et al* (2011). These observations further support the hypothesis that both asbestos exposure and inherited susceptibility are responsible for the occurrence of Mesothelioma in humans.

Presenting author email: giamarel@env.aegean.gr

By simultaneously selecting aerosol particles having different sizes, Differential Mobility Analyzers (DMAs) with multiple monodisperse-particle outlets can have a number of advantages in aerosol metrology. When used in electrical mobility spectrometers, for instance, they can significantly reduce the time required to measure the particle size distributions. Depending on the relative location of the first and the last outlet from the inlet, one can also increase the dynamic mobility range of the measured particles in a single measurement.

Based on the approach proposed by Stolzenburg (1988), we have recently developed the theoretical framework for determining the transfer function and the resolution of DMAs with multiple monodisperse-particle outlets (cf. Giamarelou et al., 2011; 2012). To describe the spreading of the transfer function due to the Brownian motion of the particles, we divide the classifier into segments defined by successive monodisperse-particle outlets. The total diffusional broadening along the whole path of the particle that leads to the i^{th} sample exit can be approximated by

$$\sigma^2_{\Gamma_{i,total}} = \sum_{j=n}^{i} \sigma^2_{\Gamma_{i,j}} . \qquad (1)$$

Here $\sigma_{\Gamma_{i,j}}$ denotes the diffusional broadening of the particles classified through the i^{th} monodisperse-particle outlet during the time they travel through the j^{th} segment of the MMO-DMA.

Fig. 1a shows the comparison of the model to the measurements with the 3-monodisperse-particle-outlet DMA tested by Chen et al. (2007). The loss-corrected theoretical transfer functions for both sample outlets, at 2.54 cm and 15.24 cm, are in perfect agreement with the experimental values. The predicted resolution for each of the three outlets agrees well with the reported measurements (Fig. 1b), indicating that the theory captures well the broadening of the transfer function for particles having diameter smaller than 20 nm.

Using the validated transfer function model we provide design considerations for building a DMA with two monodisperse-particle outlets, and predict its performance under different operating conditions. A critical parameter when designing multiple-exit DMAs is the minimum distance between the entrance and the nearest sample exit as well as between the successive sample exits so that the flow profile remains laminar.

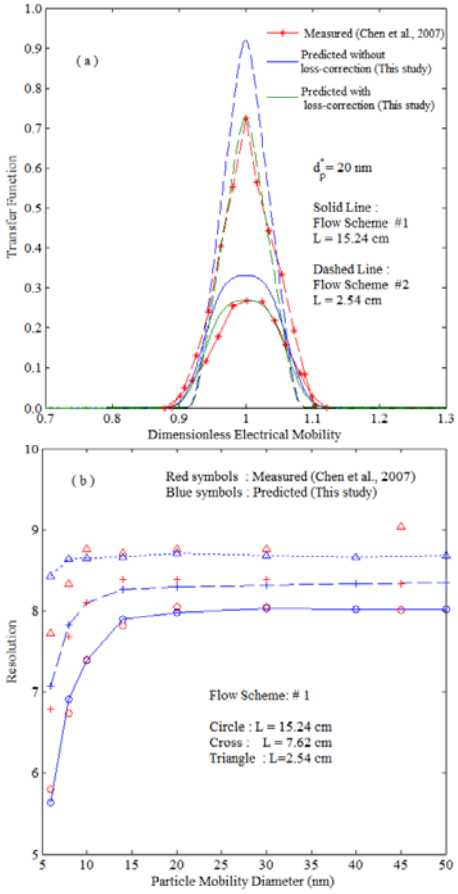

Figure 1 (a) Comparison between predicted and measured transfer function of the DMA with 3 monodisperse-particle outlets (measurements from Chen et al., 2007). The monodisperse-particle outlets are located 2.54, 7.62 and 15.24 cm downstream of the polydisperse aerosol inlet. Flow scheme #1 corresponds to 20 lpm sheath flow, 2.4 lpm polydisperse aerosol inlet flow, and 0.8 lpm for each monodisperse outlet flow. The respective values for flow scheme #2 are 20, 1.5 and 1.5 lpm. (b) Comparison between predicted and measured resolution of the DMA with 3 monodisperse-particle outlets.

Characterization of the Airmodus A20 Condensation Particle Counter

K. Lehtipalo[1,2], J. Vanhanen[1], T. Toivola[1] , J. Mikkilä[1], T. Petäjä[2] and M. Kulmala[2]

[1]Airmodus Oy, 00560 Helsinki, FINLAND

Presenting author email: katrianne.lehtipalo@helsinki.fi

Condensation particle counters (CPCs) are the basis of modern aerosol instrumentation in sub-micrometer range. CPCs can be used both as stand-alone instruments for measuring the total particle number concentration, and as counters in different kind of applications such as the differential/scanning mobility particle sizer (DMPS/SMPS).

A new laminar flow condensation particle counter, Airmodus A20, was launched in 2011. The A20 has a robust saturator design and uses butanol as condensing liquid. The aerosol flow rate is 1 LPM, achieved with a critical orifice and an external pump. Narrow pulse widths allow reaching high concentrations.

The performance of the A20 was verified in the University of Helsinki laboratory calibration setup (*e.g.* Petäjä *et al.,* 2006) using silver particles produced in a tube furnace and size selected by Hauke-type DMA. Nitrogen was used as carrier gas in the furnace, and the aerosol was neutralized with an Am241 source. Sheath flow of the DMA was 20 LPM and the aerosol flow 2 LPM, which corresponds to a size resolution of 0.3 nm. Figure 1 presents the results of the cut-off size calibration. The 50% cut-off diameter of the Airmodus A20 CPC for silver particles was 7.1 nm.

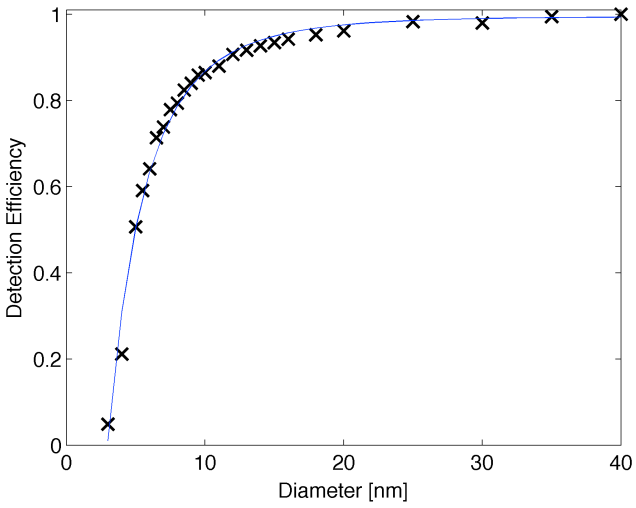

Figure 1. Cut-off size calibration of the A20, giving a cut-off size of about 7 nm for silver particles.

Concentration calibrations were conducted using 35 nm charged silver particles. The reference instrument used was an aerosol electrometer (TSI 3086B) with sample flow rate of 5 LPM. The single particle counting capability (< 10% co-incidence) of the A20 reached to about 25 000 #/cc. In higher concentrations the pulse rate started to decrease compared to the electrometer due to co-incidence in the optics. Based on calibrations, a 4th order polynomial correction function was determined for correcting the concentration. Using this correction function to the measured pulses the concentration matches with the electrometer even above 10^5 #/cc (Figure 2).

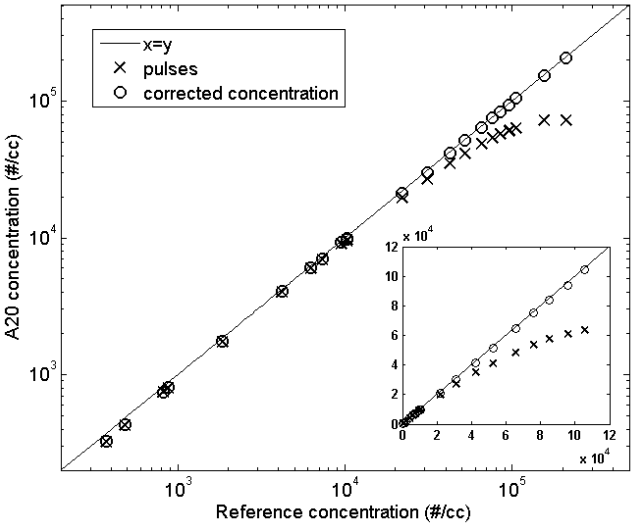

Figure 2. Concentration calibration of the A20 showing the pulse counts and the corrected concentration against the reference instrument.

The A20 bCPC was also tested in field conditions at the Hyytiälä SMEAR II measurement station (Hari and Kulmala, 2005). It proved to be suitable for long-term field measurements over large range of sizes and concentrations and compared well to other aerosol instrumentation.

Broadband Aerosol Extinction Spectrometer, a new instrument for measuring the spectral dependence of aerosols.

R.A. Washenfelder[1], J.M. Flores[2], C.A. Brock[1], S.S. Brown[1] and Y. Rudich[2]

[1]National Oceanic and Atmospheric Administration, Boulder, CO, 80305, USA
[2]Weizmann Institute of Science, Environmental Science Department, Rehovot 76100, Israel
Keywords: optical properties, spectral dependence, refractive index, absorption, scattering
Presenting author email: flores@weizmann.ac.il

The interaction between aerosols and sunlight plays an important role in the radiative balance of Earth's atmosphere. Aerosols can both absorb and scatter solar radiation causing surface cooling and heating of the atmosphere. These interactions depend on the optical properties of the aerosols (e.g. complex refractive index), which are determined by measuring the removal (extinction), redistribution (scattering), and transformation into heat (absorption) of light by the aerosols. One of the largest uncertainties in assessing the direct effect of aerosols is the contribution of light absorbing organic compounds, such as brown carbon, where absorption increases towards the UV region (Andreae and Gelencser 2006). Approximately 33.9 Tg y^{-1} of organic carbon are emitted globally (Bond et al. 2004). Measuring and deriving their optical properties are critical in calculating the effects of aerosols on radiative transfer and on our understanding of the atmospheric system.

We describe a new Broadband Aerosol Extinction Spectrometer (BAES) to measure the extinction coefficient and derive complex refractive indices of purely scattering aerosols from 360 nm to 420 nm. The BAES consists of an LED light source that is coupled into a one meter optical cavity with two highly reflective mirrors opposite of each other. The spectrum of light exiting the cavity is recorded by a grating spectrometer with a charge-coupled device (CCD) array detector. The reflectivity of the mirrors is determined from the known Rayleigh scattering of He and N_2. The extinction coefficient ($\alpha_{ext}(\lambda)$) of the aerosols is then calculated using equation 1 (Washenfelder et al. 2008):

$$\alpha_{ext}(\lambda) = \left(\frac{1 - R(\lambda)}{d} + \alpha_{Ray}(\lambda) \right) \cdot \frac{I_o(\lambda) - I(\lambda)}{I(\lambda)} \quad (1)$$

where R is the mirror reflectivity, d is the length between the mirrors, α_{ray} is the Rayleigh scattering of the carrier gas, and I_o and I are the intensities recorded with an empty and filled cavity, respectively.

We measured polystyrene latex spheres (PSL) and ammonium sulphate aerosols (AS) at different sizes and concentrations to determine extinction cross sections between 360 – 420 nm with 0.5 nm resolution. We compare measurements made with the BAES with those made by a cavity ring down (CRD) at 407 nm. The extinction cross section measurements were used together with Mie theory to derive complex refractive indices (RI) using one diameter for PSL (Figure 1) and AS.

We further demonstrate how by measuring the extinction cross section for different sizes, we can determine the RI for each wavelength measured by the BAES, with 0.5 nm resolution.

The implications for determining the complex refractive index as a function of wavelength in the UV region for absorbing substances will be discussed with preliminary results of two different absorbing substances: Suwannee river fulvic acid (SFRA), which is a proxy for humic-like substances, and nigrosine dye, which is a proxy for highly absorbing aerosols.

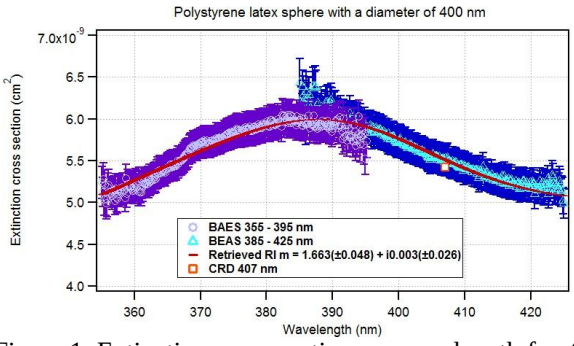

Figure 1. Extinction cross section vs. wavelength for 400 nm diameter PSL particles for two BAES channels, with spectral coverage from 355 – 395 nm (purple circles) and 385 – 425 nm (blue triangles). The red line represents the best Mie fit curve with a retrieved refractive index of m = 1.663 + i0.003. The orange square represents the measurement with a CRD at 407 nm.

Presenting author email: agnieszka.kupc@univie.ac.at

Ever since P.J. Coulier's experiments in 1875 the role of small particles acting as nuclei during the formation of cloud droplets has been studied. Only five years later John Aitken (1880) built the world's first instrument to measure particle concentrations of ambient air, today known as condensation particle counter (CPC). Yet it took until 2004 when Hering and Stolzenburg patented a method to use water as the condensing fluid in a laminar, thermally diffusive flow particle counting instrument.

The present study investigated the performance of a new Nano Water-based Condensation Particle Counter (N-WCPC, TSI 3788) to effectively measure airborne nanoparticles of various compositions. The N-WCPC's performance was assessed through comparison with the well established ultrafine CPC (TSI 3776), which was used as counting reference due to its identically specified lower cut size. In addition an aerosol electrometer (AE, TSI 3068B) was used as the primary reference for characterising aerosols over a mobility diameter range from 1.8 to 51 nm. An initial assessment of the urban aerosol in a light industrial area near a bus depot and motorway was carried out, followed by a comprehensive characterisation in the laboratory. The electrospray-based characterisation setup described by Liu et al. (2005) was used to produce particles from different materials such as sucrose, NaCl, proteins, and emery oil. Finally indoor air and a candle aerosol were assessed.

Size distributions of these aerosols were determined by a Nano Scanning Mobility Particle Sizer (nanoSMPS, TSI 3936N). Throughout the characterisation both counters and the AE always measured in parallel using a flow splitter (Figure 1).

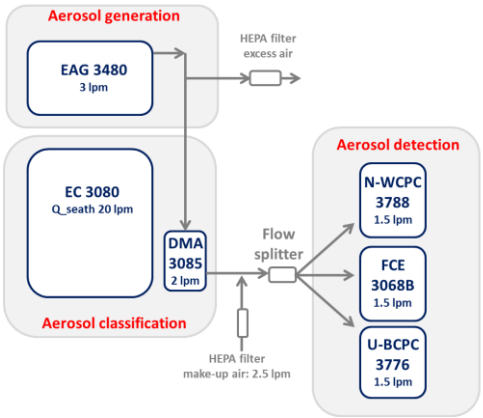

Figure 1. Schematic of the characterisation set-up

All measurements were performed at standard laboratory conditions with regards to operating temperatures. An inlet flow rate of 1.5 L/min was used by all three aerosol detection instruments.

The concentration linearity between the two CPC's with regards to a 64 hour urban background measurement is shown in Figure 2. This data was averaged over 5 min periods and demonstrates the excellent agreement between both particle counters for that aerosol, irrespective of the working fluid they use.

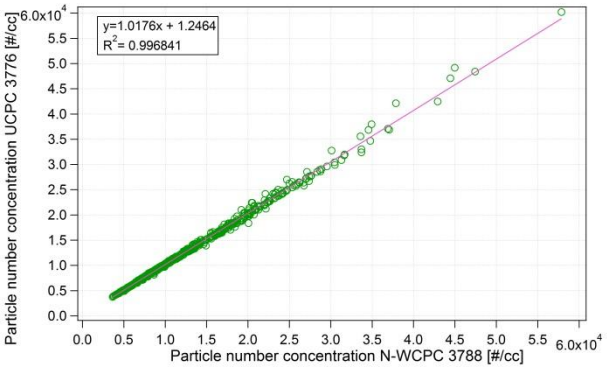

Figure 2. Linearity between particle number concentrations in urban background aerosol measured by the new N-WCPC and the UCPC

Size distributions of the urban aerosol observed were dominated mainly by particles below 150 nm in diameter, with a mode around 30 nm dependent on the actual traffic level.

Concerning the aerosol of different compositions generated in the laboratory, the counting efficiencies for the two CPC's were determined for each particle material using the ratio of the particle number concentration measured to the concentration determined by the aerosol electrometer.

This research has received funding from the EC's Seventh Framework Programme under the grant agreement no. 215072 (Marie Curie Initial Training Network "CLOUD ITN"), and from the Austrian Science Fund (project no. P 19546, L593)

This paper presents the calibration and performance characteristics of a novel sensor designed to measure particulate concentration in the exhaust of engines and vehicles. The Pegasor Particle Sensor (PPS) operates by electrostatically charging particles drawn in its enclosure and then measuring the current produced by the charged particles as they leave the sensor. The basic principle of directly measuring the current escaping with charged particles was first described by Lehtimäki (1983). In the PPS the particles are charged by ions generated by corona discharge. Corona discharge is generated around a sharp tip at high voltage and is carried away as the pumping flow of an ejector. This charged flow mixes with the sample flow of the ejector pump and produces charged particles. After charging, the particles are neither collected on any filter nor accumulate on any part of the sensor. However, as charged particles leave the sensor, they produced an electrical current escaping the Faraday cup. Measurement of this current is proportional to the particle concentration.

In practical sensor realization and in addition of producing the electrically charged pump flow, clean air is used to cool and shield the critical insulators from soot deposition. As a result, all contamination-sensitive parts (corona tip, insulators) are shielded by clean air flow. The fact that the ion-containing pump flow is mixed extremely rapidly prior to the ejector nozzle enables efficient particle charging in minimal volume. This enables low internal gas volume in the sensor, and consequently, rapid response time. Those characteristics make the sensor ideal for automotive use, where rapid response time, high sensitivity and protection of sensitive components from a direct exposure to exhaust gases are required.

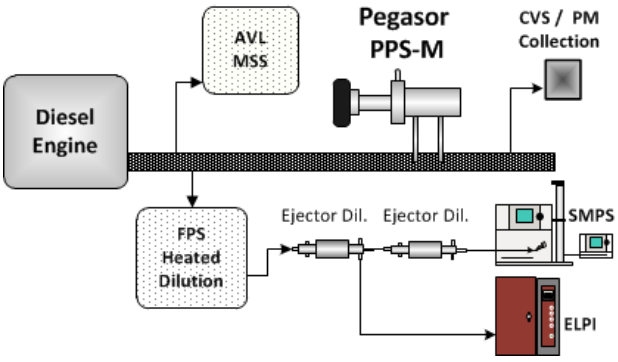

Figure 1. Setup used for the calibration of the PPS.

In this study the sensor is calibrated to measure the mass and number concentration of particles in the exhaust of diesel vehicles and engines, using the setup shown in Figure 1. A number of tests with a Euro 5 engine have been conducted under both steady-state and transient conditions and the signal of the sensor has been correlated to the mass and number of particles measured (Figure 2) by a gravimetric filter, an AVL micro-soot sensor and SMPS and ELPI instruments.

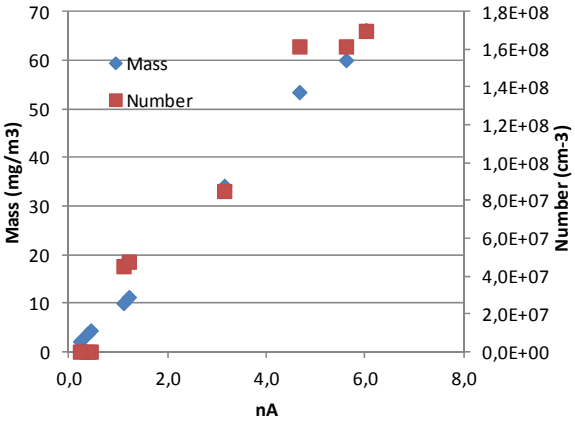

Figure 2. Correlation of sensor signal (x-axis) with diesel engine particle mass and number concentrations.

The calibration obtained with diesel measurements was compared to a laboratory calibration made with DOS test aerosol. The water CPC used as a reference instrument in the laboratory calibration was calibrated with single charged aerosol reference (SCAR, Yli-Ojanperä et al., 2010) to ensure the accuracy in the reference measurement.

The production and use of nanomaterials has risen at a constant pace over the recent years. Besides the tremendous beneficial properties of nanomaterials, they have also been reported to potentially cause adverse health effects. Inhalation is seen as the major uptake route and hence the assessment of exposure to airborne nanoparticles is of high relevance, particularly for workplaces where these particles are produced or processed. The established measurement technology for aerosol characterization is usually bulky and requires trained personnel for its operation and data evaluation. Easy-to-use, portable and battery operated devices are hence required. However, only a limited number of such devices exist.

The presentation will describe the development of a portable and battery operated instrument which allows for an extensive analysis of the workplace aerosol, but also limits the required effort for data evaluation. The developed instrument is based on electrical mobility analysis. Initially, larger particles are removed in a pre-separator with 450 nm cut-off and low pressure drop (Asbach et al., 2011). The remaining particle fraction then is charged to a known charge distribution (Kaminski et al., 2012) in a unipolar diffusion charger. The aerosol is then fractionated in a mobility classifier and the concentration of the classified aerosol measured in two sequential detectors. Due to the different particle size and morphology-dependent characteristics of the two sensors, this arrangement not only allows for the measurement of the particle number concentration but also provides insight into the size dependent particle morphology. Therefore, this measurement procedure may facilitate a first online distinction of engineered nanoparticles from background particles. In case of suspicion of the presence of engineered nanoparticles in the workplace air, an electrostatic precipitator (ESP) additionally can be enabled to sample aerosol particles onto substrates for consecutive SEM/EDX analysis that will provide a definitive proof for the presence or absence of engineered nanoparticles in the workplace air. The ESP is designed to deposit particles homogenously across the substrate when used along with the abovementioned charger and therefore also allows for a quantitative analysis. A thermal precipitator (Azong-Wara et al., 2009) can be used in addition to sample over a full work shift, i.e. 8 hours and provide averages of the size distribution, chemical composition and morphologies of the particles during the shift.

The presentation will cover the development of the instrument, experimental evaluation of its components and first results from the complete system.

By simultaneously selecting aerosol particles having different sizes, Differential Mobility Analyzers (DMAs) with multiple monodisperse-particle outlets can have a number of advantages in aerosol metrology. When used in electrical mobility spectrometers, for instance, they can significantly reduce the time required to measure the particle size distributions. Depending on the relative location of the first and the last outlet from the inlet, one can also increase the dynamic mobility range of the measured particles in a single measurement.

Based on the approach proposed by Stolzenburg (1988), we have recently developed the theoretical framework for determining the transfer function and the resolution of DMAs with multiple monodisperse-particle outlets (cf. Giamarelou et al., 2011; 2012). To describe the spreading of the transfer function due to the Brownian motion of the particles, we divide the classifier into segments defined by successive monodisperse-particle outlets. The total diffusional broadening along the whole path of the particle that leads to the i^{th} sample exit can be approximated by

$$\sigma^2_{\Gamma_{i,total}} = \sum_{j=n}^{i} \sigma^2_{\Gamma_{i,j}} . \qquad (1)$$

Here $\sigma_{\Gamma_{i,j}}$ denotes the diffusional broadening of the particles classified through the i^{th} monodisperse-particle outlet during the time they travel through the j^{th} segment of the MMO-DMA.

Fig. 1a shows the comparison of the model to the measurements with the 3-monodisperse-particle-outlet DMA tested by Chen et al. (2007). The loss-corrected theoretical transfer functions for both sample outlets, at 2.54 cm and 15.24 cm, are in perfect agreement with the experimental values. The predicted resolution for each of the three outlets agrees well with the reported measurements (Fig. 1b), indicating that the theory captures well the broadening of the transfer function for particles having diameter smaller than 20 nm.

Using the validated transfer function model we provide design considerations for building a DMA with two monodisperse-particle outlets, and predict its performance under different operating conditions. A critical parameter when designing multiple-exit DMAs is the minimum distance between the entrance and the nearest sample exit as well as between the successive sample exits so that the flow profile remains laminar.

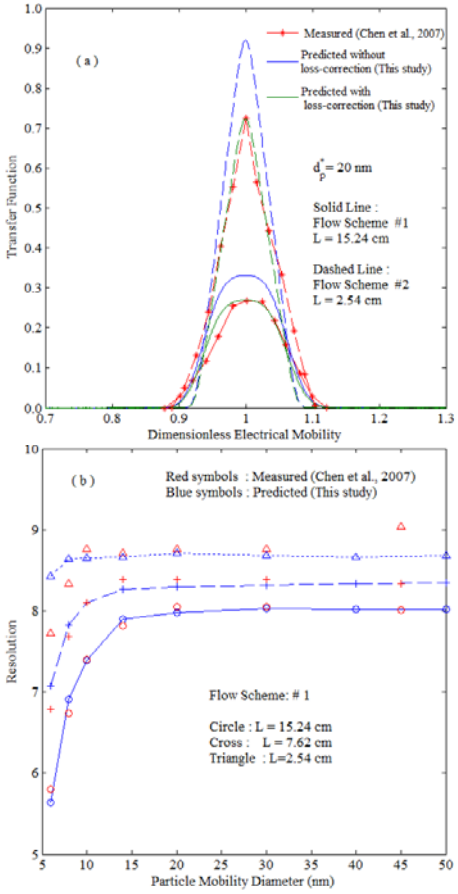

Figure 1 (a) Comparison between predicted and measured transfer function of the DMA with 3 monodisperse-particle outlets (measurements from Chen et al., 2007). The monodisperse-particle outlets are located 2.54, 7.62 and 15.24 cm downstream of the polydisperse aerosol inlet. Flow scheme #1 corresponds to 20 lpm sheath flow, 2.4 lpm polydisperse aerosol inlet flow, and 0.8 lpm for each monodisperse outlet flow. The respective values for flow scheme #2 are 20, 1.5 and 1.5 lpm. (b) Comparison between predicted and measured resolution of the DMA with 3 monodisperse-particle outlets.

Aerosol optical properties over East Asia: An integrating CMAQ-simulated and satellite-retrieved aerosol data using a data assimilation technique

C.H. Song, R.S. Park, K.M. Han and M.E. Park

Advanced Environmental Monitoring Research Center (ADEMRC), School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), 1 Oryong dong, Buk-gu, Gwangju 500-712,Republic of Korea

Keywords: AOD, data assimilation, Direct Radiative Forcing, $PM_{2.5}$.
Presenting author email: chsong@gist.ac.kr

For a better estimation of direct radiative forcing by aerosols and particulate pollution (such as $PM_{2.5}$ or PM_{10}) over East Asia, the production of more accurate aerosol optical properties (e.g., Aerosol Optical Depth (AOD), Single Scattering Albedo (SSA), aerosol extinction coefficient (σ_{ext})) is of primary importance. For the purpose of producing the accurate aerosol optical properties, AOD, SSA and σ_{ext} over East Asia were first investigated in this study, based on US EPA Models-3/CMAQ v4.5.1 modeling. The CMAQ model simulations were improved in several ways, compared to the previous study (Song et al., 2008): (1) the wind fields from MM5 simulations were assimilated with QuikSCAT wind data; (2) the emission inventories of INTEX-B (for China and North Korea), REAS (for Japan) and CAPSS (for South Korea) were used for the year 2006 simulations; (3) for the NH_3 and BVOC (Biogenic BVOs) emissions, EDGAR and MOHYCAN emissions were adopted, respectively; (4) monthly variations for the NO_x, NH_3, NMVOCs and SO_2 were applied; (5) for the dust generation and transport in the domain, the operational ADAM (Asian Dust Aerosol Models) was used (Fig. 1); (6) all the MET/CMAQ simulations and emissions were carried out in a fine grid resolution of 30×30 km^2 for the entire year of 2006; (7) 4-D particulate species concentrations obtained from the CMAQ model simulations were converted into the 4-D AOD products, using Malm and Hand (2007)'s algorithm, which is evolved from the previous Malm (1994, 2000)'s algorithms; and (8) finally, the CMAQ-simulated AOD products were assimilated with MODIS-retrieved AOD.

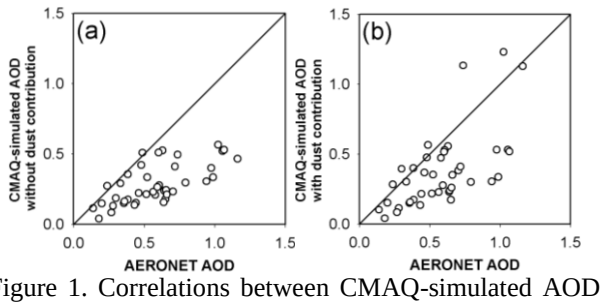

Figure 1. Correlations between CMAQ-simulated AOD and AERONET AOD in spring, 2006: (a) CMAQ-simulated AOD without dust contributions vs. AERONET AOD and (b) CMAQ-simulated AOD with dust contributions vs. AERONET AOD.

The results from the CMAQ model simulations (without assimilation) were improved greatly, compared to the previous study (Song et al., 2008) (e.g., from R=0.48–0.68 to R=0.77–0.89 for four seasons, R is correlation coefficient between CMAQ-simulated and MODIS-retrieved AODs). CMAQ-simulated SSA was also well matched with AERONET SSA, except for those near Honk Kong and Taipei, where biomass burning was strong from Jan. to Apr. It was also found that there were great matches between the vertical profiles of CMAQ-simulated σ_{ext} and LIDAR-derived σ_{ext}. The contributions of sulfate in summer, nitrate in winter, sea-salt in winter and dust in spring were large in East Asia. Especially, the large contribution of nitrate in winter to the AOD distribution over East Asia is remarkable compared to the previous study (Chung et al., 2010). In order to produce more accurate AOD products, the CMAQ-simulated AOD was assimilated with MODIS-retrieved AOD. Both the assimilated and AERONET AODs were better correlated with each other, compared to the correlation between CMAQ-simulated AOD and AERONET AODs (Table. 1). The obvious benefits for this study are that, with the improved aerosol optical properties, particulate pollution or PM forecasting over East Asia (e.g., AOD can be served as a proxy to $PM_{2.5}$) and direct radiative forcing by aerosols can be much better estimated in future.

Table 1. Statistical analysis among CMAQ-simulated and assimilated and AERONET AODs for four seasons, 2006.

AERONET vs.	period	R	RMSE	MNGE	MB	MNB

Temporal variations of the single scattering albedo in the southwestern Iberian Peninsula (Portugal)

S.N. Pereira[1], F. Wagner[1] and A.M. Silva[1]

[1]Évora Geophysics Centre, University of Évora, Évora, 7000, Portugal
Keywords: optical properties, single scattering albedo
Presenting author email: sergiopereira@uevora.pt

The direct effect of aerosol particles in terms of cooling or warming they can produce of the atmosphere depends, among other factors, on the single scattering albedo (ω_0) which is the ratio of the aerosol scattering to the extinction coefficients (σ_{sp} and σ_{ap} respectively).

This work presents an analysis of the temporal variations of the single scattering albedo, near the surface, at Évora, Portugal. Measurements of spectral scattering and absorption coefficients in the period of 2007 to 2009 were used. The scattering coefficients were measured at 450, 550 and 700 nm wavelengths with the three-wavelength integrating nephelometer (TSI, model 3563) (see e.g. Anderson et al., 1996) and the absorption coefficient was measured at 670 nm with the multi-angle absorption photometer (MAAP model 5012) (Petzold and Schönlinner, 2004).

The single scattering albedo was computed as $\omega_0(\lambda) = \sigma_{sp}(\lambda)/(\sigma_{sp}(\lambda) + \sigma_{ap}(\lambda))$ at the wavelength $\lambda = 670$ nm. Different temporal scales ranging from daily to seasonal scales were studied.

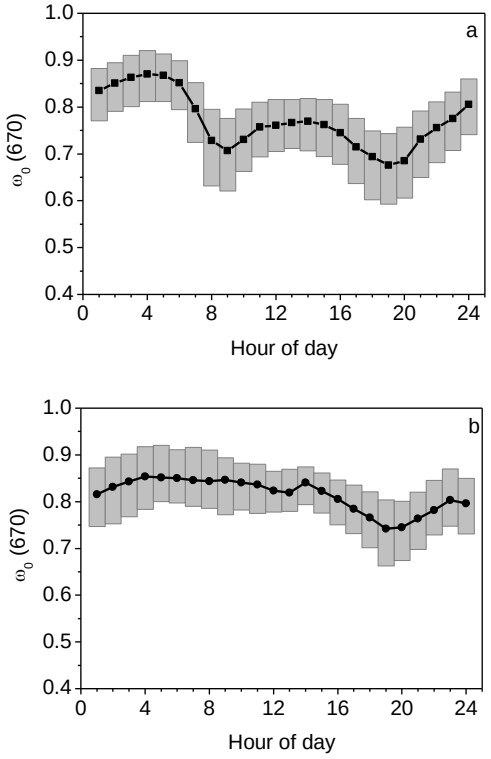

Figure 1. Median daily variation of the single scattering albedo considering (a) the working days (Sunday to Friday) and (b) Sundays in the period between 2007 and 2009. The grey bars stand for the P25 and P75 quartiles.

The mean value (± one standard deviation) of $\omega_0(670)$ for the whole period was found to be 0.77±0.11. The monthly mean values were in the range of 0.72 (November) and 0.81 (August) and a seasonal trend was observed which was characterized by lower values during winter/autumn and higher values during summer/spring seasons. The decrease in the single scattering albedo during the colder seasons corresponds to a relatively more absorbing aerosol population caused by the increase in anthropogenic production related to both traffic and wood burning for heating. Thus contributing to the increase of both scattering and absorption coefficients, but with the later increasing relatively more (Pereira et al., 2011a; Pereira, 2011).

The daily cycle of the single scattering albedo highlights the local particle production, namely related to traffic in the area. Figure 1 shows the daily variation of $\omega_0(670)$ considering the working days, from Monday to Friday (with the usual city activities being carried out) as well as Sundays, when the city activity is mainly suppressed, in particular during the morning hours.

Retrieval of Single Scattering Albedo values from Brewer spectrophotometer irradiance measurements at Uccle, Belgium

V. De Bock[1] and H. De Backer[1]

[1]Observations department, Royal Meteorological Institute of Belgium, Uccle, Belgium
Keywords: single scattering albedo, aerosol modelling, aerosol measurement, optical properties
Presenting author email: Veerle.DeBock@meteo.be

Aerosols can significantly affect the radiative balance of the Earth, both in a direct, semi-direct and indirect manner. Because of a lack of information concerning the temporal and spatial distribution of aerosols, they are key contributors to the uncertainties in current climate studies (Andreae, M. O. *et al*. 2005). The influence of aerosols is especially important in the UV spectrum, since the impact of UV radiation on human health, the biosphere and atmospheric chemistry depends strongly on the characteristics and quantity of aerosols in the atmosphere.

To gain a better understanding of the effect of aerosols in the UV, knowledge of the parameters that determine the optical and physical properties of aerosols is essential. More than 80% of the aerosol effect on UV radiation due to increasing turbidity is determined by the Aerosol Optical Depth (AOD) and the Single Scattering Albedo (SSA) (Petters, J.L. *et al*., 2003).

There are many studies on the retrieval of the SSA in the visible part of the spectrum, but less research has been done to determine the SSA values for the UV wavelengths (Petters, J.L. *et al*., 2003). The difficulty in estimating the SSA in the UV range is due to rather large uncertainties existing on ground based and space measurements in this wavelength range (Buchard, V. *et al.*, 2011). But since several studies (such as IPCC, 2007) indicate that significant uncertainties in global columnar SSA may constitute the largest single source of uncertainty in the current modeling estimates of aerosol climate forcing (Kazadzis, S. *et al*., 2010), it is necessary to improve our knowledge on the SSA in the UV.

It is possible to obtain SSA values with an reverse engineering procedure using UV irradiance measurements from the Brewer spectrophotometer, coupled with a Radiative Transfer Model (RTM). In such a procedure, the SSA value is changed until the modeled and observed UV irradiance are in agreement.

The RTM that will be used here is the Tropospheric Ultraviolet and Visible Radiation Model (TUV model version 3.0, Madronich 1993). This RTM can be used to model the UV irradiances for completely cloudless circumstances. The TUV model needs different input parameters, such as the ozone value, the AOD value, the cloud optical depth and the surface albedo. For the ozone value, the Direct Sun (DS) value (from the Brewer instrument) closest to the time of observation is used. At Uccle, we have developed different methods to retrieve the AOD from Brewer measurements at different wavelengths, using either the direct sun measurements (which lead to AOD at 306, 310, 313, 316 and 320nm) or the sun scan measurements (which enabled the retrieval of AOD at 340nm) (De Bock, V. *et al*., 2010). For this study, we will use the values retrieved from the DS measurements at the 5 different wavelengths to derive the SSA at the same wavelengths. We use 0.05 as surface albedo value and 0.0 as cloud optical depth.
The resulting SSA at the different wavelengths will be presented.

Presenting author email: Jin.Kim@dlr.de

Soot particles generated from combustion processes are mixtures of elemental (black) and organic carbon. Because of their strong contribution to light absorption, many field and lab studies have been carried out to investigate their optical properties. However, a full characterisation including chemical and physical analyses is scarce. We present an optical closure study, which is complemented by chemical and physical characterisation of soot particles. Our main goals were a better understanding of the complex refractive index of the organic carbon fraction and the closure of modelled and measured soot optical properties.

Absorption and scattering coefficients of soot particles, generated from a propane diffusion flame under varying fuel-to-air (C/O) ratios, were measured with a three-wavelength nephelometer and a particle soot absorption photometer. Intensive optical properties such as single scattering albedos (SSA) and Ångström exponents were derived from the measured absorption and scattering coefficients. In addition to optical measurements, information on particle size distribution, morphology and elemental carbon to total carbon (EC/TC) ratio were obtained from scanning mobility particle sizer measurements, transmission electron microscopy analyses and thermal-optical analyses respectively. Based on these data, optical properties of soot particles were modelled and compared with the experimental data.

Particles generated under low C/O ratios had high elemental carbon fraction (EC/TC > 0.7) and were fractal-like aggregates (mobility diameter ~ 100 nm, fractal dimension = 1.74 ± 0.6, primary particle radius = 5 – 6 nm). Rayleigh-Debye-Gans (RDG) theory (Sorensen, 2001) could model their optical properties well as shown in Figure 1. In contrast, particles produced under high C/O ratios had low elemental carbon fraction (EC/TC < 0.2), were smaller (mobility diameter < 50 nm) and spherical in shape. Their optical properties were better modelled with Mie theory as can be seen in Figure 1.

By minimising the difference between the calculated and measured SSA and Ångström exponents for particles with high organic carbon (OC) content, refractive index of OC at different visible wavelengths were deduced as presented in Table 1. The estimated values are in close agreement with values previously reported by Kirchstetter *et al.* (2004) and Adler *et al.* (2010) and they show strong wavelength dependence. The OC component is speculated to be similar to polycyclic aromatic hydrocarbon (PAH) compounds, which have strong absorption in the ultra-violet spectral region (Schnaiter *et al.*, 2006). The OC refractive index inferred from this study is deemed valuable since there is still limited data on optical constants of OC.

Table 1. Estimated real (n) and imaginary (k) parts of organic carbon refractive index.

λ/nm	n	k
467	1.59 ± 0.02	0.11 ± 0.03
530	1.47 ± 0.03	0.04 ± 0.02
660	1.47 ± 0.03	0 + 0.01

Modelling light scattering by mineral particles with small-scale surface roughness

M. Kahnert[1,2], T. Nousiainen[3], M. A. Thomas[1], and J. Tyynelä[3]

[1]Swedish Meteorological and Hydrological Institute, Research Department, SE-601 76 Norrköping, Sweden

[2]Chalmers University of Technology, Department of Earth and Space Science, SE-412 96 Gothenburg, Sweden

[3]Department of Physics, P. O. Box 48, FI-00014 University of Helsinki, Finland

Keywords: Mineral dust, scattering, surface roughness.

Presenting author email: michael.kahnert@smhi.se

Small-scale surface roughness is a morphological feature that is frequently encountered in mineral aerosols, ice-cloud particles that have experienced riming, as well as interplanetary and interstellar dust particles. Modelling the optical properties of such particles is notoriously difficult, since the particles' size parameters are often much larger than unity, while the surface roughness features typically vary on a scale smaller than the wavelength of light. To accurately model the light scattering process in the presence of subwavelength-scale surface structures requires the use of numerically exact methods for solving Maxwell's equations. However, for particles with large size parameters such methods are computationally highly demanding and can be plagued by ill-conditioning problems. To address these problems, a T-matrix approach has recently been proposed and tested which combines the use of group theory with a perturbation method for solving the light-scattering problem (Kahnert and Rother, 2011). This approach has been tailored to particles with small-scale surface perturbations.

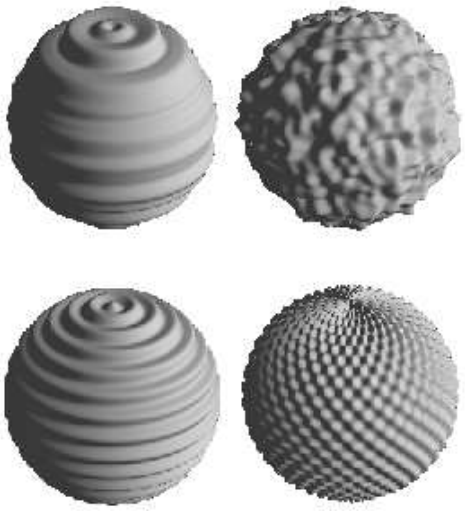

Figure 1: Example of model particle used in this study.

We apply this method to perform a comparative study of different models for small-scale surface roughness, as illustrated in Fig. 1. The emphasis is on comparing 2D- and 3D-roughness models, as well as regular and stochastic surface perturbations. The comparison are performed for size parameters of $x = 5$ and $x = 50$, as well as for refractive indices m=1.6+0.0005i and 3+0.1i. The former is taken as a proxy for silicate particles, and the latter is typical for hematite particles, both at visible wavelengths.

The results clearly show that the effect of small-scale surface roughness on the scattered intensity and polarisation is strongly dependent on the size parameter and the refractive index. 2D-roughness models predict a stronger impact of surface roughness on optical properties than 3D-roughness models. Stochastic surface perturbation cause a more pronounced modulation of the scattered polarisation and of the depolarisation ratio, while regular roughness structures can have a stronger impact on the scattered intensity and its angular distribution.

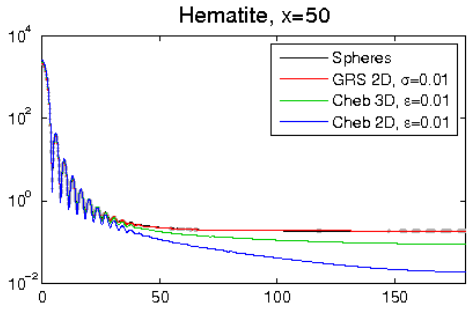

Figure 2: Phase function computed for hematite, x=50.

As an example, figure 2 shows the phase function computed for m=3+0.1i and x=50. In this case, particles with a 3D and, even more so, 2D regular surface perturbation deviate strongly from corresponding results for unperturbed spheres at scattering angles $> 50^\circ$. Particles with irregular surface perturbations scatter similarly to unperturbed spheres.

Physical and optical properties of atmospheric aerosol in Eastern Antarctica

A. Mangold[1], H. De Backer[1], V. De Bock[1], C. Hermans[2], I. Gorodetskaya[3] and W. Maenhaut[4]

[1]Royal Meteorological Institute of Belgium, Brussels, Belgium; [2]Belgium Institute for Space Aeronomy, Brussels, Belgium; [3]Catholic University of Leuven, Leuven, Belgium; [4]Ghent University, Ghent, Belgium
Keywords: atmospheric aerosol, optical properties, physical properties, AOD
Presenting author email: alexander.mangold@meteo.be

Aerosols play an important role in atmospheric physics and chemistry. They provide surfaces for photochemical reactions and they attenuate, scatter and absorb solar radiation and re-distribute in this way the energy coming from the sun, influencing photochemical reactions, the temperature at the surface and within the atmosphere and exerting a positive or negative radiative forcing. In addition, aerosols influence the formation, the properties and the lifetime of clouds. Aerosol measurements at several wavelengths are further important to derive information about aerosol type.

The Belgian Antarctic research station Princess Elisabeth, inaugurated in February 2009, is situated north of the Sor Rondane Mountains in Dronning Maud Land, East Antarctica, on the Utsteinen ridge (71°57'S, 23°20'E, 1390 m asl, Pattyn *et al.*, 2010). The station is designed as a zero-emission station with power supplied by wind turbines, solar panels and batteries. Two diesel-generators serve only as back-up. The station is manned only during austral summer. In winter, station and instruments operate in automatic mode with remote control. The station is located around 180 km inland, where aerosol concentration and composition can be different from coastal sites.

A Cimel 8-wavelength (UV-A to near-IR, measuring aerosol optical depth) Sun photometer belonging to the AERONET network (aeronet.gsfc.nasa.gov) has been installed since 2009 on the top of the station's roof with a perfect field of view. In 2010, a 7-wavelength (UV-A to near-IR) aethalometer (Magee Scientific, absorption coefficient, mass concentration of light-absorbing aerosol) and a Tapered Element Oscillating Microbalance with Filter Dynamics measurement system (TEOM-FDMS, total aerosol mass concentration) have been set up inside a container-size shelter about 60 m south of the research station, with the air inlet on the top of the shelter. In addition, a Brewer spectrophotometer (total ozone column, spectral UV radiation, UV-B aerosol optical depth) was installed at the end of 2010 on the roof of the main station. In February 2012, a 3-wavelength nephelometer (Aurora 3000, Ecotech, scattering coefficient), an ultrafine condensation particle counter (U-CPC, model 3776, TSI, total aerosol number concentration), and a Laser Aerosol Spectrometer (LAS, model 3340, TSI, aerosol size distribution) completed the instrument set-up in the aerosol shelter. Data of an automatic weather station (Van Den Broeke *et al.*, 2005), installed about 300 m away from the station are used for additional data interpretation.

The main wind direction at the location is ESE, connected with an average wind speed above 5 m/s. The aerosol measurements are thus most of the time not affected by the station's activities or emissions.

In addition to the austral summer measurements, the first two months of winter data from the TEOM-FDMS and the aethalometer could be collected during winter 2011. The winter measurements of light-absorbing aerosol mass concentration and of the absorption coefficient are especially interesting because the Antarctic background conditions could be measured.

The mean black carbon (BC) concentration (at 880 nm) was 2.6±6.1 ng/m^{-3}. The high standard deviation indicates that the averaging period (1 hr) might still be too short, causing negative values. The mean BC concentration detected at 370 and 470 nm together was 9.5±5.8 ng/m^{-3}, and the mean over all seven wavelengths was 5.9±4.8 ng/m^{-3}.

The mean absorption coefficient detected at 880 nm (BC absorbs strongest at this wavelength) was 5.3±4.8 Mm^{-1}. At 370 nm, the absorption coefficient was 23.9±12.4 Mm^{-1}, revealing that not only pure BC was present as absorber. The mean absorption Angstrom exponent (370 to 880 nm) was 2.0±1.3, reflecting that several absorbing aerosol types were present, as pure BC shows an absorption Angstrom exponent around 1.

During February 2012, the aethalometer and the nephelometer have been operated simultaneously. Therefore, both scattering and absorption coefficients have been measured, and a direct measurement of the single scattering albedo was possible. However, due to the very low aerosol concentrations in Antarctica, the instruments operate at their lower detection limit and careful data interpretation is necessary. E.g., the average aerosol optical depth (AOD) at 500 nm is only 0.02.

We will present data of the recent austral summer, when all instruments have been set up together for the first time. The measured aerosol size distribution and total number concentration will give further insight, which aerosol types were present.

This work was supported by the Belgian Federal Science Policy under grants EA/34/1A and EA/34/1B. Many thanks go to all expedition team members who helped in Antarctica to realise what has been done.

One of the largest uncertainties in the radiative forcing of climate is due to atmospheric aerosols. In fact, dust particles in the atmosphere play a relevant role in the climate system by altering the earth's energy budget through the scattering and absorption of solar radiation. The Absorption Angström Exponent (AAE) quantifies the absorption of solar radiation by atmospheric aerosols, being defined as the negative of the slope of a log-log plot of the aerosol absorption optical depth (AAOD) versus wavelength. Values of the AAE close to 1 are refered to urban aerosols (black carbon) while dust particles present AAE values larger than 2. However, AAE depends of the wavelength range (Bergstrom et al., 2007). On the other hand, the Extintion and Scattering Angström Exponent (EAE and SAE) are used to evaluating the extinction and scattering of solar radiation due to atmospheric aerosols. These two parameters depend primarily on the size of the particles, ranging from 4 for very small aerosols to 0 for large particles.

Simultaneous measurements of a passive remote sensor (sunphotometer CIMEL) and ground-based "in situ" instruments (integrating nephelometer and PSAP) are used to the characterization of the aerosol optical properties during desert dust events over Granada from 2005 to 2010. The main objective of this study is to analyze the wavelength dependence of aerosol optical properties, focusing on the aerosol absorption and scattering properties during these desert dust events.

Column-integrated characterization of the atmospheric aerosol has been performed by means of a sun-photometer CIMEL CE-318-4 included in the AERONET network (Holben et al., 1998). This sun-photometer makes direct sun measurements with a 1.2º full field of view at 340, 380, 440, 670, 500, 870, 940 and 1020 nm. In addition, the CIMEL instrument performs sky radiances, both in almucantar and principal plane configurations, at 440, 670, 870 and 1020 nm. At surface, we have measured the aerosol scattering coefficients (σ_{sp}) at three wavelengths (450, 550 and 700 nm) using a nephelometer (TSI model 3563). The aerosol absorption coefficients (σ_{ap}) were measured using a Particle Soot Absorption Photometer at three wavelengths (467, 531 and 650 nm).

We have computed SAE and AAE between 440-1020 nm wavelength ranges at the atmospheric column. At the surface, we have computed the SAE between 450-700 nm wavelength ranges while that AAE has been determinate between 467-650 nm wavelength ranges. During desert dust events high mean value of AAE and low mean value of SAE have been found at the atmospheric column. Simultaneously, these same parameters were determined at the surface. The SAE (AAE) showed slight higher (smaller) mean value at the surface than at the atmospheric column (Table1). These results could be related to two reasons: the different wavelength ranges used in the computation of the SAE and AAE at the column and at the surface, and the relatively high contribution of urban aerosol near the surface. In no-Dust conditions high mean SAE value and mean AAE value close to unity were found at the atmospheric column. This suggests the prevalence of the fine particles at the study site with an important contribution of absorbing aerosol at the atmospheric column in agreement with Lyamani et al. (2011) who showed that the aerosol over Granada contain a large fraction of absorbing particles. Additionally, the fine particles were dominant during no-dust conditions at the surface as indicated the high mean SAE value. However, the AAE showed a slight mean higher value in no-dust conditions than during desert dust events at the surface. This result could be due to resuspension processes of local mineral particles associated with anthropogenic activities.

Table 1. Scattering and Absorption Angström Exponent at surface and column-integrated over Granada.

	Dust		No-Dust	
	SAE	AAE	SAE	AAE
CIMEL	0.4±0.2	1.6±0.2	1.2±0.4	0.9±0.6
PSAP	--------	1.3±0.2	-------	1.4±0.3
NEPHE.	0.9±0.6	-------	1.6±0.4	-------

DIAPASON: A better assessment of the impact of Saharan dust on PM measurements

G.P. Gobbi [1], H. Wille[2], R. Sozzi[3], S. Frey[2], A. Bolignano [3], F. Costabile[1], F. Angelini[1], and F. Barnaba [1]

Introduction

Mineral particles from the North African deserts are among the natural contributions mostly affecting the PM levels in southern Europe (e.g., Gobbi et al., 2007). The EU Air Quality Directive 2008/50/EC allows Member States to subtract the contribution of natural sources before comparing the ambient PM concentrations to the relevant limit values set by the directive itself. It is therefore important to detect and characterize desert-dust advections by means of reliable, operational techniques.

Methodology

The EC LIFE+2010 DIAPASON Project (Desert dust Impact on Air quality through model-Predictions and Advanced Sensors ObservatioNs), intends to build on and upgrade the guidelines set by the EC to quantify the effects of Saharan advections (EC, 2011). At the core of DIAPASON stands the prototyping of affordable remote sensing devices (Polarization Lidar-Ceilometers, PLCs). These will be used in conjunction with optical particle counters to "certify" the presence of Saharan dust.

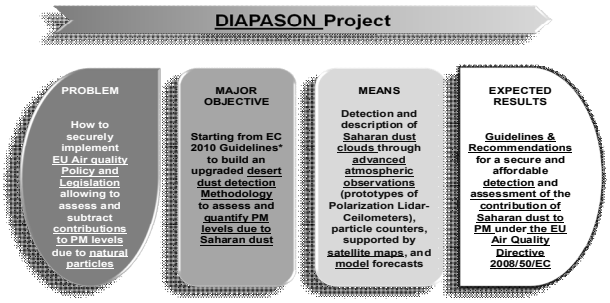

Figure 1. A snapshot of the DIAPASON project: Problems, Objectives, Means, and Expected Results

Results and discussion

An example of the DIAPASON approach is given in Figure 2, where EU guidelines' steps to identify Saharan advections (model forecast and PM levels at background sites) are "certified" by the actual observation of the dust cloud profile made by a research polarization lidar (e.g. Gobbi et al., 2000). This communication will discuss a one-year set of such comparisons.

Conclusion

DIAPASON aims at translating the results of research-based assessments into an operational, cost-effective, user-oriented methodology. It will be first implemented in Rome to be then easily transferable to the countries in Europe facing similar environmental problems. As an added value, the DIAPASON PLC-based approach will also be able to detect and monitor, with profiling capabilities, advections of other natural particulate matter as volcanic ash or wild-fire plumes, also considered in the EC 2011 Guidelines, bearing further benefits on civil protection and air traffic security.

We present results from the extensive field campaign CLACE 2010 (Cloud and Aerosol Characterization Experiment) performed in summer 2010 at the Jungfraujoch (JFJ) and Kleine Scheidegg (KLS) in the Swiss Alps. The main goal of this campaign was to investigate the vertical variability of aerosol optical properties around the JFJ and to show the consistency of the different measurement techniques considering explicitly the effects of relative humidity on the aerosol light scattering. Various aerosol optical and microphysical parameters were recorded using in-situ and by remote sensing techniques. The in-situ measurements of aerosol size distribution, light scattering, light absorption and scattering enhancement due to water uptake were recorded at the JFJ at 3580 m a.s.l. A unique set-up allowed remote sensing measurements of aerosol columnar and vertical properties from KLS located about 1500 m below and in the direct vicinity of JFJ (horizontal distance of approx.4.5 km, see Fig. 1). Two satellite retrievals from the Spinning Enhanced Visible and InfraRed Imager (SEVIRI) and the Moderate Resolution Imaging Spectroradiometer (MODIS) and back trajectory analysis were added to the comparison to account for a wider geographical context.

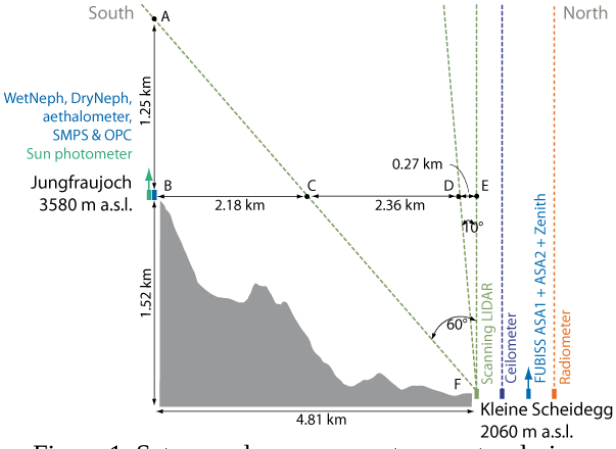

Figure 1. Set-up and measurement geometry during CLACE 2010

All in-situ and remote sensing measurements were performed in clear correspondence. The ambient extinction coefficient measured in-situ at the JFJ agreed well with the LIDAR (Light Detection and Ranging) retrieval at JFJ altitude, if certain assumptions on the unknown lidar ratio were taken. The comparison was clearly affected by the orography due to the exposed location of the JFJ on a saddle between two mountains and next to a large glacier. The local relative humidity (RH) around the JFJ was often larger than in the line of the LIDAR measurement, especially when the wind originated from South via the glacier. An example result is seen in Fig. 2, where the squared correlation coefficient of the ambient in-situ aerosol extinction coefficient vs. the LIDAR retrieved value is seen for different heights and RH data classes for an example lidar ratio of LR=75sr.

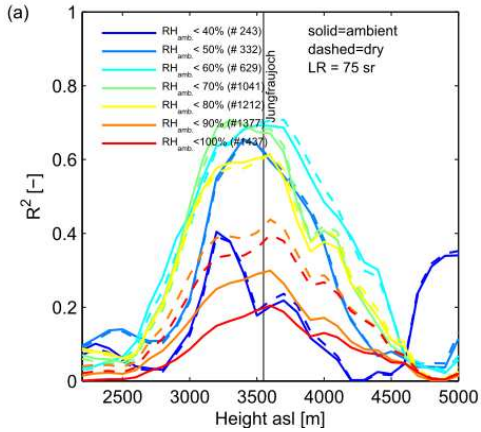

Figure 2. Squared correlation coefficient of the ambient in-situ extinction coefficient compared to the LIDAR retrieved value (at LR=75sr) at different heights above the LIDAR and for different ambient RH classes.

The dominance of long-range transported Saharan dust was observed in all measurements for several days, but for a shorter time period in the in-situ measurements due to the vertical structure of the dust plume. The columnar aerosol optical properties retrieved from SEVIRI and MODIS showed the same magnitude and a similar temporal evolution as the ground based measurements from KLS and JFJ. The remaining differences are attributed to the complex terrain and simplifications in the aerosol retrieval scheme in general.

Light scattering by ice-covered carbonaceous aerosol particles

S.S. Vlasenko[1],E.F. Mikhailov[1]

[1]Department of Atmospheric Physics, St.-Petersburg State University, Russia
Keywords: heterogeneous ice nucleation, hygroscopic growth, light scattering.
Presenting author email: Sergey.Vlasenko@paloma.spbu.ru

The formation of ice particles in the atmosphere has an appreciable impact on the radiation transfere, and hence on the Earth climate. The atmospheric clouds glaciation mainly happens via a variety of heterogeneous processes with involving of aerosol particles (ice nucleation, deposition freezing, immersion freezing, etc). Therefore the atmospheric ice particles certainly contain foreign inclusions and this can have some effect on their optical properties. The most interesting is a case when ice covers light-absorbing aerosol such as soot or smoke particles because multiple studies predict an increase of scattering and absorption cross section of absorbing core encapsulated into non-absorbing shell (Fuller 1999, Liu *et al.* 2008)

This study is a laboratory experiment aimed to quantify the effect of water crystallization on light scattering by water-covered smoke particles. To measure the optical properties of iced aerosol we improved the experimental setup designed for studying soot-water drop agglomerates (Mikhailov *et al.* 2006). This setup is schematically presented in Fig.1.

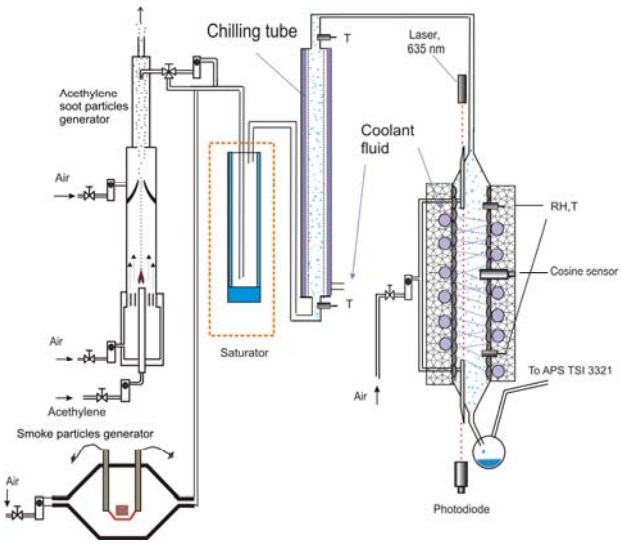

Figure 1. The experimental setup.

The carbonaceous aerosol was produced by combustion of acethylene (black soot) or wood (smoke). Then particles passed through saturator into chilling tube where aerosol flow can be gradually cooled down to -40^{0}C. The cooling led to vapour condensation and formation water shell on the particles. Depending on temperature in the tube this shell froze or kept liquid that made possible to observe the effect of phase transition on the optical properties of particles under consideration. After chilling tube the smoke particles entered optical cell which could be kept at temperature about -10^{0}C that guaranteed against ice fraction melting. A collimated laser beam at 635nm was used as a light source for the optical cell. The intensity of transmitted light was measured with a photodiode to calculate extinction volume coefficient and total light scattering was measured with an integral cosine sensor mounted in the middle of the cell. Provided the proper calibration the single scattering albedo of aerosol could be derived from the measuring data. The preliminary results are presented in the table 1.

Table 1. The single scattering albedo for carbonaceous aerosol particles covered with water or ice.

Soot type	Dry soot	Soot+water	Soot+ice
Acethylene soot	0,24±0.03	0,26±0.03	0,31±0.03
Wood smoke	0,74±0.03	0,80±0.03	0,88±0.03

Evidently the freezing of water shell leads to increase of the single scattering albedo for both types of examined soot aerosol

First ambient aerosol measurements with a polar nephelometer

M. Paixão[1], T. Müller[1] and A. Wiedensohler[1]

[1]Department of Physics, Leibniz Institute for Tropospheric Research, Leipzig, Germany
Keywords: aerosol optics, nephelometer, scattering coefficient, Saharan dust.
Presenting author email: paixao@tropos.de

In this work we present the first results of a campaign of measurements with a polar nephelometer of the angular scattering coefficient of ambient aerosol particles held on Cape Verde Islands, 2011. During the term of the campaign, the aerosol was dominated by marine and Saharan dust particles.

Aerosol particles are known to contribute to climate change (Forster, 2007). The asymmetry parameter or phase function of aerosol particles plays a key role in a proper evaluation of its radiative forcing effect. The polar nephelometer for aerosol monitoring comes to fill this lack of ambient aerosol measurements.

From the first designs of integrating nephelometers, introduced by (Beuttell and Brewer, 1949), several improvements have been made mostly regarding the detection limit and light source. That allowed the development of a larger number of applications other than measuring the horizontal visibility. Most of the studies rely on the spectral dependency of the scattering coefficient and its relation to the aerosol size distribution.

The Aurora4000 offers not only information about the total and backscattering coefficients of light by aerosols particles but also more detailed information about the angular characteristics in the forward hemisphere, measuring the scattered light for several illumination sectors by blocking part of the emitted light with a controllable shutter. For more details about the instrument please refer to (Müller, 2012). In this way, it's possible to evaluate a quasi-phase function from the differences of the scattering intensities, e.g. I(0°)-I(10°), I(10°)-I(20°), and so on, and by fitting the Henyey-Greenstein equation, determine the asymmetry parameter

Preliminary results

The data set of the campaign was divided in two periods according to date (end of November, and beginning of December 2011), due to dust load and calibration reasons.

The Figure 1 shows the time series from the first part of the campaign of the total scattering coefficient for the nephelometer wavelengths (450, 525, 635 nm) in the left, and the Ängstrom exponent, in the right axis. There is a clear change in the values of the Ängstrom exponent when the scattering values begin to increase due to the entry of continental air mass loaded with dust particles.

Comparing the dust concentration to the scattering coefficient for the second part of the campaign, in Figure 2, it's possible to identify two different correlations: the black cross shows the correlation when the aerosol is dominated by dust particles, from day 345 to 351, recalling that marine aerosol is always present, whereas the grey circle represents a more mixed state of aerosol particles.

In addition, the evaluation of a quasi-phase function in the forward hemisphere is in progress, and comparison with the results from Mie Theory will be performed. Future analysis includes the development of a reliable method to derive the asymmetry parameter together with size distributions measurements.

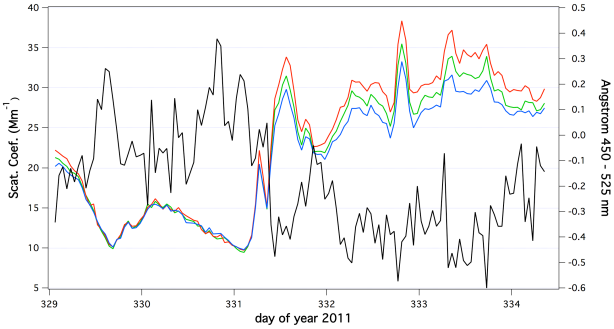

Figure 1. Time series of total scattering coefficient for blue, green and red channels (450, 525 and 635 nm, respectively) in left axis, and Ängstrom exponent (black line) in the right axis for the first part of the campaign.

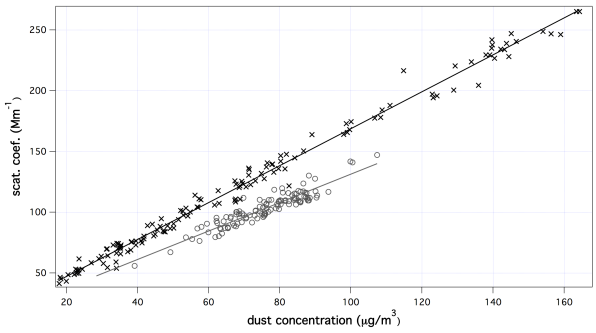

Figure 2. Correlation plot of total scattering coefficient (525 nm) and dust concentration in Cape Verde for the second part of the campaign.

SPECTRAL DEPENDENCE OF IN-SITU AEROSOL OPTICAL PROPERTIES

F. Costabile[1], F. Angelini[1], F. Barnaba [1] and G.P. Gobbi [1],
[1] ISAC-CNR,Via Fosso del Cavaliere 100, Rome, 00133, Italy
Keywords: aerosol particles, Mediterranean, absorption, Angstrom exponent.
Presenting author email: f.barnaba@isac.cnr.it

Introduction

Aerosols play a significant role in the atmosphere from air pollution to climate. The Mediterranean is a unique area in terms of aerosol composition (e.g., Barnaba and Gobbi, 2004), climate (Giorgi and Lionello 2008), and interaction with urban emissions (e.g.:Costabile et al., 2010). Here, one-year in situ, multi-wavelength observations of aerosol absorption and scattering in the visible region will be discussed, with the objective to analyse optical impacts of aerosol populations, the focus on absorbing/ultrafine particles.

Methodology

Measurements, carried out in Rome in 2010-11, include scattering (σ_{sp}) and absorption (σ_{ap}) coefficients by 3-λ integrating nephelometer (Ecotech), and 3-λ PSAP (Radiance Research), total particle counts by CPC (TSI) and OPC (FAI).

Results and discussion

Distinctive diurnal and seasonal features of the aerosol properties and trends were observed (Fig. 1, Fig.2).

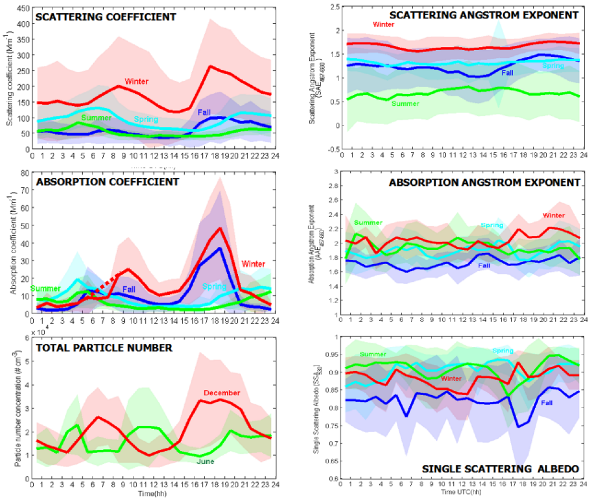

Figure 1. Seasonal change (color code) and diurnal cycles of absorption and scattering coefficients @530 nm, AAE and SAE (467-660 nm), SSA@467nm, and total particle number concentration.

An optical classification of different aerosol types was obtained by combining Single Scattering Albedo (SSA), Scattering Angstrom Exponent (SAE, 467-660 nm), and Absorption Angstrom Exponent (AAE, 467-660 nm), together with total particle number. The optically relevant aerosol populations include: dust, marine aerosols, inorganic and organic accumulation mode, biomass burning, organic condensation mode, soot mode, Aitken mode, and aged nucleation mode particles.

Conclusion

Results , indicate a strong impact of absorbing and UFP aerosols on the spectral dependence of both scattering and absorption properties. In general an enhanced absorption due to UFPs can increase the wavelength dependence of SSA, as well as decrease SAE.

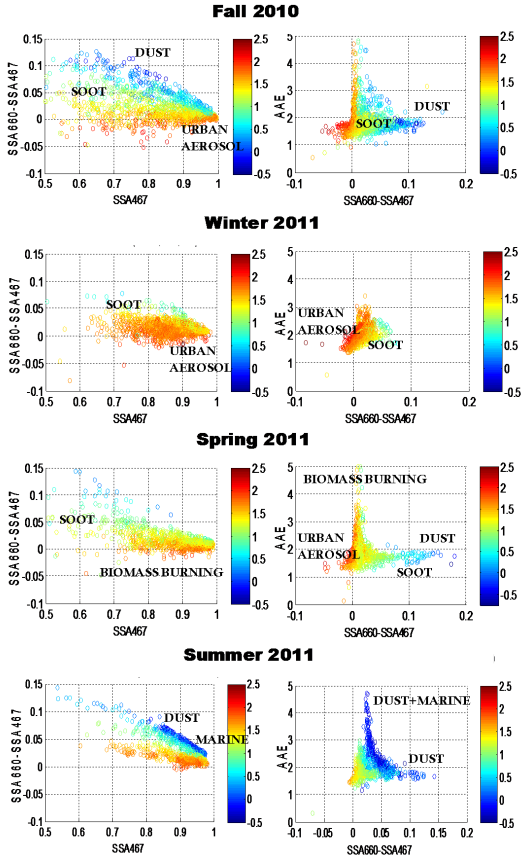

Figure 2. Seasonal Relationships linking SAE, AAE, and SSA @467 nm. Left column: SSA (x axis) and spectral variability (dSSA =SSA 660 nm - SSA 467 nm, y axis). Right column: dSSA (x axis) and AAE (y axis). (Color code=SAE).

Key words: Aerosol optical depth; Ångström exponent; Radiative forcing; AERONET, Pakistan.
email: khanalamso@gmail.com

Very few studies have been published that focus on aerosols in Pakistan. Therefore, the present study has the potential to fill a geographic gap in our present knowledge of aerosol characteristics, radiative properties and the aerosols' impact on regional climate.

Aerosol Characteristics and radiative forcing have been analyzed through the ground-based Aerosol Robotic Network (AERONET) over the two megacities of Lahore and Karachi for summer (April-June) and winter (December-February) of 2010-11. The average AOD values in summer and winter are 0.66±0.30, 0.50±0.18 and 0.67±0.40, 0.34±0.12 in Lahore and Karachi respectively.

The relationship between the Absorption Ångström Exponent and the Extinction Ångström Exponent provided an indication of the relative proportions of urban-industrial and mineral dust aerosols over the two sites. The averaged aerosol ARF values over Lahore and Karachi for the entire period covered by the observations were −22.5±5.9 Wm^{-2} and −18±2.2 Wm^{-2} at the TOA and −96±13 Wm^{-2} and −60±6.8 Wm^{-2} at the surface, respectively, giving an averaged atmospheric forcing of 74.56±16.8 Wm^{-2} over Lahore and 41.85±6.4 Wm^{-2} over Karachi, which indicates significant heating of the atmosphere at both sites. The average heating rate during summer was 2.3±0.1 and 1.2±0.2 $Kday^{-1}$ and during winter was 1.8±0.4 and 1.1±0.1 $Kday^{-1}$ over Lahore and Karachi respectively.

Seasonal distinctions and temporal trends in frequency of different types of hygrograms in West Siberia

S.A. Terpugova, T.A. Dokukina, E.P. Yausheva and M.V. Panchenko

V.E. Zuev Institute of Atmospheric Optics, Tomsk 634021, Russia
Keywords: scattering coefficient, relative humidity, hygrogram
Presenting author email: swet@iao.ru

Transformation of the atmospheric aerosol under impact of the relative humidity modifies its scattering and absorbing properties and, hence, the climatic effects. Correct account for the aerosol in radiative and climatic models needs knowledge of the seasonal and regional peculiarities of the aerosol hygroscopicity.

In this paper we analyze the results of the 12-year long (2000-2011) study of transformation of aerosol particles at artificial humidification in the near-ground layer of the atmosphere near the city of Tomsk (56.5°N, 85.05°E). The parameter under investigation was the angular scattering coefficient at the angle of 45° and wavelength of 0.51 μm as function of relative humidity (hygrogram).

At the initial stage of our investigations we used the single-parameter representation of the angular scattering coefficient as a function of relative humidity:

$$\mu = \mu_0(1-Rh)^{-\gamma}, \quad (1)$$

where μ is the angular scattering coefficient, μ_0 is the angular scattering coefficient due to the dry matter of aerosol particles, γ is the parameter of condensation activity, and *Rh* is relative humidity. Parameter γ depends, first of all, on the ratio of soluble and insoluble species in the dry matter of aerosol particles.

As our data show, only about 70% of measured hygrograms can be satisfactory described by formula (1). Along with such a dependence, two other types of hygrograms are observed in the atmosphere (Terpugova et al, 2004).

Figure 1 shows the schematic plots of different types of hygrograms and their fraction in different years and seasons. The prevalent type of hygrograms in summer is G_0 (70-80% in all years). The fraction of hygrograms G_0 in winter and autumn is 50-70%, and in spring it does not exceed 40%. The number of situations with hygrograms of G_1 type diminished in all seasons since 2000 till 2011 from ~ 40% to ~ 10%. Respectively, the number of days with G_2 hygrograms has ascended. It is most noticeable in spring, when the type G_2 becomes prevalent (the quantity of hygrograms of this type increased up to ~ 60%). The values *Rh**, at which the derivative of the scattering coefficient upon 1- Rh (in logarithmic scale) rapidly changes, or has a break, are 60±5% in the case of hygrogram G_1 and 70±3% for G_2 type in all seasons.

Obviously, in the case of hygrogram G_0 we observe uniform water vapor uptake by particles, without explicit phase transition. In the case of hygrogram G_1, particles at low relative humidity weakly absorb water, but the particle substance is gradually dissolved. When some critical value *Rh** is reached, the concentration of solution becomes so that the saturated vapor pressure over the droplet decreases, and subsequent condensation of water vapor becomes more intensive. As for the hygrogram G_2, at the value of relative humidity *Rh** the particle substance is dissolved in the condensing water, so the droplet volume dramatically increases, and hence, the scattering coefficient also grows.

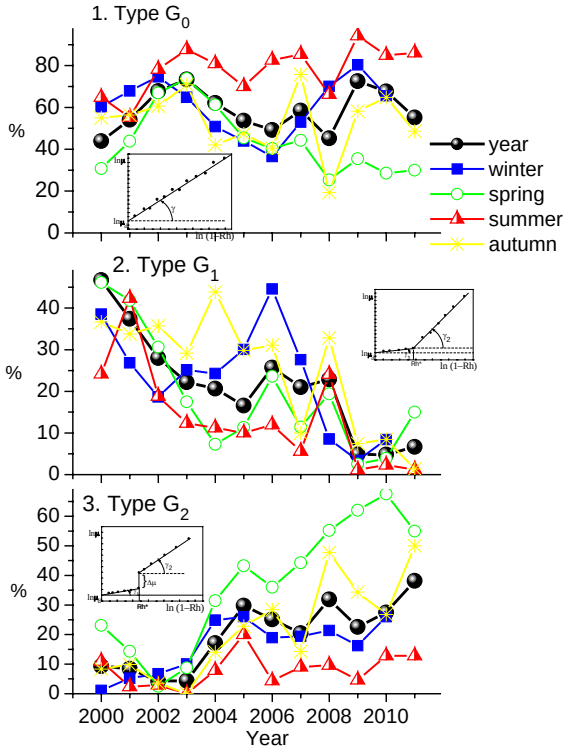

Figure 1. Different types of hygrograms and frequencies of their realization

Considering the shape of the dependence and the value of relative humidity at which the phase transition occurs, one can estimate the presence of different soluble salts in the aerosol particles. According to the data generalized by Martin (2000), the most close values to that observed in our experiments are NH_4NO_3, NaBr (60%); $(NH4)_3H(SO4)_2$ (69-70%); NaCl, KCl, $NaNO_3$ (73-75%).

The role of aerosols in the radiative forcing of the planet remain highly uncertain (IPCC 2007). Changes in the concentration and nature of aerosol cause serious concern since it affects the climate in regional and global scale. Trends in Aerosol Optical Depth (AOD) and Angstrom parameter over a regional scale have been reported earlier, but very few studies address the issues related to the changes in aerosol properties on a global scale. In this study, using AERONET surface observations, the trends in the fundamental aerosol properties like AOD, fine mode AOD, coarse mode AOD and Single Scattering Albedo (SSA) is analysed globally along with its effect on regional climate. The association of these aerosol trends with the decadal population rate of the sites are also investigated.

Trend analysis over 71 surface based observations showed a significant spatial inhomogenity. Asian continent shows a significant increasing trend in AOD compared to the other continents. Many of the Asian sites exhibit an alarming rate of increase in AOD from approximately 0.01 to 0.03/year. We have also observed that increasing trends in AOD not always coincide with the sites having increasing population rate. Simultaneous trend analysis of Fine AOD, Coarse AOD and SSA along with AOD present a comprehensive picture of the aerosol trend of each site under study.

In the current scenario of changing aerosols and its influence on the global climate, present study provides an opportunity to improve the understanding of the changing aerosol optical properties over the globe.

Optical properties of SiO_2 particles : inversion data from laboratory IR absorption spectra.

Due to their ability to absorb and to scatter radiations, airborne particles play an important role in the energy budget of the earth-atmosphere system. It is assumed that aerosols are one of the atmospheric constituents participating to the cooling effect, but estimates are highly uncertain owing to the large spatial and temporal variability of aerosol concentration and physical properties.

The measurements from space-borne instruments are the only means for observing aerosol distributions from local to global scale. In particular, thermal infrared imagers such as MODIS or SEVIRI are routinely used to detect aerosols. Nevertheless, these broadband sensors are not suitable to distinguish the aerosol composition. Recent high spectral resolution sounders such IASI or Tanso-FTS are able to overcome these limitation. However, to fully exploit the hyperspectral instruments capabilities it is essential to have reference optical properties of various particles and mainly refractive indices.

Indeed, the knowledge of refractive indices is essential because it describe the proportioning of scattering and absorption of light by such particle matter. Moreover, the refractive index is strongly depending on the aerosol composition, size and shape.

The aim of this work is to measure high resolution transmittance spectra of model airborne SiO_2 particles in the infrared region and to use a Mie inverse algorithm to retrieve complex refractive indices. Refractive index measurements are generally performed by measuring absorbance or transmittance with bulk material of interest or particles diluted in solid pellets. In this study, we have recorded transmittance spectra of calibrated airborne particles by IRTF spectroscopy.

Aqueous solutions of calibrated SiO_2 microspheres (Bangs Laboratories, Inc.) were generated using an atomizer (TSI 3076). After drying, the continuous flow of aerosol particles was directed into a 10 m absorption length multipass cell within an IRTF spectrometer (Antaris Thermo Scientifique). The size distribution of the particles was measured at the exit of the multipass cell using an aerodynamic particle sizer spectrometer (TSI APS 3321). Concentration between 500 and 6000 particles per cubic centimetre were used for each 3 particle diameter: 0.5, 1 and 2 µm. 300 IRTF records were collected and averaged at a spectral resolution of 2 cm^{-1}. The IRTF spectra for SiO_2 microspheres (Ø = 2 μm) is displayed Fig1 showing an intense band around 1100 cm^{-1} .

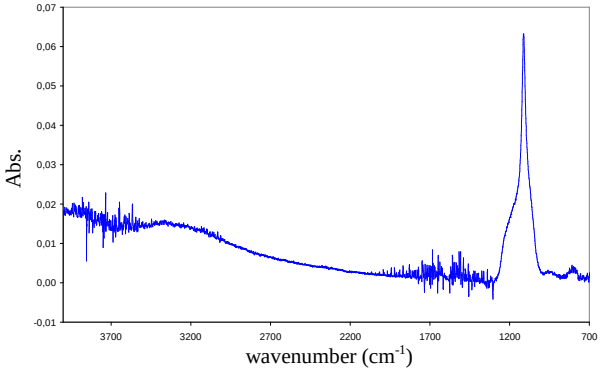

Fig. 1: Absorption spectra of calibrated SiO_2 particles Ø = 2 μm, [SiO_2] = 1430 particle.cm^{-3}.

The complex refractive indices of particles are obtained at each wavenumber by combining the Mie theory, the Kramers-Kronig relations, and a Levenberg-Marquardt algorithm. This inverse model allows avoiding some errors introduce by the extrapolated formulas of Kramers-Kronig relations. This methodology has the advantage to can be applied for any spherical particles.

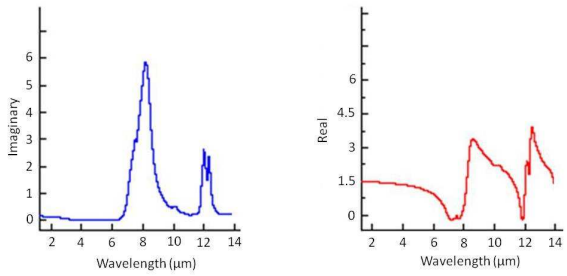

Fig. 2: Retrieved imaginary and real refractive indices of SiO_2 particles.

Experiments with particles (Ø = 0.5 μm and Ø = 1 μm) are currently in progress highlighting size dependence.

Climatlogy of aerosol optical properties with a synergy of remote sensing/altitude in situ measurements.

M. Hervo, K. Sellegri, J-C. Roger.

LaMP/OPGC, Université Blaise Pascal, Clermont-Ferrand, France.

Understanding spatial and temporal variability of aerosol particles in the atmosphere is important to characterize their contribution to health, visibility and climate. The aerosol vertical distribution is less documented than the horizontal variability because of the difficulty to make continuous altitude measurements compared to ground-based platforms.

For the first time to our knowledge, a long term in situ and co-located remote sensing study of optical aerosol properties has been realized at an elevated research station. The Puy de Dôme (1465m above sea level) is ideally situated to investigate aerosols vertical variability in both Planetary Boundary Layer and Free Troposphere.

We used a combination of in-situ (Nephelometer, MAAP, HTDMA, SMPS, OPC, AMS, TEOM) and remote sensing (LIDAR, Sun Photometer) instruments to realize a climatology of the optical aerosol properties. Mie calculation were computed from the size distribution measured by the SMPS and the OPC, grown at the ambient relative humidity from the HTDMA measurements. The synergy between the different instruments sampling in-situ allowed us to calculate a refractive index. During intensive field campaigns we also performed a complete optical closure to test the routine methodology of calculation of this refractive index. Aerosol mass vertical profile retrievals algorithms were then applied using the in-situ information.

Using the Lagragian model HYSPLIT we performed a classification of the air masses arriving at the Puy de Dôme and their corresponding aerosol properties. We found significant differences in the Angstrom coefficient, the single scattering albedo and the LIDAR ratio between, local, oceanic and Saharan air masses. We highlight the importance of a correct mass-extinction ratio and a well-known hygroscopicity to compute vertically resolved mass distribution from LIDAR extinction.

Combined observations with multi-wavelength Raman lidars and sun photometers on the southern Iberian Peninsula

Objectives of this study were the combination of lidar and sun photometer data from different stations and consequently the determination of the vertical and horizontal distribution as well as the characterisation of free tropospheric aerosol layers.
Lidar measurements performed in Granada (37.16° N, 3.6° W, 680 m above sea level (asl)) and Évora (38.57° N, 7.91° W, 290 m asl) on the southern Iberian Peninsula were compared within this study. The distance between the two EARLINET stations (*Bösenberg et al.*, 2003) is about 410 km. The ground-based lidar systems in Granada and Évora both enable the determination of extinction coefficients at 355 and 532 nm, backscatter coefficients at 355, 532 and 1064 nm as well as the depolarisation ratio at 532 nm. Besides ground-based lidar measurements, sun photometer data from several AERONET stations (*Holben et al.*, 1998) and from two further sun photometers were used. Additionally, CALIOP data (*Winker et al.*, 2007) was compared to the data of the ground-based lidars.
A layer of Saharan dust was observed in the free troposphere over both lidar stations on 29 August 2011. In the evening the layer was detected between 2.6 and 3.7 km asl over Évora and between 2.9 and 3.4 km asl over Granada. Example profiles of extinction and backscatter coefficients as well as lidar ratios (LRs) and Ångström exponents (AEs) from ground-based lidar measurements in Granada and Évora are shown in Fig. 1. The data was averaged over 30 min. The layer mean backscatter and extinction-related AEs at the pair of wavelengths 355, 532 nm were larger over Granada than over Évora. Urban and industrial pollution from Granada or Moroccan sources might cause the higher values observed in Granada. The contribution of those sources is not evident in Évora. Throughout the whole period the AEs at both stations were clearly below 1. This indicates a strong contribution of large mineral dust particles. Differences were also found in δ_p from both stations. Over Granada δ_p is decreasing in the proximity of a small cloud that was observed within the dust layer around 21:10 UTC. The originally non-spherical dust particles, might have a spherical shape close to the cloud due to hygroscopic growth. This would lead to lower values of δ_p. To conclude, different processes suffered by the aerosol particles during their transport can be considered responsible for the observed differences.

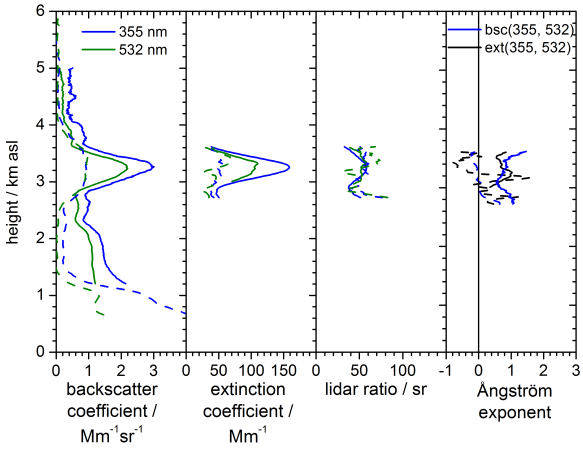

Figure 1: Profiles of extinction and backscatter coefficients, LRs and AEs from lidar measurements in Granada (solid) and Évora (dashed) from 20:00 to 20:30 UTC.

Optical properties of the aerosol and their spatial and temporal distribution have been investigated by means of passive remote sensing instruments aboard satellites such as MODIS, or ground-based sun photometers networks, e.g. AERONET. However, these instruments cannot provide information about the vertical layering of aerosol. The aerosol vertical distribution is of crucial importance in radiative transfer calculations and in the study of aerosol-cloud interaction (Forster *et al* 2007).

Satellite-borne Lidar CALIOP, aboard the CALIPSO, provides high vertical resolution profiles of aerosol and cloud optical properties on a global scale (Winker *et al* 2007). In this work, all the available Level 2 profiles, from 2006 to 2011, from night passes over California with a Cloud-Aerosol Discrimination (CAD) score smaller than -80 (80 % confidence of correct aerosol classification, i.e. cloud free) have been grouped into seasons and regions (north, central and south) in order to provide the extinction coefficient of aerosol and its variability in California as shown in Figure 1.

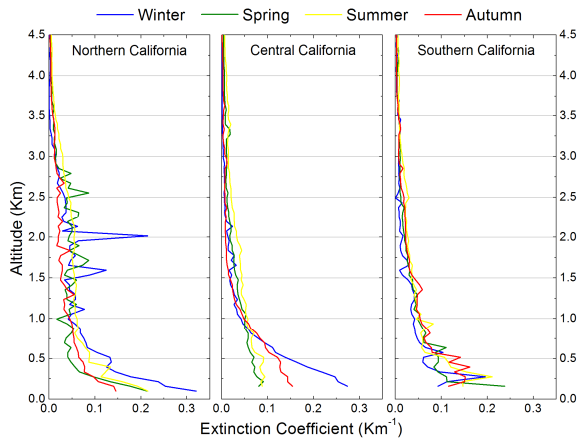

Figure 1. Seasonal variability of the mean extinction coefficient in the different regions of California.

On the other hand, we validated the CALIPSO vertical profiles with the vertical profiles retrieved from two aircraft field campaigns that took place in California. In May 2010 a total of 18 flights over the Los Angeles basin (southern California) under the frame of the CALNEX field campaign and, in June 2010, a total of 22 flights over Sacramento and the Sierra Nevada foothills (northern California) during the CARES field campaign. The extinction coefficient is derived from scattering and absorption coefficients measured on the aircraft and clouds are screened out from the data sets. Since CALIPSO profiles are night profiles, we matched them temporally with flights in the previous or next day, and spatially within the latitude/longitude region flown by the aircraft during that day. Thus, four aircraft profiles were compared with the CALIPSO profiles and they are show in figure 2.

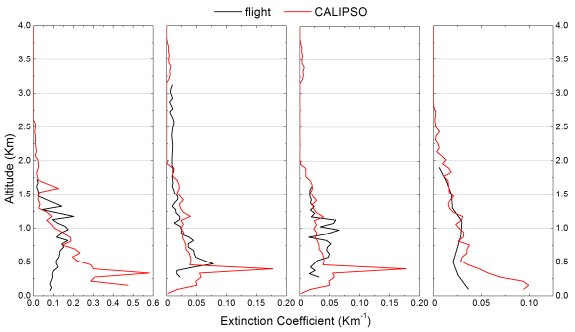

Figure 2. CALIPSO and aircraft profile comparison for 4 days

The comparison agrees well at altitude greater than 500 meters (750 meters in the May 6th case) but there are differences in the lower part, mainly due to the time difference between profiles and the changes in the boundary layer that the day/night difference implies.

The seasonal and regional profiles show differences in the lower part (the one that disagree with the aircraft profiles) showing larger extinction in northern and central California, especially in the winter. The other main difference is the layer of aerosol at about 2 Km in northern California during winter. This is probably due to long transport of aerosol (pollution and dust) coming from Asia.

Funding for this work was provided by CARB under agreement no. 08-323. The statements and conclusions in this report are those of the researchers and not necessarily those of the California Air Resources Board.

*Presenting author email: af@aerodyne.com

We present preliminary results on the optical characterization of aerosols during the ClearfLo (Clean Air for London) Intensive Operating Period from mid-January to mid-February, 2012 at a rural site southeast of London, England. The site, situated at the Kent Showground in Detling, is located approximately 50 km southeast of central London. Over the course of the campaign, sampled air masses appeared to be of local (A249 motorway proximate to the site), regional (Thames Estuary) or long range (continental Europe) origin depending on the direction and strength of the prevailing winds.

Aerosols were collected from two separate inlets mounted approximately 9 m above the ground that were outfitted with 2.5 micron cutoff impactors. The first inlet was routed to a number of instruments, including a CAPS PM_{ex} (Aerodyne Research) particle optical extinction monitor [Massoli, et al., 2010] and a Multi-Angle Absorption Photometer (MAAP) (ThermoFisher), both operated a nominal wavelength of 630 nm. The second inlet was routed to a CAPS PM_{ex} monitor operated at 450 nm and a Photo-Acoustic Soot Spectrometer (PASS-3) (Droplet Measurement Technologies) which provided particle absorption at three wavelengths (780 nm, 532 nm and 405 nm). The second inlet was equipped with a particle thermal denuder (Aerodyne Research) which could be operated at temperatures up to 250 ºC. [Huffman, et al., 2008] The sample flow was alternated between the denuder and a bypass line every 10 minutes.

Figure 1 shows optical extinction, absorption and the calculated single scattering albedo (SSA) measured at 630 nm shown as 1 hour averages as well as ambient carbon monoxide levels. Extinction levels varied from 7 to 230 Mm^{-1}; the absorption varied between 1 and 32 Mm^{-1}, corresponding to nominal black carbon levels of ~1 to 5 micrograms m^{-3}. The SSA averaged ~ 0.85 over this period. Peak extinction and absorption levels occurred over a two and a half day period starting at noon on January 30. Examination of carbon monoxide concentrations over this period indicates that the air mass responsible for these high readings was well mixed and not of local origin. HYSPLIT-based back-trajectory calculations indicate that these high extinction and absorption levels corresponded to outflow from continental Europe. The dramatic dropoff in particle extinction and absorption levels at the end of this period corresponded to an increase in wind speed (although not a change in direction) and a large decrease in carbon monoxide levels. Periods of low SSA corresponded to air masses dominated by emissions from local sources (e.g., exhaust from local traffic).

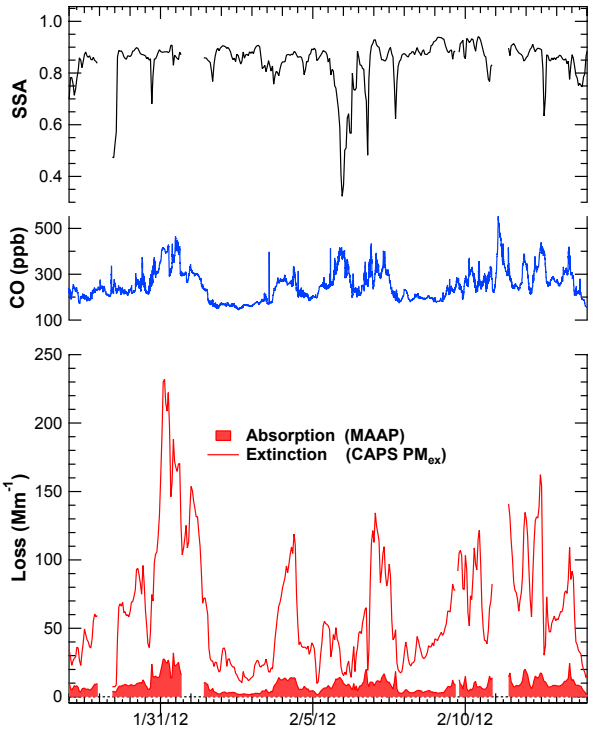

Fig. 1 (bottom) Plot of absorption and extinction levels (1 hour averages) at 630 nm measured using the MAAP and CAPS PM_{ex} monitors respectively. (middle) Carbon monoxide levels. (top) Single scattering albedo (SSA) calculated from data in bottom panel.

Long term measurements of aerosol optical depth in the UV range in central Poland

J. Jarosławski

Institute of Geophysics Polish Academy of Sciences, ul. Księcia Janusza 64, 01-452, Warsaw,
Keywords: aerosol optical thickness, Brewer spectrophotometer .
Presenting author email : januszj@igf.edu.pl

Aerosol optical thickness (AOT) is an important parameter describing the total content of aerosol in the atmosphere. The measurement of this parameter at different wavelengths allows to obtain additional information about atmospheric aerosols, such as particle size distribution. Most AOT measurements are performed in the visible and infrared part of the solar spectrum mainly because of the difficulty in measuring process (weak signal, atmospheric ozone and SO2 absorption bands). AOT in the UV range can't be obtained by simply extrapolation from the longer wavelengths range, because the dependence of AOT on the wavelength varies with the aerosol type. Knowledge of aerosol optical properties in the UV range is also very helpful in analysis of changes in the solar UV radiation intensity in the atmosphere. In certain circumstances the atmospheric aerosol can modify the intensity of solar UV radiation in the similar way as atmospheric ozone.

In this paper the results of nearly 20 years of measurements of AOT at 320 nm are presented. Measurements have been performed by the Brewer spectrophotometer, the instrument originally constructed to measure the total ozone content using the method described in Jarosławski *et al* (2003). Daily means of AOT measured during 1992-2011 period are shown on Fig. 1. Mean value of AOT is equal to 0.35. The measurement period is limited to the clear sky days (at least a part of the day)

A number of cases with the value of AOT exceeding several times the mean value is associated with episodes of long range transport of biomass burning or saharian dust aerosol in the region of measurement (Jarosławski, Pietruczuk 2010).

The lowest values of AOT are always greater than 0.1. The elevated low levels of AOT in 1992-1994 are associated with the remnants of Pinatubo eruption in 1991. An increase of minimum values of AOT can be also observed over the past few years. This increase is consistent with a similar increase of PM10 concentrations observed in the region.

When it comes to long-term changes in AOT, after a slight decrease in the nineties there is no significant change in n AOT after 2001.

Concerning the seasonal variation of AOT, a double maximum in spring and autumn and a minimum in the winter occurs. The main reason for this variability is seasonal biomass burning to the east and south of Poland. Winter minimum probably results from measurement conditions: sunny days in the winter occur when clean air from the north or north-east is transported to the measurement point.

Retrieving aerosol properties over the Mediterranean basin with a climate model

N. Hatzianastassiou[1], P. Ginoux[2], V. Ramaswamy[2]

[1]Laboratory of Meteorology, Department of Physics, University of Ioannina, Ioannina, Epirus, 45110, Greece
[2]Geophysical Fluid Dynamics Laboratory/NOAA, Princeton, New Jersey, 08540, USA
Presenting author email: nhatzian@cc.uoi.gr

The broader Mediterranean basin is an ideal study region for aerosol physico-chemical, optical, radiative properties and climatic effects. This is because of: (i) the existence of a great variety of natural and anthropogenic aerosol types, such as dust, sea-salt, biomass burning, or urban, and (ii) the large magnitude of aerosol radiative and climatic effects in this world area, which is vulnerable to climatic changes (IPCC, 2007). The particularity of the greater Mediterranean basin with regards to aerosol properties arises from the fact that the area hosts various aerosol sources, as for example some of the world's largest deserts, i.e. Sahara and Middle-East, the Mediterranean Sea, or continental lands with environments ranging from pristine (e.g. alpine) to heavily polluted (megacities). The great magnitude of Mediterranean aerosol effects is due to the combination of significant aerosol loadings and large solar radiation amounts. In order to study the regional complex aerosol related properties, processes (micro-physical, chemical and radiative), and climatic effects, which exhibit a strong spatial and temporal variability, solutions enabling extended spatial coverage and consideration of multiple interactions between the various surface and atmospheric components are required. Such solutions are only ensured by aerosol and climate models, for which the Mediterranean basin is also a challenge to assess their ability to reproduce aerosol properties, processes and climate feedbacks.

In the present study, the state-of-the-art AM2 (Delworth et al., 2006) and AM3 (Donner et al., 2011) atmospheric model component of the NOAA Geophysical Fluid Dynamics Laboratory (GFDL) general circulation model (GCM) is used to estimate the composition and concentration of aerosols, and to quantify the contribution of the different sources to the Mediterranean aerosol burdens. The model results, from 1980s to 2000s, in terms of aerosol optical properties are evaluated against in-situ and remote sensing surface and satellite measurements, namely AERONET, AVHRR, MISR and MODIS. Aerosol concentrations at surface are compared against data from EMEP (Co-operative programme for monitoring and evaluation of long range transmission of air pollutants in Europe) as well as surface measurements. Emphasis is also given to the vertical distribution of Mediterranean aerosol, and model profiles are compared to version 3.0 CALIOP (Cloud-Aerosol Lidar with Orthogonal Polarization) and EARLINET (European Aerosol Research Lidar Network) data. Moreover, AM2 and AM3 aerosol properties are compared with each other and against measurements in order to evaluate the consequences of aerosol related changes/improvements made to the new version (AM3) of GFDL model (Donner et al., 2011).

In Figure 1, the AM3 aerosol optical depth (AOD) fractions contributed by sulfate, black carbon (BC), organic carbon (OC), sea-salt and dust aerosols on an annual basis are depicted. Sulfate aerosols (fractions from 29.6 to 79.2%) are by far dominating AOD over the European continent, especially its central parts. BC fractions do not exceed 3.9%, with maxima over central Europe, whereas OC contributions reach 15% over East Europe and maximize (up to 27%) in northern Russia and Scandinavia. Sea-salt dominates aerosol burdens over the Atlantic Ocean (AOD fractions of 20-62%) whilst dust contribution is major (20-58%) over North Africa and Middle-East. Therefore, aerosol contributions exhibit a strong spatial variability, which is further varying from one season to another (results not shown here). Thus, sulfate contributions are smallest/largest in winter/summer, while BC and OC fractions reach maximum values (21.3 and 32.6%, respectively) in winter and autumn. Fractions of sea-salt become largest in winter (maximum values of 91.2% off the coasts of British islands and Scandinavia) while dust fractions always dominate AOD over North Africa, taking maximum values (72.8%) during spring.

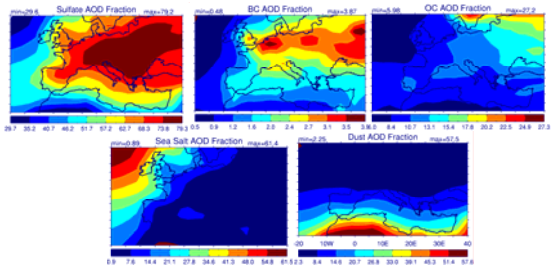

Figure 1. AOD fractions over the greater Mediterranean basin contributed by sulfate, black carbon, organic carbon, sea-salt and dust aerosols.

The performed comparisons against satellite and surface measurements reveal a reasonable agreement, and this is also valid for aerosol vertical distributions, while a significant improvement is evident from AM2 to AM3 model results. This diagnostic aerosol study will be followed by climate simulations tailored to address specific aerosol issues in the Mediterranean region.

Keywords: Atmospheric Aerosols

Atmospheric aerosol is noted by the Fourth Intergovernmental Panel for Climate Change (IPCC 2007) as a key component to fully understand the climate change. Atmospheric aerosol particles scatter shortwave and longwave radiation and absorb radiation. Furthermore atmospheric aerosol particles can act as cloud condensation nuclei and thus they can modify cloud droplet size and cloud albedo.

In spite of the strong efforts in the last decade for aerosol characterizations by spaceborne missions and international networks, there are lacks of large observations of columnar aerosol properties at night-time. The knowledge of these properties will allow us to have a whole picture of the daily behavior of the atmospheric aerosol, covering the different stages in the evolution of the planetary boundary layer and pre-convection and pre-photochemistry processes that affect the atmospheric aerosol. The knowledge of AOD at night-time would also contribute to aerosol transport and chemistry models validation efforts, and can be also used as constraints for Lidar measurements.

Since March 2007 a star photometer is been operating on the rooftop of the Andalusian Centre for Environmental Research (37.16ºN, 3.60ºW, 680 m a.s.l; South-East of Spain). This works present the first analysis of long-term day- and night-time columnar aerosol optical properties from 2007 to 2010. To this end AERONET sun photometry measurements has been also used. Technical specifications of the star photometer are in Pérez-Ramírez et al., (2008), while calibration procedures and uncertainties are in Pérez-Ramírez et al., (2001).

For the whole study period, mean aerosol optical depth (AOD) at 440 nm (± standard deviation) is 0.18±0.10 and 0.19±0.11 for day- and night-time respectively, while the mean Angström exponent (α) is 1.0±0.4 and 0.9±0.4 for day- and night-time. The ANOVA statistical test reveals that there are no significant differences between the AOD and α obtained at day-time and those obtained at night-time. Additionally, the mean day-time values of AOD and α obtained during this period are within the values obtained in the surrounding AERONET stations. On the other hand, AOD presents an evident seasonal pattern characterized by large values in summer (mean values of 0.20±0.10 both at day and night) and low values in winter (mean values of 0.15±0.09 at daytime and 0.17±0.10 at nighttime), both at day- and night-time. The Angström exponent presents clear seasonal pattern (more remarkable at daytime) with low values in summer (mean values of 0.8±0.4 and 0.9±0.4 at day and night) and relatively large values in winter (mean values of 1.2±0.4 and 1.0±0.3 at day and night), These seasonal patterns are explained by the differences in the meteorological conditions and in the strength of aerosol sources between day and night. Additionally, the spectral analysis of the Angström exponent has revealed larger contribution of the fine mode particles to AOD and larger fine mode particle radius at night-time; The changes of meteorological conditions between day-and night, the aging processes and the changes in local aerosol sources may explain these changes in the fine mode characteristics between day and night.

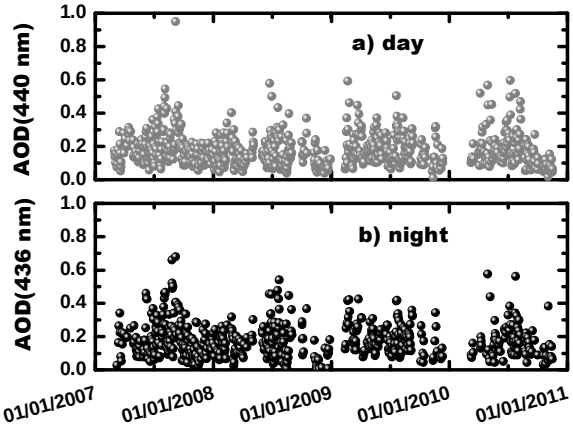

Figure 1: Temporal evolutions of (a) Day-time mean values of aerosol optical depth at 440 nm and b) Night-time mean values of aerosol optical depth at 436 nm.

Filter-based aerosol light absorption (σ_{ap}) instruments are simple in concept and have been operated long-term at remote field sites since the 1980s (e.g., Bodhaine, 1995). Unfortunately, there are several issues with filter-based instruments that can lead to uncertainties in the reported σ_{ap}. Müller *et al.* (2011) and references therein summarize these issues, which include sensitivity to measurement conditions such as humidity and pressure, artifacts due to scattering aerosol depositing on the filter, discrepancies between manufacturer and actual instrument properties (such as flow rate, spot size, and wavelength) and changes in response as a function of filter loading, measurement biases due to the presence of organics/liquids. Corrections have been developed to account for many of these issues (e.g., Bond *et al.*, 1999), although the artifacts related to presence of organics/liquids are not yet well enough understood to parameterize (e.g., Lack *et al.*, 2008).

Aerosol absorption can also be obtained by utilizing non-filter-based measurements of aerosol extinction (σ_{ep}) and scattering (σ_{sp}) and taking the difference: $\sigma_{ap} = \sigma_{ep} - \sigma_{sp}$. The disadvantage of this approach is that it uses the difference between two large numbers to get a small number (σ_{ap} is typically a small fraction (~10%) of σ_{ep}). Also, until recently, measurements of σ_{ep} were typically made by prototype instruments requiring expert attention and thus not suited to long-term, remote monitoring.

Aerodyne Research Inc. has developed a new, commercially available instrument which uses Cavity Attenuated Phase Shift (CAPS) spectroscopy to measure extinction (Massoli *et al.*, 2010). Using this CAPS instrument in conjunction with a nephelometer to measure scattering, could provide a robust, long-term way of monitoring aerosol absorption, assuming instrument uncertainties for the difference method are less than the uncertainties associated with filter-based absorption measurements.

Here we present σ_{ep} and σ_{ap} closure results from five months of measurements made at Storm Peak Laboratory (SPL) in Steamboat Springs, CO in the winter/spring of 2011. A CAPS instrument, an integrating nephelometer and a particle soot absorption photometer (PSAP) sampled off a common inlet at SPL during the STORMVEx campaign. Figure 1 shows the relationship between extinction measured by the CAPS and extinction calculated from the sum of nephelometer scattering and PSAP absorption. The scattering and absorption measurements have been adjusted to 630 nm to match the CAPS extinction wavelength.

In addition to an analysis of the extinction closure (shown in Figure 1), we will (a) evaluate how absorption from the filter-based PSAP measurement compares with absorption derived from $\sigma_{ep,CAPS}$ - $\sigma_{sp,neph}$; explore potential causes of discrepancies between the measured and derived extinction and absorption; and finally look in more detail at a couple case studies involving biomass burning. A laboratory experiment utilizing a similar suite of instruments is planned for spring 2012 – pending successful completion of those measurements preliminary results from that experiment will also be presented.

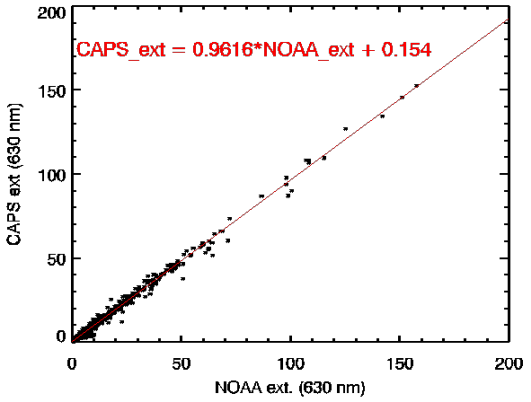

Figure 1. Comparison of $\sigma_{ep,CAPS}$ with $\sigma_{ep,neph+PSAP}$ ($\sigma_{ep,neph+PSAP}$ is called NOAA_ext on plot)

Presenting author email: michael@iao.ru

The role of Siberia is of great importance to understand the climate change due to it covers about 10% of Earth's land surface. It extends longitudinally and latitudinally for several thousands of kilometres, so its ecosystems are represented by steppes, different types of forest, wetlands, tundra and arctic deserts. Assuming that increasing global temperature and CO_2 fertilization can likely lead to an extension of the annual photosynthesis period and forest growth, Kulmala *et al.* (2004) suggested a possible feedback mechanism linking forests, aerosols and the climate effect of CO_2 through the intensification of metabolic processes causing enhanced non-methane BVOC emission and organic aerosol production as well. Taking into account that the main part of boreal forests is located in Siberia, this possible feedback makes this region important not only because of studying GHG budget, but also because of it can be an important source of natural secondary aerosols. The most detailed data on new particle formation and growth in the troposphere over Siberian forests were reported by Dal Maso *et al.* (2008). In the overview done by Kulmala *et al.* (2011) authors arrived at a conclusion that continuous and comprehensive measurements of GHGs and aerosols over Siberia are still lacking, and, as a solution, they proposed a plan to carry out in the future a so-called Pan Siberian Experiment (PSE).

Understanding the importance of this problem, we decided to establish two monitoring stations for continuous measurements of aerosol and trace gas (CO_2, CH_4, O_3, NO_x, SO_2, CO) concentrations in order to fill up the gap in data. The first one is a so-called TOR-station (56°28'40"N, 85°03'14"E), and another one – Fonovaya Observatory (56°25'07"N, 84°04'27"E).

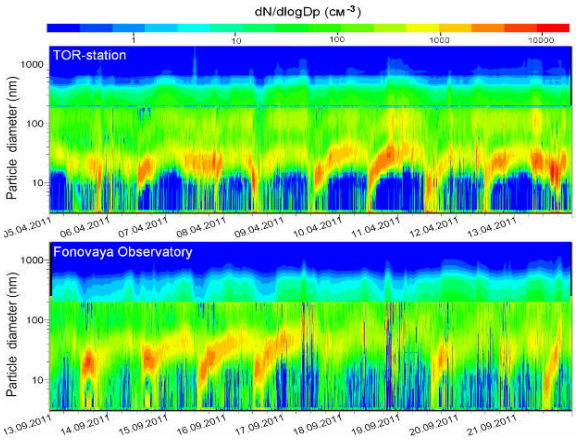

Figure 1. Golden day NPF events observed at TOR–station and Fonovaya Observatory.

Measurements of aerosol size distributions have been carrying out since March 2010 at TOR-station and since May 2011 at Fonovaya Observatory by means of the improved versions of Novosibirsk automated diffusion battery (Reischl *et al.*, 1991) and the GRIMM aerosol spectrometers (#1.109 and #1.108).

Analysis of the data obtained to date showed that new particle formation (NPF) happens frequently in the atmospheric boundary layer over Siberian boreal zone. A series of NPF bursts followed day after day were found in spring and early autumn (Fig. 1). Seasonal variation pattern of NPF event frequency is presented in Figure 2, which shows that the number of events in Siberia are more often observed during spring (from March to May) and autumn (secondary frequency peak in September).

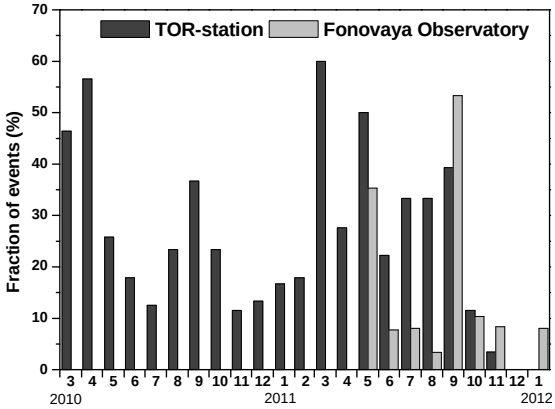

Figure 2. Seasonal variation of NPF events.

The most strong nucleation bursts occurred in March and April. The highest formation and growth rates of ultrafine particles reached values of 2.3 cm^{-3} s^{-1} and ≈25 nm h^{-1} in April. The observed seasonal pattern of event frequencies is similar to one observed in Hyytiälä (Kulama *et al.*, 2005). The fact of similarity between the NPF processes occurred in the boreal forests of Southern Finland and West Siberia allows a conclusion to be drawn that secondary aerosol formation in these regions may have a significant climatic effect in the temperate latitudes of the Northern Hemisphere.

Formation of new particles is an important process that can affect the concentration of cloud condensation nuclei and thus influence clouds and climate. Nucleation of new particles in atmosphere has been shown to correlate with sulphuric acid concentrations. Recent laboratory studies found that ammonia enhances the nucleation rate by a factor of 100-1000 compared to pure sulphuric acid. Despite this effect the nucleation rate observed in the atmosphere can still not be explained by just these two compounds (Kirkby et al., 2011).
There is evidence that organic compounds are involved in the nucleation process (Metzger et al., 2010). For a better understanding of the influence of organics on the nucleation, experiments with pinanediol were performed during the CLOUD 4 campaign. Pinanediol is produced during photooxidation of α-pinene thus mimicking a biogenic compound after an oxidation process in the atmosphere.

Pinanediol, SO_2 and ozone were added to the cloud chamber. Then UV lights induced OH formation from ozone photolysis leading to sulphuric acid production and OH radical reactions with pinanediol. The gas phase composition was measured by a Proton Transfer Reaction Time Of Flight Mass Spectrometer (PTR-TOF-MS). The cluster composition was retrieved by an Atmospheric Pressure interface Time Of Flight Mass Spectrometer (APi-TOF,). (Junninen et al., 2010) This instrument can determine the composition of ions in the CLOUD chamber in the mass/charge range up to 3300 Th.

During the nucleation experiments the APi-TOF revealed a large number of clusters formed by the interaction between sulphuric acid and oxidation products of pinanediol. The elemental composition of small ions and ion clusters was identified and the findings were compared with the gas phase organic composition retrieved from the PTR-TOF-MS. Since the concentration of oxidation products was very small in the CLOUD chamber, more experiments at a higher OH concentration were performed at the PSI smog chamber.
We will present the oxidation pathways of pinanediol and the observed oxidation products. The measurements of the gas phase composition will be related to the cluster composition and discussed.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. Keywords: nucleation events, number size distribution, SMPS, classification

Thessaloniki is a densely populated coastal city of northern Greece with high concentrations of atmospheric particulate matter (PM) frequently observed in the city centre. Several studies have investigated the concentration levels, the chemical composition of PM, as well as the size distribution of particle mass concentrations over the city (Voutsa *et al*., 2002; Petrakakis *et al*., 2007; Terzi *et al*., 2010;). Preliminary measurements of the size distribution of aerosol number concentration in Thessaloniki were conducted during winter-time at a kerbside site and an urban background site (Terzi et al., 2007). The size distribution of aerosol number concentration during the summer-time and the relationships with PM mass, photochemical pollutants and meteorological parameters was investigated in Siakavaras et al., (2008), while a classification of the nucleation events during the same period was recently reported (Siakavaras et al., 2011).

In this paper we analyse the differences between particle nucleation and growth events observed during the summer period at two monitoring stations (Venizelou – kerbside site, and Eptapyrgio – urban background site). Two identical Scanning Mobility Particle Sizers (TSI Model 3034) have been employed to measure simultaneously the size distributions of the particles having diameters in the range 10-487 nm at the two sites. Gaseous pollutants (CO, NO_x, SO_2 and O_3) and meteorological parameters (wind speed, wind direction, temperature and relative humidity) were also recorded during the measurements. The experiments were conducted during June to October 2009.

Nucleation events were classified in 5 categories based on their intensity. At Venizelou (kerbside site), 6% of the days were classified as class Ia events, 3% as class Ib, 10% as class II, 14% of the days exhibited no clear particle formation patterns and were considered as undefined and 67% of the days showed no event. At Eptapyrgio (urban background site) 8% of the days were class Ia events, 7% class Ib, 5% class II, 5% were undefined and 75% of the days showed no nucleation.

Characteristic differences between the classes can be seen in Fig. 1. For Class Ia the diurnal variation of the particle number concentration shows a significant increase starting at 07:00 at Venizelou and at 12:00 at Eptapyrgio, whereas for the non-event days, the diurnal variation is less pronounced for both stations. Nucleation events were more frequent during July, and for both stations correlated well with high concentrations of SO_2 and NO_x.

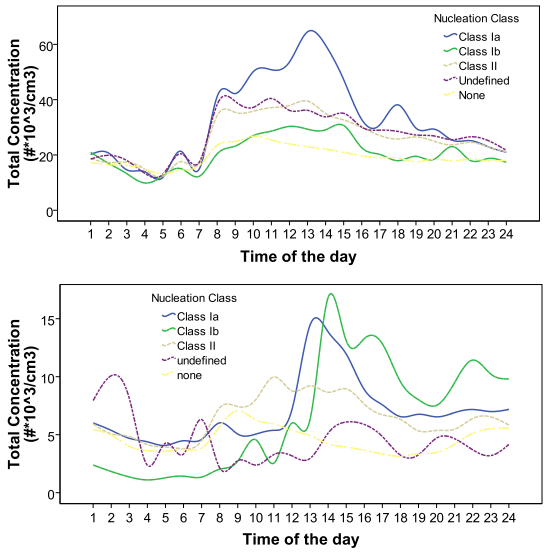

Figure 1. Average diurnal variation of particle number concentrations during nucleation event days of all classes at Venizelou (upper part) and Eptapyrgio (lower part)

Presenting author email: rocio.fernandez@dgeo.uhu.es

Urban air quality impairment by ultrafine particles (diameter < 0.1 µm) has become a matter of concern due to the adverse effects on human health (Araujo and Nel, 2009). Most of the studies of ultrafine particles in urban air quality have focused on vehicle exhaust emissions. Thus, ultrafine particle emissions in vehicle exhaust have been subject to limit values in a recent stage of the EURO standards.

We present a study on how industrial emissions contribute to ultrafine particle concentrations in downwind urban ambient air. This research is based on experimental data collected in the ambient air of the industrial city of Huelva (SW Spain) over 18 months (particle number concentration, black carbon and levels and composition of $PM_{2.5}$ with daily resolution). This city is affected by emissions from the second largest Cu-smelter in Europe, phosphoric acid and fertilizer production plants and an oil refinery and petrochemical plant. In order to quantify the process contributing to ultrafine particles concentrations (N), two components (N1 and N2) were segregated by the methodology of Rodríguez and Cuevas (2007). N1 accounts for vehicle exhaust emissions and may also include compounds nucleating/condensing immediately after emission. N2 is correlated with SO_2 and accounts for new particle formation due to nucleation and rapid particle growth to detectable sizes (Fernández-Camacho et al., 2010b).

In order to identify the sources contributing ultrafine particles, Principal Component Analysis were performed to data for particle number concentration and $PM_{2.5}$ chemical composition. Three Principal Components were observed: APC-1, showing a high association with species linked to industrial emissions from the Cu-smelter (nss-$SO_4^=$, As, Sb, Pb, Zn and Sn), the phosphoric acid and fertilizer plant (nss-$SO_4^=$, P and NH_4^+) and the oil refinery (nss-$SO_4^=$, NO_3^-, NH_4^+, V and Ni). The presence of N2 in this PC is attributed to ultrafine sulphate particle formation in the plume during inland transport prompted by sea breeze from 09:00 to 17:00 GMT (Fernández-Camacho et al., 2010b); APC-2 associated with road traffic emissions: vehicle exhaust emissions (OM and N1) plus road dust (Al, Ca, Fe, Ti, Mn and K). The presence of N1 in this factor is in agreement with the weekly cycles of NO_x and N1 particles, which exhibits high values during working-day rush hours (view details in Fernández-Camacho et al. 2010b); APC-3 showing high factor loading for typical sea salt components (Cl, Na and Mg). As expected, neither of the particle number components, N1 or N2, was associated with this factor.

Only two sources contributed significantly to the particle number N: road traffic accounted for 50 ± 9%, whereas industrial emissions accounted for 44 ± 7% of N. Figure 10 shows the daily mean averaged values of the particle number N, classified from the highest to the lowest concentration (100^{th} to 1^{st} percentile), and the contribution of the identified sources. When vehicle exhaust is the main source, ultrafine particles typically show (24-h mean) concentrations within the range 14700 – 5000 cm^{-3} (50^{th} – 1^{st}), with 60% of these being linked to this source and 30% to industrial emissions. In contrast, when daily mean levels of N are within the range 50000 – 25500 cm^{-3} (100^{th} - 70^{th}) industrial and vehicle exhaust emissions accounted for 49 and 30%, respectively.

The results of this study show that industrial emissions are the main cause of ultrafine particles episodes in Huelva city.

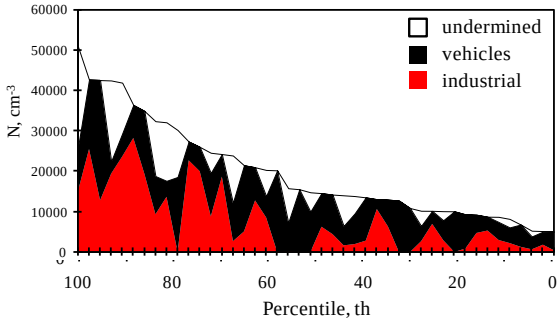

Figure 1. Daily averaged values of N classified from highest to lowest concentration highlighting the contribution of the industrial, vehicle exhaust and undetermined fraction contributions.

Basic Statistics of New Particles Formation Events at Kosetice Station

N. Zikova[1,2] and V. Zdimal[1]

[1] Department of Aerosol and Laser Studies, Institute of Chemical Process Fundamentals of the AS CR, v.v.i, Prague, 16502, Czech Republic (ICPF)

Keywords: nucleation, number size distribution, SMPS
Presenting author email: zikova@icpf.cas.cz

Introduction: Atmospheric aerosols have been studied extensively due to the confirmed influence of aerosols on global climate, aerosol – clouds interactions, atmospheric visibility, human health etc. (Kerminen *et al* 2005; IPCC, 2007; Wichmann *et al*, 2000). However, the uncertainties connected to the effects of aerosols on phenomena in the atmosphere are considerable – there are various sources of aerosol particles, having different chemical compositions and particle size distributions (PSD). Concerning changes of PSD, the most important processes are new particle formation events (NPF).

A NPF event, sometimes called a nucleation event, is characterized by a formation of ultrafine particles in the size range between 3 and 25 nm. The result of the NPF event is a new mode in the PSD. The formation of particles and their further growth by condensation and/or coagulation are key processes influencing the dynamics of the atmospheric aerosol PSD (Kulmala *et al* 2001).

In this work, we present a basic statistical evaluation of NPF at Kosetice background station in the region of middle Europe. The evaluation is based on the NPF classification according to Dal Masso et al. (2005). The individual days were classified into three categories – NPF event, Non-event and Undefined days.

Methods: The evaluated data were collected during the first three years of measurements (2008 - 2010) at Kosetice observatory, located in the Czech Highlands (49°35'N, 15°05'E, altitude 534 m a.s.l.). The observatory is a background meteorological station operated by the Czech Hydrometeorological Institute, and is a part of the national professional meteorological measurement network, specialized in the environmental quality monitoring. In 2008, the observatory became a part of the EUSAAR network and was equipped by an IfT-SMPS (Scanning Mobility Particle Sizer) provided by the Leibnitz Institute for Tropospheric Research (IfT) in Leipzig.

The SMPS samples every 5 minutes over the mobility size range from about 10 nm to 900 nm. Data in 5 minutes time resolution have been processed according to the EUSAAR standards into one-hour arithmetic means of particle number concentration.

Results: It has been found that the average annual cycle of NPF events (Fig. 1) has two maxima, the first in April and the second between July and September. The main minimum is located in the colder part of the year. The Non-event days follow an inverse annual cycle; Undefined days are approximately evenly spread over the year.

The variability between the three years is not high (Fig. 2), especially ratio of NPF events to all classifiable days varies only by several percent. What differs, however, is the ratio of Undefined and Non-event days to all classifiable days. While during the first two years there were slightly more Undefined than Non-event days, during the third year, the relationship is the opposite.

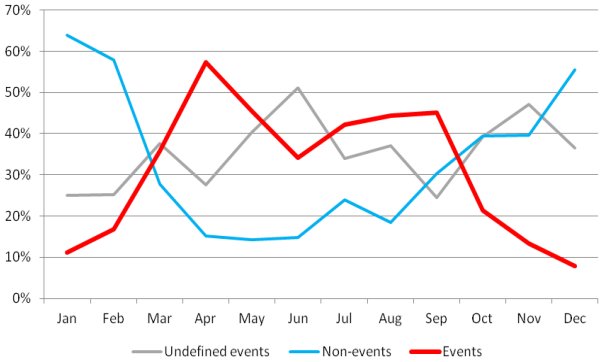

Fig 1. Annual cycles of ratios of NPF Events, Non-events and Undefined days to all classifiable days. Averaged from three years of measurement.

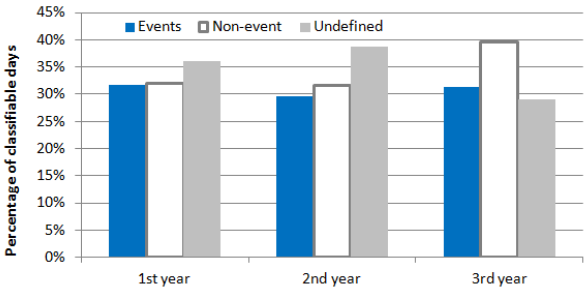

Fig 2. Ratio of NPF Events, Non-events and Undefined days to all classifiable days in the individual years.

Aerosol particles are known to have several climate and health effects (IPCC, 2007). Therefore, aerosol particle formation and subsequent growth has been intensively investigated in a variety of environments (Kulmala *et al*, 2004; Hirsikko *et al*, 2011). Particle formation event frequency, formation and growth rates of freshly nucleated particles depend on several triggering and inhibiting factors, i.e. concentration and size of background aerosol particles, anthropogenic/natural sources of nucleating and condensing vapours, air mass trajectories and turbulent atmospheric mixing

Particle formation may take place several times a day, both during daylight and night-time (Hirsikko *et al*, 2011 and references therein). Hirsikko *et al* (2012a) observed that particle formation took place during several consecutive periods during the same day in a mining area with informal settlement in South Africa on 108 days. The aim of this work was to investigate driving factors behind the observed multiple daytime nucleation events (Hirsikko *et al*, 2012b).

The analysis was based on the observations of particle size distributions in diameter ranges 0.8-42 nm and 12-840 nm with an Air Ion Spectrometer (Mirme *et al*, 2007) and a Differential Mobility Particle Sizer, respectively. In addition, ancillary data were deployed, i.e. trace gas and meteorological parameters (Venter *et al*, 2012), as well as modelled air mass trajectories (www.arl.noaa.gov/archives.php) and boundary layer heights (www.ecmwf.int/research/ifsdocs/CY37r2/index.html). Temporal evolution of sulphuric acid concentration proxy was estimated based on SO_2 concentration, global radiation and condensation sink due to background aerosol particles (Dal Maso *et al*, 2005; Petäjä *et al*, 2009).

Days when the ancillary data were deficient or air mass origin, path and wind direction were changing notably between the particle formation events were rejected. Eventually, we were able to investigate multiple nucleation events followed by subsequent growth on 29 days. The results indicated that typically: 1) the first nucleation event took place between 06:00-09:00, 2) the second event was observed between 09:00-12:00 and 3) the third occurred late in the afternoon (approximately 15:00-18:00). Common to all of these particle formation events was that they occurred during day light hours, which allowed photochemical reactions and enhanced boundary layer mixing compared to night-time.

The first particle formation event of the day was associated with increasing sulphuric acid concentration, and sometimes also with very high condensation sink. These observations together with the timing of the event indicated that nucleation was observed with ground based instruments when a residual or inversion layer, influenced by emissions from the regional industry, mixed into the boundary layer. The particle formation was suppressed when the sulphuric acid concentration had decreased low enough.

The second particle formation event of the day was promoted by decreasing condensation sink and increasing concentrations of suitable vapours. Our results indicated that the sulphuric acid concentrations were insufficient to explain the second event. Therefore, it was probable that other vapours, such as oxidation products of monoterpenes, were involved in the particle formation and growth. The third particle formation event of the day was typically associated with different air mass paths or wind directions compared to the morning particle formation episode.

Our observations indicated that by investigating case study examples we were able to gain new information on the driving factor of multiple particle formation events. A similar investigational approach is also recommended for environments where multiple nucleation events might occur.

We would like to express our acknowledgements to Tshepo Lenake, Rustenburg Municipality, the Finnish Academy (project no 117505; no 132640), and the North-West University.

Studies with increasing number have been published in the last years due to the important role of fine particles in several atmospheric processes and effects on climate and human health. New particle formation events are observed all over the world both in polluted and clean, background air. Similarly, in Hungary NPF events can be detected in polluted cities like Budapest (Salma *et al* (2011) as well as in rural air at K-puszta. Our former results showed that in rural air these events can be frequently observed, NPF events are classified on 25-30% of the days (see Figure 1).

In this work we summarize our results on the particle formation at K-puszta station between Nov. 2008 and Dec. 2011. The size distribution of the particles between 3-800 nm is evaluated. On the basis of DMPS spectra the classification of particle formation events is carried out according to the recommendations of Yli-Juuti *et al* (2009). The event classification is studied with respect to the seasonal variation and the frequency of the particle formation event types (event, non-event and unclassified) is also discussed.

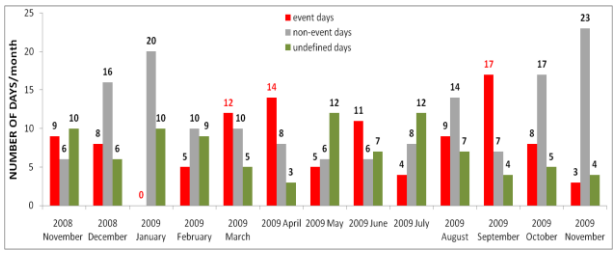

Figure 1. Event classification statistics (November 2008-November 2009), K-puszta.

Generally, in new particle formation (NPF) winter is the most inactive period (Figure 1), while the number of NPF events is found to be the highest in spring and in autumn. As a consequence of the seasonal variation of the NPF events, the frequency of the nucleation mode (3-25 nm) is the highest during spring and autumn. On the other hand, in winter the accumulation mode (100-800 nm) showed the highest, while in spring and summer the lowest frequency. This seasonality is also shown by the "typical" seasonal number size distributions. This means that in spring the freshly formed particles, while in winter the aged particles characterize the aerosol size distribution.

The growth rate (GR) of the freshly formed particles is also calculated (Hirsikko *et al* (2005), Yli-Juuti *et al* (2009). Our results show that at K-puszta the particle GR is highly variable; and has no significant seasonal variation. The rates were estimated between a few and 14 $nmhr^{-1}$ except one day with a growth rate of 18 $nmhr^{-1}$. The average GR was 5.67 $nmhr^{-1}$. On the other hand, the formation intensity of new nucleation mode particles (smaller than 25 nm) is also estimated. The calculation is based on the method considering the change of the particle number concentration in each size modes per unit time. According to our preliminary results the new particle formation rate varies in a wide range of values (e.g. the average formation rate for 10 nm particle size range was found between 2.31-21.8 particles $cm^{-3}sec^{-1}$.

Antarctica is very isolated continent, especially during the winter, and has had no known sources of secondary aerosol particles on its surface (Ito, 1989) until present. However, during the Finnish Antarctic Research Program (FINNARP) 2009 expedition, the first evidence of Antarctic particle formation due to continental biogenic precursors was observed.

The Finnish Antarctic Research Station Aboa ($73^{\circ}03'S$, $13^{\circ}25'W$) is build on a nunatak (mountaintop) Basen, 500 m a.s.l., some 130 km from the open ocean. During the Antarctic summer, lots of meltwater form close to the nunataks that are peaking out from the thick ice mass. These meltwater ponds hold a variety of biological activity in them (Jungblut *et al.*, 2005), e.g. cyanobacteria *Nostoc commune* (Vaucher), a species very tolerant for extreme conditions (Dodds *et al.*, 1995) and commonly found from Basen and the Antarctic mountains.

The concentrations of neutral $10-500$ nm and charged $0.8-42$ nm particles as well as their size distribution and quartz filter samples were taken from the atmosphere, about 3 m above the ground level. The measurement devices were kept inside a small container, approximately 200 m upwind from the main station. In addition, samples of the cyanobacterial mat of *N. commune* and water from the meltwater ponds were taken. The ponds were approximately 2.5 km upwind from the measurement site. Different chemical compounds from the filter as well as water and *N. commune* samples were analyzed later in Finland with a comprehensive two dimensional gas chromatography-time-of-flight mass spectrometry (GCxGC-TOF-MS).

During the campaign three periods of frequent new particle formation (NPF) and subsequent growth were observed - in the beginning of the campaign, in the beginning of January and in the end fo the campaign. The growth rate for the charged cluster ions as well as for neutral Aitken mode particles were high for Antarctica (Kulmala *et al.*, 2004), order of $1-10$ nm/h. The most intense and almost continuous nucleation happened after the melting of the ponds and the exposure of *N. commune* during the last two NPF periods; 1st to 3rd and 17th to 21st of January, 2010. The events started from the smallest cluster sizes and the particles grew very rapidly. In addition, the shape of the events was suggesting that the formation took place on a small scale, close to the station. To our knowledge, this has not been observed earlier in Antarctica.

We also estimated the contribution of the ponds to the aerosol budget at our measurement site. These calculations revealed that the ponds can be very important source areas for secondary aerosols during the summertime in Antarctica. In addition, we used HYSPLIT backtrajectories to estimate the origin of the growing Aitken mode particles during the same periods. The results showed that the particles originated from the inland mountains few hundred of kilometres away.

Even though the total surface area of the nunataks is quite small, they are important source regions for secondary organic aerosols during the summer in Antarctica. Furthermore, in a warming climate, it is likely that more meltwater ponds will open up during the summertime and they will exist longer. This could increase both the aerosol number concentrations and their condensational growth and finally CCN and cloudiness. Our results will help in estimating the climatic feedbacks of aerosols and future climate in Antarctica.

The secondary formation of atmospheric nanoparticles through gas-to-particle conversion occurs in many areas over the world. After subsequent condensational growth to sizes relevant for cloud formation, these particles become important for the global radiation balance. Potentially, the nanoparticle formation route might be responsible for up to 50% of world's cloud condensation nuclei (Merikanto et al., 2009), with a large uncertainty which stems from poor knowledge of formation routes. In this study, we seek to widen our knowledge in one of the formation routes. A basic question in this context is:

How frequent are ship-induced new particle formation events, and what conditions are favourable for their appearance?

In our NanoShip project, particle number size distribution measurements are carried out at a site at the Danish peninsula Jutland during 2012 to investigate if formation events are linked to winds from the North Sea. Also data from the Norwegian and Dutch EUSAAR sites Birkenes and Cabauw measured from late 2008 until present are used to infer the appearance and frequency of formation events during conditions with winds from south-east and north-west respectively.

By following the growth process of nanoparticles during the formation, and using back trajectories it is possible to infer where the formation of 1.5 nm diameter particles has taken place over the North Sea. This method is described by Kristensson et al. (2011).

Figure 1 shows an example of a formation event at Birkenes with a strong particle mode appearing larger than 15 nm in diameter around 10:00 local time, grown to around 25 nm in diameter at 12:00, and finally to sizes well above 50 nm in diameter in the evening. The growth rate suggests that the particles of around 25 nm in size have been formed as 1.5 nm diameter particles roughly 6 hours previously over the sea north of the Danish peninsula Jutland (thick line in Figure 2). Hence, formation events take place over densely trafficked ship lanes.

Maps will be superimposed for a full event probability distribution as function of geographical coordinates over the North Sea based on the data from the three sites.

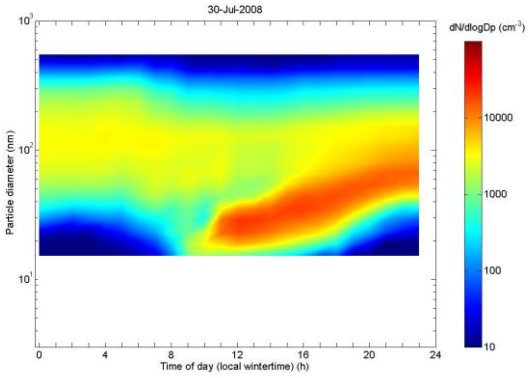

Figure 1. Particle number size distribution at Birkenes (Norway, rural site) during July 30, 2008.

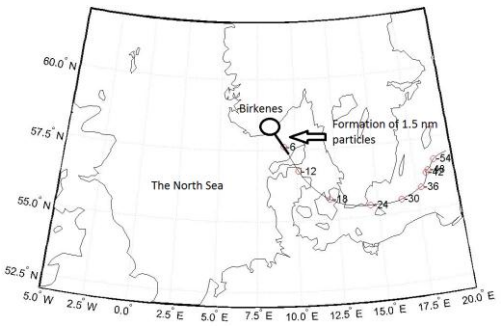

Figure 2. Back trajectory analysis recalculating the origin of a nucleation event observed at Birkenes at 100 m a.s.l at 12:00 July 30, 2008. Circles denote position of trajectory each 6 hours.

Presenting author email: jenni.kontkanen@helsinki.fi

Atmospheric new particle formation is proposed to happen via heterogeneous nucleation on molecular clusters or the activation of the clusters in the size range of 1–2 nm (Kulmala *et al*., 2000). There are numerous observations of sub-2 nm charged clusters and recent measurements have also proven the existence of neutral clusters (Lehtipalo *et al*., 2009). However, still many questions related to the exact particle formation mechanism remain. In this work we aim to shed light on these issues by using direct measurements of atmospheric sub-2 nm charged and neutral clusters.

Measurements were conducted from March 14th to May 16th 2011 at the SMEAR II station in Hyytiälä, southern Finland. The total nanoparticle concentration was measured with a particle size magnifier (PSM; Airmodus A09; Vanhanen *et al*., 2011) and ions were measured with a Neutral cluster and Air Ion Spectrometer (NAIS). In addition, sulfuric acid concentration was simultaneously measured using a Chemical Ionization Mass Spectrometer (CIMS). The total nanoparticle concentration and ion concentration were calculated for six size classes ranging from 0.9 nm to 2.1 nm in mobility diameter. The concentration of neutral clusters and particles due to the ion-ion recombination was estimated from the ion spectrometer data. The concentration of other neutral species was then calculated by subtracting the concentrations of ions and recombination products from the total concentration.

During the measurement period a continuous pool of sub-2 nm nanoparticles was observed (Kulmala et al., 2012, Kontkanen et al., 2012). This nanoparticle population was dominated by neutral clusters and particles not originating from the ion-ion recombination as their concentration exceeded the concentrations of ions and their recombination products most of the time. Particularly during new particle formation events the dominance of neutral species was clear. However, when the total concentration was low (typically at night), the ion concentration was often larger than the concentration of neutral clusters and nanoparticles. The typical concentration of neutral clusters was 1000–10000 cm^{-3}, the concentration varying stronger than the ion concentration.

To resolve atmospheric nucleation we studied the concentration of neutral clusters and ions in different size classes. During new particle formation events the concentration of neutral clusters seems to have its minimum at the size of 1.7–1.9 nm indicating that the growth from that size is clearly higher than the growth to that size. On the other hand, when the concentration of neutral clusters is normalized with the concentration of ions of the same size the minimum occurs at the size of 1.3–1.5 nm. These results indicate that the clusters smaller than 1.3 nm are subcritical clusters and clusters larger than 1.9 nm are growing clusters or nanoparticles. Thus, the critical size for nucleation seems to be 1.3–1.9 nm.

Several studies have shown that sulfuric acid has a crucial role in new particle formation. Our results support these observations as there is a strong correlation between the concentration of neutral clusters and nanoparticles and the concentration of sulfuric acid, especially during new particle formation. On an average new particle formation event day during our measurement period the growth rate of clusters from 1.3 nm to 1.7 nm was about 0.5 nm/h (determined from the PSM data) and from 1.7 nm to 3 nm about 1.5–2 nm/h (determined from the NAIS data). As the sulfuric acid concentration during the events was observed to be about $5 * 10^6$ cm^{-3}, the growth from 1.3 to 1.7 nm can be explained by sulfuric acid only. However, the growth from 1.7 to 3 nm needs a contribution of other, likely organic, compounds.

To conclude, our results suggest that 1) at least in Hyytiälä neutral clusters and nanoparticles dominate over small ions and their recombination products, 2) the critical size for the nucleation is 1.3–1.9 nm, and 3) sulfuric acid is responsible for the growth of clusters to the size of 1.7 nm. After that also other compounds are needed.

Keywords: CCN, Nucleation, New Particle Formation and Growth

New particle formation (NPF) in the atmosphere is a global phenomenon that has been shown to take place in a wide variety of environments (Kulmala et al., 2004). Particles grown from NPF can affect the Earth's radiation balance directly by scattering sunlight and indirectly by having the potential to grow large enough to act as cloud condensation nuclei (CCN), and moreover, can activate to cloud droplets, resulting in even greater scattering of radiation which leads to a cooling effect on the climate. However, the magnitude of aerosol indirect effects remains the single largest uncertainty in current estimates of anthropogenic radiative forcing and causes large uncertainties in the calculations of future climate change. The growth of NPF to reach CCN size may take several days, and since many aerosol dynamical as well as meteorological effects interact during such a time span, it has been difficult to determine CCN production rates on the basis of experimental observations.

Here, we address CCN production due to secondary particle formation based on the characteristics of NPF events observed in a semi-rural environment, Puijo station, Kuopio city, Eastern Finland. The station is on the top of the Puijo observation tower; 62° 54′ 32″ N, 27° 39′ 31″ E, 306 m a.s.l and 224 m above the surrounding lake and located about 2 km northwest of the center of Kuopio city, Eastern Finland. The surroundings of the station are different in each side. There are distinct sectors for cleaner and more polluted air, which give us a good opportunity to investigate the effects of local emission sources on aerosol particle formation. More detail of the station can be found in Leskinen et al. (2009). This study makes use of continuous 3 years of particle size distribution carried by Differential Mobility Particle Sizers with particle size ranges of 7-800 nm.

In order to estimate the production of potential CCN, we calculated the increases in concentrations of particles in the 50–800 nm, 80–800 nm size ranges on nucleation event days. We first determine visually the time t_1 when the leading edge of the growing nucleation mode reaches the lower limit of the size range in question (i.e. 50 & 80 nm), and denote by t_2 either the time the particle concentration in the given size range reaches a maximum, or midnight, whichever comes first. The concentration increase in the given size range is then determined from the difference of the concentrations between times t2 and t1 (Laaksonen et al., 2005). Moreover we compared CCN production (CCN_P) in Puijo station with CCN_P in Pallas station, Lapland, Northern Finland (Lihavainen et al., 2003).

For Puijo, the average increase of CCN_P in 50 and 80 nm size ranges were 5237 #cm^3 and 1375 #cm^3. We then compared the average CCN_P values from Puijo research station to the average CCN_P from sizes 50 and 80 nm in Pallas station in Northern Finland (table 1. in Lihavainen et al., 2003). The results show that the ratios of average CCN_P in Pallas to CCN_P in Puijo were 15.1 % and 14.3% for sizes greater than 50 and 80 nm, respectively. The obtained results implied that new particle formation events are a larger source of CCN in Eastern Finland as in Northern Finland. This is probably due to higher amount of anthropogenic contributions in Kuopio than in Lapland.

We will show a comprehensive statistical comparison of the Puijo data sets with respect to meteorological and trace gases of nucleation events to elucidate the different process govern new particle formation for this station.

Formation of halogen-induced secondary organic aerosol (XOA)

K. Kamilli[1], J. Ofner[2], C. Zetzsch[2], A. Held[1]

[1] Junior Professorship in Atmospheric Chemistry, University of Bayreuth, 95440 Bayreuth, Germany

Caused by their potential of stratospheric ozone depletion and surface ozone destruction, reactive halogen species (RHS) are a very important topic of atmospheric research. Crucial sources for halogens in the troposphere are halogen-release from sea-salt aerosol (Finlayson-Pitts, 2003) and heterogeneous reactions on those aerosol surfaces (Rossi, 2003). RHS seem to interact with secondary organic aerosol (SOA) precursors similarly to common atmospheric oxidizing gases like OH radicals and ozone. Although aerosol formation from reaction of RHS with typical SOA precursors was previously studied, e.g. by Cai et al. (2006), no data are available on bromine-induced aerosol formation from organic precursors yet. The potential interaction of RHS with performed SOA has recently been studied (Ofner et al., 2012).

An aerosol smog-chamber was used to examine the halogen-induced secondary organic aerosol (XOA) formation under atmospheric conditions using simulated sunlight. With a concentration of 10 ppb for the organic precursor and 2 ppb for molecular chlorine and 10 ppb for molecular bromine the experimental setup is close to ambient conditions. By combined measurements of the aerosol size distribution, the ozone and the NOx concentrations, as well as the decay of the aerosol precursor, determination of aerosol yields and aerosol growth factors could be achieved. Thereby the decay of the aerosol precursor was analyzed by capillary gas chromatography coupled with flame-ionization detection (GC-FID) and the aerosol size distribution was measured using a Scanning Mobility Particle Sizer (SMPS). Additionally, with the decay rate of the precursor and the calculated photolysis rates of molecular halogen species, based on the well-known spectrum of the solar simulator, mechanistic details on the XOA formation pathways can be determined.

We observed XOA formation even at very low precursor and RHS concentrations with a diameter mode at about 20 nm and a number concentration up to 10000 particles cm^{-3}. While the XOA formation from chlorine is very rapid, the interaction of bromine with the organic precursors is about five times slower (see Figure 1).

These studies may be related to natural XOA formation in sea-salt dominated environments, where we find organic species as precursors from biogenic or anthropogenic sources and photolyzed RHS from the surface or the sea-salt aerosol.

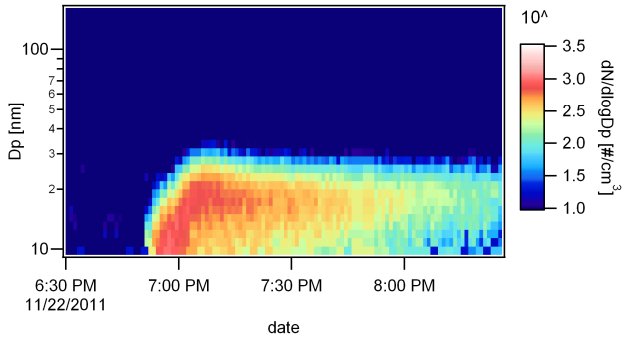

Figure 1. XOA formation from limonene and bromine in a 700 L aerosol smog-chamber.

New results about aerosol particle formation in the atmosphere can be obtained applying air ion mobility distribution measurement technique together with traditional methods (e.g. Hõrrak et al., 2008). This work continues the recent study of negative air ions (Luts et al., 2011) and shows how enhanced concentrations of water vapor, iodine, ammonia, and diethylamine (DEA) modify the composition and mobility distribution of the positive ions at different age.

An advanced method to study the formation of secondary aerosol particles starting from gas phase reactions including trace gases and ions was examined for the positively charged particles. We produced new air ions in laboratory experiments and traced their evolution within the age interval from few tenths of a second up to few ten seconds. We investigated the changes in size and mass distribution of ions concurrently by means of two instruments: 1) Air Ion Spectrometer (AIS, Airel Ltd) and 2) mass spectrometer (MS, Sciex API-300).

The huge amount of different organic compounds in the background air complicates the interpretation of the data comparing to negative ions. Nevertheless, the results demonstrate the ability of the method to trace the temporal evolution of positive air ions. In all observed cases, the noticeable MS peaks are up to *m/z* 836. We modified the concentration of water vapor and trace gases in the reaction chamber by evaporation of water, liquid organics or sublimation of iodine. Iodine vapor was found to have a substantial effect in our previous study (Luts et al., 2011). DEA and ammonia as organic compounds with high proton affinity (PA) are expected to play substantial role in positive ion chemistry.

Mass spectra of the background air consist of a large number of peaks, the most prominent are at *m/z* 130, 294, 321, 378, 408. Water vapor tends to grow up the peaks at *m/z* 378 and 408. Diethylamine changes the spectra substantially; new peaks at *m/z* 189, 190, 210, 304 appear. Also, surprisingly iodine has an essential effect on MS – new peaks appear at *m/z* 482, 483, 619. Ammonia induces the new peaks at *m/z* 269 and 322. The distribution of all peaks and their intensity depends on the age of ions. The composition of positive air ions at an age of about 0.5 s was clearly different from that at about 20 sec.

Size distribution of positive ions at different age affected by trace gases demonstrated that iodine leads to enhanced concentration of the charged aerosol particles above 3 nm, which, in turn, decrease substantially the concentration of cluster ions due to ion-aerosol attachment (Figure 1). The burst of positive ions did not require any accompanying high concentration of water. Moreover, high relative humidity (RH) suppresses the ions between 3 and 20 nm. On the contrary, in the case of negative ions (studied previously), high RH strengthens the effect of iodine. It should be emphasized that in the case of positive ions the effect of iodine appears only at ion ages of about 20 seconds, when compared to the negative ions, where the effect was observed almost instantly.

Both diethylamine and ammonia induce new MS peaks. DEA does not evoke any substantial change in the AIS spectra. Ammonia induces moderate increase in the concentrations of the ions in the region 2 to 4 nm and in the region from 7 to 20 nm.

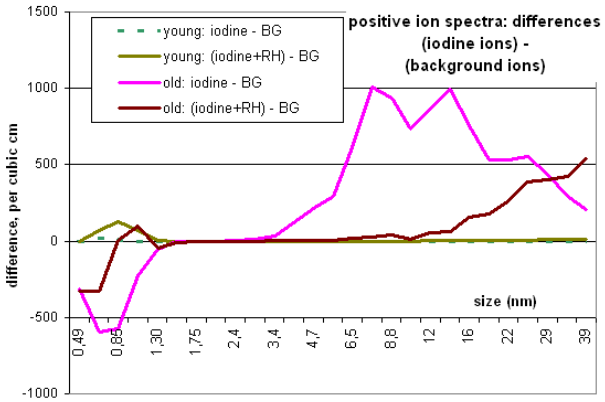

Figure 1. Differences in the AIS size distributions of positive ions induced by enhanced concentration of iodine and enhanced humidity.

The formation of new nanometer sized particles around 1.5 nm diameter during so called new particle formation events is frequent in the atmosphere. After condensational growth to cloud condensation nuclei (CCN) sizes, the nanometer sized particles have a potential to influence the global radiation balance of the atmosphere. Potentially, up to 50 % of world's CCN come from formation events (Merikanto et al., 2009).

There are an increasing number of ground stations in Europe, where measurements of the particle size distribution are performed, and hence at these sites a full characterization of formation events can be performed. However, there is a lack of information where and when the formation events take place in between the stations. For example, in favourable regions we expect "hot-spots" with a higher frequency of events and conversely "cold-spots" where gaseous precursor concentrations necessary for the formation are low.

Fortunately, this information is possible to attain. In Kristensson et al. (2011) we explain briefly the methodology, which employs existing particle number size distribution data from field sites and meteorological back trajectories. With this methodology it is possible to calculate as an end product the probability of formation of 1.5 nm diameter particles during formation events in the boundary layer in grid cells with arbitrary horizontal resolution over a European geographical mesh.

We have chosen to develop this methodology in the NanoMap project for the EUSAAR site Hyytiälä in southern Finland, since there are over 15 years of size distribution data, which gives high geographical coverage and statistics.

In Figure 1 is shown an example of the applied methodology for Hyytiälä. Only 10 months of data are used for this plot, which gives a scattered impression in the different grid cells. However, it shows that the methodology can be extended to several years of data, and that we can calculate the probability of formation with a high horizontal resolution around the station.

The calculated probability further away from the Hyytiälä site needs to be validated with the observed probability of events at a different site than Hyytiälä. Since there are two stations where size distribution data is collected for many years rather close to Hyytiälä (Pallas in northern Finland and Aspvreten in southern Sweden), this is certainly possible to do.

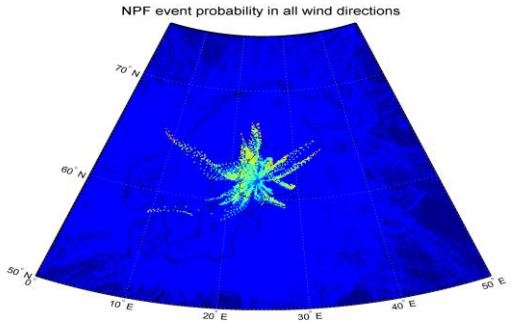

Figure 1. The probability (relative scale) of formation of 1.5 nm diameter particles during formation events around the Hyytiälä field site. Plot is based on data between Jan 1 2005 and Oct 31 2005 and the geographical grid box resolution is $0.2 \times 0.1^\circ$ in the latitudinal and longitudinal direction respectively.

The main deliverable of the NanoMap project is to make the methodology possible to apply at any site in Europe with a dense station network, where it is possible to validate the formation probability at nearby sites. With respect to the position of European sites, it is obvious that the methodology can be applied for the entire Nordic area and parts of Western Europe along a transect from Germany, Holland all the way down to northern Italy.

Simultaneously, we are trying the FLEXPART trajectory model (Stohl et al., 2005), which additionally incorporates estimates of particle dispersion. However, the development time needed is much longer, and in the meteorological back trajectory method, we already have a method up and running, which is evidently powerful and soon easily available to the scientific community

Research on new particle formation (NPF) in the atmosphere has been very active during the last two decades. This phenomenon has been observed in various environments around the world (Kulmala *et al.*, 2004). One of the longest and most comprehensive data sets of atmospheric aerosol properties is available from the University of Helsinki SMEAR II station in Hyytiälä, southern Finland (Hari and Kulmala, 2005). Ambient aerosol size distributions have been measured at Hyytiälä since January 1996 with a DMPS system covering particle size range 3 – 1000 nm (3 – 500 nm until end of 2004; see Aalto *et al.*, 2001). Aerosol measurements are complemented by measurements of basic meteorological variables, trace gas concentrations (SO_2, O_3, CO, CO_2, NO, NO_x), and quantities related to the soil and forest surrounding the station.

Until end of 2011 we have observed 1337 days with regional NPF events, i.e. formation of new 3 nm particles followed by particle growth to sizes of 30 – 50 nm typically within 10 – 20 hours. Most of the events occur at spring time from March to May. The number of nucleation events detected at Hyytiälä varies from year to year in the range 60 – 120 per year. The reasons behind this quite substantial variation are not yet found. We have, however, established that the variation of the galactic cosmic ray intensity due to the 11 year solar cycle is not connected to the particle formation intensity at Hyytiälä (Kulmala *et al.*, 2010).

Mean values and observed trends in the quantities relative to NPF are listed in Table 1. There is no statistically significant trend in the formation rates of 3 – 25 nm particles. In contrast, the growth rates are increasing by 3% per year relative to their 16 year mean value. Concentrations of sulphuric acid, which is the most important precursor vapor in atmospheric NPF, can be approximated with a simple proxy model (Petäjä *et al.*, 2009). This proxy takes into account the source from SO_2 and the condensation sink by pre-existing particles. Both the SO_2 concentration and CS are decreasing in Hyytiälä, but the relative change in SO_2 is larger. This leads to a decreasing trend of 4% per year also in the H_2SO_4 proxy concentration, and suggests that the observed increase in the particle growth rates could be caused by increased concentrations of organic compounds and their oxidation products. As the emissions of these biogenic organic compounds are highly temperature dependent, increasing global temperatures can lead to a larger fraction of newly formed particles reaching cloud condensation nuclei sizes and this way NPF becoming more significant to climate.

Characterization of new particles formation events at Izaña Mountain Observatory (Tenerife, Canary Islands): formation, growth rates and influencing atmospheric parameters

M.I. García[1], S. Rodríguez[1], R.D García[1] and Y. González[1]

[1]Izaña Atmospheric Research Centre, (IARC/CIAI), AEMet, Santa Cruz de Tenerife, E-38001, Spain

Presenting author email: mgarciaa@aemet.es

We present a study of new particle formation events in the low free troposphere over Tenerife (Canary Islands). The study is based on 4 years (2008-2011) observations of particle number size distribution in the Izaña Global Atmospheric Watch Observatory. This site is placed at 2400 meters above the sea level. The site remains almost permanently above the marine stratocumulus layer typical of the subtropical oceans. The low troposphere is strongly inhibited, in such a way that the 'dry' troposphere is separated from the 'humid' marine boundary layer by the subtropical inversion layer (linked to trade winds). The study data set includes particle size distribution, measured with a Scanning Mobility Particle Sizer (10 – 500 nm), reactive gases (NOx, SO_2, O_3 and CO), meteorological parameters and radiation. The objective of this study is to identify the context in which New Particle Formation (NPF) events occur.

Ultrafine particle (<100 nm) concentrations showed a strong diurnal evolution, with a maximum during daylight. This evolution was prompted by the development of buoyant slope winds, which also resulted in increases in the concentrations of water vapour, reactive gases and nanoparticles (3 – 10 nm; Rodríguez et al., 2009). We observe that, in most of cases, the increases in the ultrafine particles were associated with burst in the nucleation mode particles (< 20 nm). In many cases these burst were followed by a subsequent particle growth up to diameters within the range 50 – 100 nm, resulting in New Particle Formation (i.e. banana type, Fig.1).

These NFP episodes were observed with any wind direction, being also associated with the arrival of polluted air from below due to the action of upslope winds. The frequency of NPF events showed a significant variability, within the range 2 - 14 events / year. The events are more frequent in summer. Growth rates of nucleation particles (diameter < 25 nm; Dal Maso et al., 2005) typically exhibits values within the range 1 - 5 $nm \cdot h^{-1}$. The frequency of NPF events, as well as the growth and formation rates is somewhat lower than those observed in the polluted continental boundary layer (Kulmala et al., 2004). This is attribute to the much lower concentrations of gas phase precursors in this free troposphere site (e.g. SO_2 concentrations are ~ tends to hundreds of ppt during daylight).

A day-to-day event classification was performed. Different subgroups were segregated, and the parameters that may influence on the NPF formation were studied.

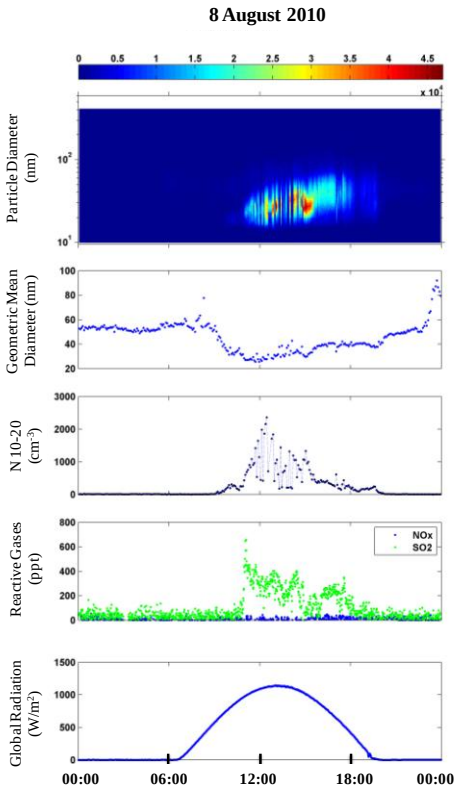

Figure 1. NPF and its comparison with atmospheric parameters

Atmospheric aerosol particles – the majority of them are formed in the atmosphere – have great importance in the environment. The ubiquitous secondary particles are produced from different precursor gases, they can be found in urban, background and remote air. The investigation of different processes leading to new particle formation is of great importance, since these particles play a key role in important atmospheric processes like in the formation of cloud and precipitation, in the control of shortwave radiation balance or in climate control.

It is well known that the physical characteristics of the atmosphere (meteorological parameters) also affect the occurrence of new particle formation (NPF) events; for this reason in this work this relationship is studied. The relationship between NPF and meteorological parameters such as temperature, wind speed and direction, relative humidity, precipitation, global radiation is presented. Besides, trajectory analysis (source regions, change of meteorological parameters (mixing height, precipitation, global radiation) is also involved in the evaluation. The backward air trajectories are calculated by Hysplit Trajectory Model (Draxler and Rolph, 2012; Rolph, 2012).

In this work we summarize our results on the influence of meteorological parameters on new particle formation at K-puszta, Hungary. Between November 2008 and November 2009 105 NPF events were classified (Yli-Juuti *et al.*, 2009): in winter 13, in spring 31, in summer 24 and in autumn (4 months) 37 NPF events were observed.

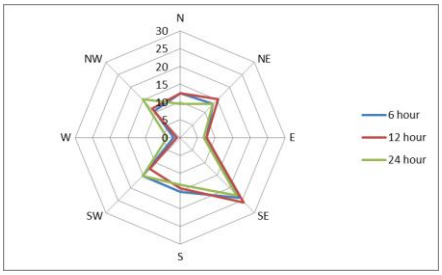

Figure 1. Direction of backward trajectories during NPF events (November 2008-November 2009), K-puszta.

The preliminary results of backward trajectory analysis are presented in *Fig. 1*. In the figure the frequency of NPF events as a function of 6, 12 and 24 hour backward trajectory directions is presented. One can see that from Nov. 2008 and Nov 2009 the contribution of southern trajectory directions was rather important. This contribution was the most definite in winter and autumn, while in summer NPF events are mainly occurred in northern air masses (*Table 1*).

Table 1: Summary of the seasonal occurrence of NPF events as a function of the direction of air trajectories.

		6 hour	12 hour	24 hour
Spring	Northern	29	39	42
	Southern	52	48	48
Summer	Northern	54	54	54
	Southern	38	38	38
Autumn	Northern	35	35	30
	Southern	59	57	57
Winter	Northern	23	23	23
	Southern	77	77	69

Presenting author email: olivier.connan@irsn.fr

A Natura 2000 protected wetland (Marais Vernier) located in the Seine estuary (West of France) was equipped with instruments in September 2010 to study dry and wet fluxes of pollutants on an annual scale. This site is located away from any nearby anthropic sources (the nearest road is 500 m away) and can be representative of medium and large scale atmospheric transport, with the possible very occasional influence of major industrial sites (oil refinery) during brief meteorological episodes. The IRSN (Institute for Radiological Protection and Nuclear Safety), studied the radiological and chemical pollutants (^{7}Be, PAH, PCB, and trace metals) in aerosols and rainwater on one year to obtain the dry and wet deposition fluxes separately. The dry deposition pollutants was quantified by combining chemical measurements performed in atmospheric aerosols with an eddy covariance technique, allowing deposition velocities to be obtained by turbulent correlation between fluctuation of vertical wind and airborne particles number. Eddy covariance allows to obtain a deposition velocity for aerosol (V_d in $m{\cdot}s^{-1}$), which will give the deposition flux for any atmospheric pollutants if concentrations are known.

The first objective of this study was to obtain the fluxes of chemical constituents over the wetland and to assess the atmospheric transfer of pollutants into the area considered. Particular attention was devoted in this study to accurately separating dry deposition from wet deposition; in fact, a better understanding of the dry deposition velocity parameter V_d and its dependence on meteorology (atmospheric turbulence, roughness length u*, and sensible heat flux H) is a major issue for the IRSN and scientific community (Fowler *et al*, 2009), in order to have available relevant data for better parameterization of dispersion and deposition models in the event of a radiological accident.

The second objective was to be able to establish relations between V_d, roughness length u* and sensible heat flux H in a sizeable data set. Being able to assess the relative importance of wet (rain) and dry deposition over a year also contributes to improve understanding transfer in case of radiological accident especially at large scale.

For this study, the site was equipped with an opening collector for rain (Eigenbrodt UNS 130/E), a partisol (FRM2000) for collecting trace metals Cd, Pb, Ni, Zn, and Hg, a partisol (FRM2000) equipped with a ChemComb cartridge to collect gaseous and particulate PAH and PCB, a particle counter (TSI 3010, 0.01 - 3 µm) and a sonic anemometer (YOUNG 81000V). Samples for chemical analysis were taken monthly to get integrated fluxes. For particles number, we used Particle Size Selector for measured particles above 0.1 µm (and then to be able to correlate dry deposition velocity with the atmospheric aerosol size).

The dry deposition velocities V_d measured over a year by eddy covariance have led to the establishment of reliable laws as a function of the meteorological parameters H (for H < and > 50 $W.m^{-2}$) and u* (Figure 1) thus allowing dry deposition fluxes to be recalculated precisely on a monthly scale. Dry velocity deposition from these rural area varying from 2.3 to 4.7 10^{-4} $m.s^{-1}$, which is lower than values commonly used in operational models (5 10^{-3} $m.s^{-1}$).

From Vd calculated precisely, we have estimated the dry fluxes of the chemical constituents PAH, PCB and metals.

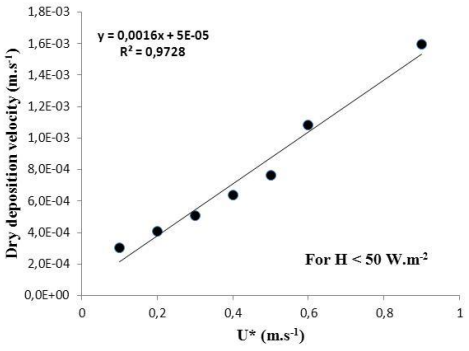

Figure 1. Dry deposition velocities Vd function of friction velocities U*, for H<50 $W.m^{-2}$.

Results from this study show HAP fluxes close to 44 $\mu g.m^{-2}.year^{-1}$, metal traces fluxes are 0.1-115 $\mu g.m^{-2}.year^{-1}$ depending of the element and PCBs indicate fluxes close to 10 $\mu g.m^{-2}.year^{-1}$.

This work allowed to use the eddy covariance over a long period to improve knowledge on Vd in function of micrometeorological, to clarify fluxes of pollutants on a rural particular site, to have a better understanding of the respective contribution of dry and wet deposition.

In the case of an accidental or chronic atmospheric pollution by a nuclear plant, aerosols' deposition transfer coefficients must be known. A major issue is to determine the impact of aerosols contained in the radioactive plume on urban areas with the smallest uncertainties. In this case, local deposition must be known in urban canopy. In dry atmospheric conditions, transfer coefficients are defined by the dry deposition velocity V_d (m s^{-1}), the ratio between the aerosol dry deposition flux (particles m^{-2} s^{-1}) and the aerosol concentration (particles m^{-3}). Dry deposition depends on aerosol diameter, atmospheric turbulent conditions and deposit surface. Actually, only few dry deposition velocities were measured on urban surfaces and existing data are not linked to atmospheric conditions (Fowler *et al*, 2009). Thus, it is important to measure dry deposition velocities, associated with turbulence and local meteorological conditions to improve the knowledge and the models predictions for urban areas. In this study, a new three-step experimental methodology has been set up to approach the complexity of the urban canopy. The first step consists in a wind tunnel study and the second and third steps in *in situ* experiments with different time scales. This methodology allows to measure deposition velocities associated with turbulence and meteorological conditions, and to carry out a phenomenological study of dry deposition on urban surfaces.

Experiments are based on submicron aerosol's tracer deposition measurements: fluorescein submicron aerosol (d_p = 0.27 µm) and beryllium 7 (atmospheric aerosol, *dp* = 0.5 to 1.2 µm (Ioannidou, 2011)). The wind tunnel study was aimed at quantifying fluorescein aerosol dry deposition velocities and turbulence conditions for three urban surfaces (Roupsard *et al.*, 2011). Deposition on horizontal and vertical surfaces and thermophoresis effect by warmed horizontal surfaces were studied in the wind tunnel. The second step consists in short-time *in situ* experiments. Developed by Maro *et al.* (2010), these experiments were performed to measure fluorescein aerosol dry deposition on seven urban surface types in real urban turbulence conditions. Fluorescein aerosol was generated during 1 hour. Meteorological conditions were measured with a meteorological station and wind velocity with an ultrasonic anemometer near sampling surfaces. Surfaces' temperatures were measured to study thermophoresis effect on deposition in real conditions. Finally, submicron atmospheric aerosol's deposition under local meteorological conditions was measured on the seven surfaces by using beryllium 7 as a tracer of the accumulation mode (Maro *et al.*, 2010). This third step, named long-time *in situ* experiments, was carried out on a one year long period. Urban sampling surfaces are exposed to the atmospheric aerosol during one month and protected from precipitations. During this period, local meteorological conditions are measured by an ultrasonic anemometer and a meteorological station. Wind tunnel results are compared to short-time *in situ* results and short-time results are compared to long-time *in situ* results. With this method, physical parameters playing a role in aerosol dry deposition on urban surfaces are met, displayed and quantified. Furthermore, acute (wind tunnel and short-time *in situ* experiments) and chronic (long-time *in situ* experiments) pollution deposition conditions are met and studied.

First results give different values for V_d on same surfaces depending on experiment step (wind tunnel, *in situ* short- or long-time), with smaller values for the first and the second steps and larger values for the third step. Dependence of V_d on friction velocity and temperature gradient at the surface are quantified with few uncertainties in wind tunnel. For this range of diameter, interception and impaction prevail in isotherm conditions. Thermophoresis force is added in case of existing temperature gradient. Short-time *in situ* experiments give similar results than wind tunnel experiments. For glass surfaces, both dry deposition velocities are in good agreement with the Lai and Nazaroff model (2000), built for smooth surfaces without thermophoresis. Long-time *in situ* V_d are much larger than wind tunnel and short-time *in situ* V_d by a factor of 3 to 5. Several hypotheses will be tested to explain this difference, in particular atmospheric aerosol diameter variations with time due to condensation.

First in situ measurements of atmospheric particle dry deposition velocity by eddy-correlation method using the the new 0.1 s time-response Pegasor Particle Sensor

P. Laguionie, D. Maro, D. Hébert and F. Sanson

Institute for Radiological Protection and Nuclear Safety, Cherbourg-Octeville, 50130, France
Keywords: atmospheric particle, dry deposition, eddy-correlation, time-response.

During a nuclear accident, a radioactive aerosol, a gas and particles mixture, can be released into the atmosphere. Over short spatial ranges, *i.e.* distances less than about 10 km from the accident location, radioactive aerosol and atmospheric aerosol differ in terms of physicochemical properties. Beyond these short ranges, both aerosol particle granulometric spectra are undistinguishable. As a result, parameters constraining atmospheric particle deposition processes can be input into operational models to estimate surface radioactive contamination.

After release into the atmosphere, radionuclides scatter, then deposit on both natural (*e.g.* meadows, fresh water areas) and anthropogenic (*e.g.* building fronts, bituminous coating) surfaces. Radionuclide deposition can occur during either rain/snow falls or dry spells giving respectively wet or dry deposits. Wet deposition leads to high surface albeit short-duration radionuclide concentrations. By contrast, dry deposition lead to lower but persistent concentrations and so become dominant in mass balance over time. In this work, only dry-deposition has been considered. Currently, atmospheric particle dry-deposition velocity estimates encompass several orders of magnitude (Fowler *et al.*, 2009). Such a range is hardly explainable due to the lack of experimental micrometeorology data, especially regarding turbulences that drive particle deposition.

Currently, among the plethora of available estimation methods, only one directly estimates atmospheric particle deposition velocities in relation to turbulent processes occurring near surfaces: the eddy-correlation method. The latter accounts for turbulence created on a surface upstream from the measurement point (footprint concept). In practice, this method indirectly gives the dry deposition velocity ($m.s^{-1}$) by dividing the dry deposition flux ($particles.m^{-2}.s^{-1}$) by the measured particle concentration in the air ($particles.m^{-3}$). And the dry deposition flux is the outcome of the covariance between wind vertical velocity and atmospheric particle concentration. But, this method has hardly been carried out in situ because of measurement device technologic limitations. Indeed, the closer the measurement from the surface, the smaller the atmospheric eddy size and so, the shorter sampler device time-response to signal variations. In highly heterogeneous environments, measurements have to be done close to surfaces (less than 1 m) in order to discriminate particle deposition velocities with each surface. Being at less than one meter, a 10 Hz measurement frequency is necessary to characterise the whole atmospheric turbulence spectrum and concentration variations. Consequently it also requires measurement devices with time-response inferior or equal to 0.1 s.

So far, wind velocity has been measured using an ultrasonic anemometer (UA, 0.1 s time-response) and atmospheric particle concentration using an Electrical Low-Pressure Impactor (ELPI, 0.4 s time-response). ELPI advantage is to measure particle concentration for each granulometric class so that deposition velocity is a function of mean particle diameters. However ELPI time response is long, which precludes measurement at less than around 5 m above a surface as turbulence size is too small below 5 m (Damay *et al.*, 2009). In turn, a 5 m height cannot discriminate among several small surfaces and so measurements can only be done upstream of large (> 1000s m^2) homogeneous surfaces where air flow is stabilised. In addition, ELPI long time-response prevents from measuring in aerodynamic conditions shifting spectra towards high frequencies such as high wind speeds conditions (> 2 $m.s^{-1}$) or high atmospheric stability conditions (Horst, 1997).

Now, thanks to recent technologic breakthroughs, particle counter time-responses decrease. In particular, the Pegasor Particle Sensor (PPS) of Pegasor Oy (Ltd) can not only measure concentration with granulometric threshold sorting but also respond in 0.1 s. Consequently, for the first time, conjoint use of UA and PPS allows conducting in situ dry-deposition velocity determination method regardless of aerodynamic conditions and environmental heterogeneity.

This presentation is focused on dry-deposition velocity estimation results by eddy-correlation method conjointly using AU-PPS. Firstly, the conjoint use of AU-PPS is validated by comparing data obtained with AU-ELPI for measurements done at 5 m above a meadow with wind speeds less than $2m.s^{-1}$. Secondly, AU-PPA is used to estimate dry-deposition velocities at less than 5 m above a surface with non-constrained wind speeds. From then on, in situ dry-deposition velocity determination method by eddy-correlation can be generalised to highly heterogeneous environments and/or atmospheric conditions favouring small-scale eddies.

Turbulent aerosol fluxes in a forest clearing measured with a fast mixing-type CPC

F. Kittler[1], F. Ditas[2], B. Wehner[2] and A. Held[1]

Turbulent surface-atmosphere exchange of aerosol particles is a key control of the variability of the aerosol number concentration in the atmospheric boundary layer. A variety of micrometeorological techniques is available to quantify turbulent aerosol fluxes, e.g. eddy covariance or relaxed eddy accumulation. For eddy covariance flux measurements, fast sensors with a time resolution of 10 Hz or better are required. However, technical limitations of current aerosol instrumentation, in particular with respect to time resolution, constrain the application of direct eddy covariance for aerosol flux measurements.

Recently, a new fast mixing-type condensation particle counter (FCPC) with a time resolution of 20 Hz (Wehner et al., 2011a) has been applied successfully in the marine boundary layer near Barbados from the helicopter-borne platform ACTOS (Wehner et al., 2011b). Here, we present results of ground-based eddy covariance measurements using the new FCPC and a standard TSI CPC 3772 at the forest ecosystem research site "Waldstein" in the Fichtelgebirge mountains in south-east Germany in August 2011.

Wind and aerosol data were collected with a time resolution of 20 Hz. The particle inlet was co-located with a CSAT3 sonic anemometer at 2.5 m and 5.5 m above ground level in a forest clearing. The signal response to a change in particle number is not only due to the time constant of the particle counter, but also due to signal dampening in the sampling line. Fig. 1 shows typical response curves of the FCPC and the CPC 3772 (both sampling from the same inlet in the field) to a sudden change in particle number. With the sampling configuration used in this field experiment, evidently the FCPC adjusts to new particle concentrations within 0.2 s, whereas the CPC 3772 adjusts within ~2 s.

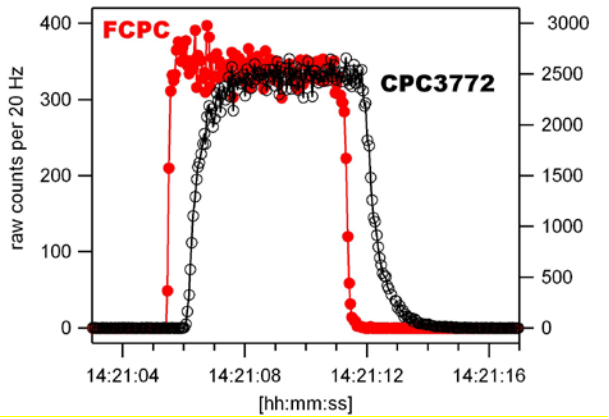

Figure 1: Response curves to step changes in particle number. Time steps from symbol to symbol are 0.05 s.

The fast response of the FCPC allows for a direct evaluation of the high-frequency contributions to the turbulent aerosol flux. So far, due to the lack of sufficiently fast sensors, this part of the frequency spectrum has been neglected, or corrected assuming spectral similarity of particle number and other atmospheric scalars. Now, the FCPC measurements can be directly evaluated at high frequencies with respect to spectral similarity with other atmospheric scalars.

We will present eddy covariance aerosol fluxes including directly measured high frequency contributions to the turbulent flux. The magnitude of these contributions will be assessed under various atmospheric conditions, and the applicability of spectral similarity with other atmospheric scalars will be evaluated. Our results will give additional insight into the process of turbulent aerosol transport, and challenge, or support, the current practice of eddy covariance aerosol flux measurement corrections.

Highly size resolved particle fluxes: Results from biannual measurements using OPCs in an urban environment.

M.J. Deventer, O. Klemm and F.Grießbaum[1, 2]

[1]Climatology Working Group, University of Münster, Münster, 48149, Germany
[2]now at LI-COR Biosciences GmbH, Bad Homburg Germany
Keywords: fluxes, turbulence, optical particle counter, size-segregated aerosols
julian.deventer@uni-muenster.de

From Feb. 2012 onwards turbulent exchange of particles between the urban surface and the urban boundary-layer is measured above the city area of Münster (NW Germany). The scope of the study is to investigate and quantify the contributions of particles of various size classes to total urban particle fluxes and to study their seasonal variability.

According to the present knowledge, cities are both sources and sinks for atmospheric aerosol particles. The input of particulate material from the regional background is mostly established through aged accumulation range particles and can constitute a major fraction of the urban PM levels. On the other hand, emission mainly originates from combustion processes, yielding large numbers of nano-sized particles, and from re-suspension of coarse particles from the urban surfaces.

Results from preliminary studies support the following assumptions: Source apportionment analysis at urban street level sites in Münster (Gietl and Klemm, 2009) suggests that a considerable portion of the urban particle masss originates from distant sources. A first size-segregated flux approach, using an electrical low-preassure impactor (ELPI) and the disjunct eddy covariance (EC) technique, showed that emission of ultrafine particles may co-occur with deposition of particles in the micrometer range. This is equivalent to the simultaneous occurrence of positive (upward) number fluxes and negative (downward) mass fluxes (Schmidt and Klemm, 2008). A more recent study (Deventer *et al.*, 2011) validated these results with the employment of an optical particle counter (OPC) in direct EC. A tipping point between upward and downward oriented particle fluxes was found to be at 168 ± 20 nm (fig. 1). The authors showed that EC in combination with a fast OPC is an appropriate tool to study these bi-directional fluxes for multiple size classes.

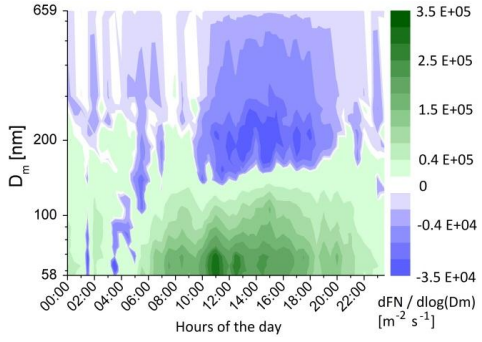

Figure 1. Contour plot of mean daily number fluxes (normalized) for all UHSAS channels. Log. Y-axis.

For this campaign, we expand the previous setup (consisting of the Ultra-High Sensitivity Aerosol Spectrometer (UHSAS)) with a Passive Cavity Aerosol Spectrometer Probe (PCASP-X2), both manufactured by Droplet Measurement Technologies, Boulder, Colorado (USA), now covering the aerosol particle size range between 0.6 – 10 µm diameters in up to 99 bins. In order to reach acceptable counting statistics and minimize random errors, we combine the initial 99 bins into 19 wider size bins. Despite this reduction of size information, the measurement yields a considerable improvement in comparison to that in previous studies. Furthermore, we will install an 11-stage electrical low pressure impactor (Outdoor ELPI, Dekati Ltd., 33700 Tampere, Finland) to collect hourly particle samples, which will be analysed with a TOF-MS in the lab. The eddy-covariance setup is placed on a 62 m above ground level (a.g.l.) high radio tower located in a military compound, southeast to the city center. For a more detailed site description see Schmidt and Klemm (2008), Griessbaum and Schmidt (2009) and Dahlkoetter *et al.* (2010).

The presentation will show results from biannual flux measurements resolved in 19 size classes for the PM_{10} range. Collected particles from the impactor stages will be used to calculate size resolved mass fluxes for numerous poly-aromatic hydrocarbons (PAHs). Furthermore, we will concentrate on the influence of atmospheric stability on fluxes as well as on the influence of varying weather conditions, wind directions, and seasons. Lastly we will locate the tipping point between upwards and downwards fluxes more precisely.

Direct numerical simulation of aerosol growth processes in a turbulent mixing layer

Antonio Attili, Kun Zhou and Fabrizio Bisetti
King Abdullah University of Science and Technology
Keywords: turbulence, numerical simulation.
Presenting author email: antonio.attili@kaust.edu.sa

The complex interaction between turbulent mixing and aerosol growth processes is investigated in a canonical turbulent flow configuration by means of direct numerical simulation. A cold gaseous stream mixes with a hot stream of vapor in a developing mixing layer. Nanometer sized droplets nucleate at the turbulent interface and subsequently grow as more vapor condenses on their surface. As the droplet number density increases, coagulation processes become important. The simulation results show that the mean aerosol number density reaches a maximum on the lean vapor side across the mixing layer, while the average droplet diameter peaks on the rich vapor side, where growth is more intense. It is also found that the size distribution function of the droplets exhibits self-similarity along the streamwise direction.

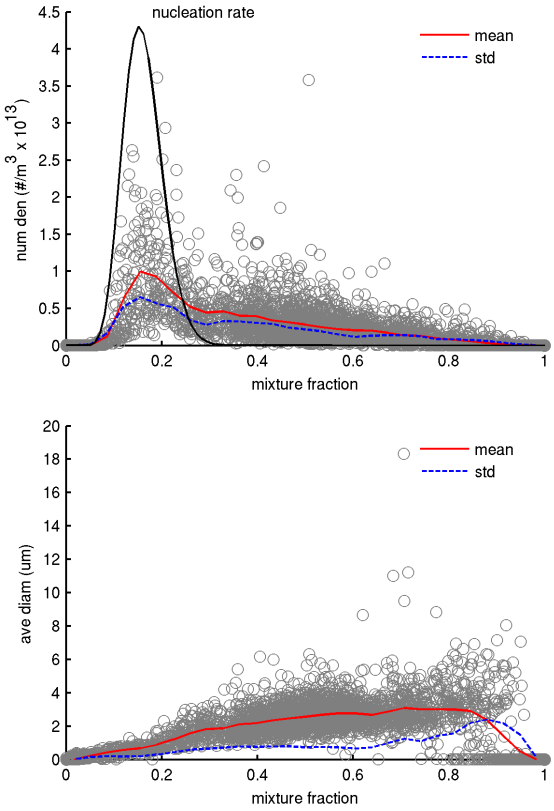

Figure 1: Scatter plots of number density and average diameter of condensing droplets in a turbulent mixing layer.

Motivation, scope, and methods

Nucleation, condensation and coagulation processes are typical of aerosols in a variety of fields, such as powder technology, cloud formation, and soot evolution. Turbulence greatly affects aerosol dynamics (Lesniewski and Friedlander, 1998; Bisetti et al., 2012). Yet, there exists little quantitative understanding about the complex interaction between turbulence and aerosols. This work investigates the evolution of a condensing aerosol in a turbulent mixing layer. The approach combines a Direct Numerical Simulation (DNS) for the flow field, the Quadrature Method of Moments (QMOM) for the statistical description of the aerosol (McGraw, 1997), and a Lagrangian particles method for the treatment of aerosol spatial transport (Koumoutsakos, 2005).

Differential transport of particles

The DNS data indicates that while particles are nucleated on the lean vapor side of the shear layer, droplets grow mostly on the rich side. The transport of particles from the lean to the rich side of the mixing layer is due to the high Schmidt Number flow typical of aerosols. Figure 1 illustrates the effects of differential transport on aerosol growth patterns. In this work, a detailed analysis of the differential transport of droplets across the layer is provided via Lagrangian and Eulerian statistics.

Aerosol particles are ubiquitous in the atmosphere and they influence the quality of life on Earth in many ways; for example through air pollution, reduced visibility, climate modulation, material and ecosystem damage, and adverse health effects. In urbanized areas road traffic has been identified as the main aerosol source, especially for ultra-fine particles, which are either directly emitted or formed in secondary reactions from exhaust gases (e.g. Järvi et al., 2009).

Important quantitative information on particle sources can be obtained using micrometeorological methods such as eddy correlation however there are few direct emission measurements in cities to date (e.g Dorsey et al., 2002; Mårtensson et al., 2006, Järvi et al., 2010; Vogt et al., 2011). In this study we present direct measurements of ultrafine particle fluxes in combination with CO_2 in two North-European cities (Helsinki, Stockholm) in order to investigate similarities or differences in the processes governing these emissions.

Given that these two cities have comparable climate, living standards (e.g. the number of cars per household), and public transport systems and that emissions of both aerosols and CO_2 due to combustion of fossil fuels for cooking and heating are relatively small in both cities, comparison should provide valuable insight in to why emissions may differ (i.e. difference in engine type, fuel type etc.)

Ultrafine aerosol number fluxes were measured using the eddy covariance method from a 105 meter high communication tower over the city Stockholm, Sweden (Vogt et al., 2011) and from a 31m tall triangular lattice tower situated on a hill around 5 km north-east of Helsinki city centre (Järvi et al., 2009). Based on simultaneous measurements of the flux of CO_2, we have estimated emission factors in relation to vehicle fuel consumption, where the CO_2 emissions act as a proxy for the fuel consumption. If fleet composition and other factors are similar, this can be extrapolated to other cities since fuel statistics and/or CO_2 emission inventories are usually available. Figure 1 shows the total aerosol flux versus CO_2 flux and the resulting mean slope is $11.1*10^9$ particles/mmol CO_2 for Stockholm and $38.2*10^9$ particles/mmol CO_2. If we assume the mean fuel consumption and consider the vehicle fleet mix in Stockholm and Helsinki (mainly gasoline vehicles) we obtain an emission factor for ultrafine particles in Stockholm of $5.95*10^{13}$ particles veh^{-1} km^{-1} and Helsinki of $2.05*10^{14}$ particles veh^{-1} km^{-1}. These value is similar to the value ($4.6*10^{14}$ particles veh^{-1} km^{-1}) based on road tunnel measurements in Stockholm by Kristensson et al., (2004) and the value obtained in a street canyon ($2.86*10^{14}$ particles veh^{-1} km^{-1}) by Ketzel et al 2003. Further work will examine different possible explanations to the difference in emission factor between Stockholm and Helsinki.

Analytical solution on the minimum scavenging efficiency particle size for below-cloud scavenging process using the harmonic mean method

Presenting author email: sooyabae@gmail.com

Removal of particle by precipitation is one of the most efficient particle sinks in the air. The scavenging process is largely divided into in-cloud and below-cloud processes (Bae *et al* 2006; 2010). Although the scavenging coefficient for in-cloud scavenging is larger than that for below-cloud scavenging, the latter is important for the removal of coarse and very fine particles from the boundary layer (Andronache, 2003).

Many previous studies showed the parameterization for important factors determining the efficiency of particle scavenging for the below-cloud scavenging process (Mircea *et al* (2000); Bae *et al* (2006); Croft *et al* (2009)).

One of the most important practical problems in scavenging studies is scavenging studies is determining the minimum scavenging efficiency particle size (most penetrating particle size), as well as the corresponding minimum efficiency. There is a particle size region where two or more mechanisms operate simultaneously and yet no one mechanism predominates. At the region, the penetration of particles through the collector is maximized and the collection efficiency is minimized. For this reason, the prediction of the most penetrating particle size in the scavenging gap is crucially important (Jung and Lee, 2006).

Jung *et al* (2011) calculated an approximated analytical solution for the scavenging gap for below-cloud scavenging process applied harmonic mean type approximation. They neglected the inertial impaction and consider only diffusion and interception in estimating most penetrating particle size.

For $0.01 < dp < 1$ μm, thermophoretic force increase about 0.5 order with the increase of particle diameter as shown in Pruppacher and Klett (1997). Andronache (2004) showed diffusion and electric charge mainly affected below-cloud wet removal for particles of $dp < 0.1$ μm. The below-cloud scavenging coefficients increase by almost one order of magnitude when the average charge on raindrops and particles exists, especially for particles of $0.01 < dp < 1$ μm. Bae *et al* (2009) showed relative contributions of thermophoresis and diffusiophoresis in the ambient condition.

Therefore it may need to include thermophoresis, diffusiophoresis, electrical effect and different expressions for inertial impaction may result different tendency (Jung and Lee, 2007).

In this study, we obtain an approximated solution of scavenging gap for the collection efficiency and scavenging coefficient adding thermophoresis, diffusiophoresis, and electrical forces. We also suggests an approximated analytical solution for the scavenging gap particle size which means the most penetrating particle size, during precipitation with harmonic mean method.

These results showed that the numerical results and approximated analytical solution were in good agreement without much loss of accuracy. The minimum collection efficiency and minimum scavenging coefficient were obtained using the currently suggested approach. The minimum scavenging coefficient diameter is a function of the geometric mean drop diameter, which becomes larger for wide drop size distributions. This study also estimated the minimum collection efficiency and minimum scavenging coefficient using the harmonic mean type approximation. The solution was compared with the numerically calculated results, which showed good agreement. The minimum scavenging coefficient increases with increasing falling velocity and drop geometric standard deviation.

Salty lakes present unique ecological systems. The results obtained in the study of chemical and biological composition of water of such lakes are presented in literature. The estimates of amounts of some chemical compounds getting into the lake from both the gas phase and aerosol are also given; however, the total aerosol emissions from the surface of bitter-salty lakes have not been evaluated previously. The goal of the study is estimation of the amounts of summer aerosol emissions by the surface of bitter-salty inland lakes in the western part of the Altai Territory.

In the summer of 2011, field works were conducted to assess the values of aerosol emissions by bitter-salty lakes of the Altai Territory – Bolshoye Yarovoye and Kuchukskoye Lakes. Lakes' areas are 53 and 181 km^2, respectively. A sampling network was deployed In the vicinity of each lake (1 point at the windward side, and 4 points at the leeward side), and simultaneous sampling was performed in all the points.

A complex for measuring the aerosol concentration and size distribution was situated in the point that was nearest to the lake at the leeward side. The complex included a diffusion aerosol spectrometer, DAS (ICCG RAS), and a photoelectric aerosol counter, Grimm 1.109 (Grimm Aerosol Technik GmbH, Germany).

The collected aerosol samples and brine samples from the lakes were studied for the ionic composition, the presence of total protein, culturable microorganisms and their diversity with the methods described in Safatov *et al* (2010).

The measured concentration values for each substance were used to solve the inverse problem - the flows of this substance from the land surface and water surfaces using a previously developed mathematical model of aerosol spread in the boundary atmospheric layer were calculated. The meteorological data required for the calculations were taken from the web site of the Air Resources Laboratory: http://ready.arl.noaa.gov/HYSPLIT.php.

The following weather conditions were recorded in the process of sampling at Kuchukskoye Lake on July 13, 2011: wind speed of 11 m/s, the angle of 33.7°, air temperature of 19.2°C and overcast of 5 points. At Bolshoye Yarovoye Lake on July 14, 2011 - the angle of 22.5°, wind speed of 5 m/s, air temperatures of 21.5°C and overcast of 5 points. Aerosol mass concentration was estimated by a number size aerosol distribution at an average particle density of 2 g/cm^3. The aerosol concentration and dispersity during the measurements at Bolshoye Yarovoye Lake slightly changed over time with an average of 13.23 ± 4.06 $\mu g/m^3$. The aerosol mass concentration during the measurements at Kuchukskoye Lake was significantly higher (due to wind-blown dust) and considerably decreased by the end of the measurements from approximately 200 - 500 to 6 - 10 $\mu g/m^3$ with an average of 157.1 ± 180.64 $\mu g/m^3$. PM_{10} during this measurement changed over time not so sharp with an average of 27.77 ± 24.26 $\mu g/m^3$.

The results of analyzing the ion composition of aerosol samples show that at the windward side of Kuchukskoye Lake aerosol contained an increased concentration of Na^+, SO_4^{2-} and Cl^- ions, and in the vicinity of Bolshoye Yarovoye Lake that of Na^+ и Cl^-. A typical dependence of concentrations of various substances in aerosol is as follows: at the windward side, an increasing concentration of the substance in the air is observed followed by passing a maximum and a gradual decrease in this concentration to the level determined for the leeward side. This indicates a significant emission of aerosol by the surface of the lakes. The coincidence of the list of the main substances present in the brine from the studied lakes with the composition of aerosol particles at the leeward side suggests that the lake brine is a precursor of aerosol found in the vicinity of Kuchukskoye Lake. For Bolshoye Yarovoye Lake containing lower concentrations of salts than Kuchukskoye Lake, this relationship is expressed to a lesser degree.

The results of mathematical simulation of aerosol emissions by the studied lakes allowed us to determine the power of flows of various substances from the surface of the lakes. Preliminary estimates show that aerosol emission by a unit of water reservoirs surfaces considerably exceeds the emission by a unit of land surface in the region of measurements. Consequently, it is the lakes that mainly contribute to air pollution in the vicinity of these lakes.

Presenting author email: marossi@arpa.emr.it

During the MONITER Project (Incinerator Monitoring in Emilia Romagna Area), the spatial and temporal variation of fine, ultrafine particles and gas phase parameters was assessed for the Bologna (Italy) area. Bologna is located in the south east of Po Valley, which is a well known atmospheric pollution critical area.

This assessment is based on measurements on selected days during different seasons in 2008/2009, covering urban, suburban and rural regions. Special focus was put on the investigation of particles in the fine (< 2.5 μm) and ultrafine (< 100 nm) size ranges, in particular the effect of meteorological parameters on the ultrafine (UFP) number concentration and size distribution was examined. The number concentrations of ambient particles in the size range of 5.6-560 nm were obtained from a Fast Mobility Particle Sizer, FMPS 3091, TSI. Meteorological parameters including ambient temperature, relative humidity, wind speed, wind direction, rainfall, and solar radiation flux, H-mixing were also monitored. The time series analysis reveals the 12 h periodicity of the particle number and significant seasonal and daily variations were observed: the morning peak is related to traffic. Significant differences were also observed in the UPF concentrations in the monitored sites depending on traffic and local conditions. A multilinear regression model of the day average concentration of UFP vs, the average meteorologic parameters was built . The models showed a good regression coefficients (adj-R^2: 0.79−0.89). However, this approach based on average values did not account for real time variations (Aggarwal, S., Jain, R., Marshall J. D. (2012)).

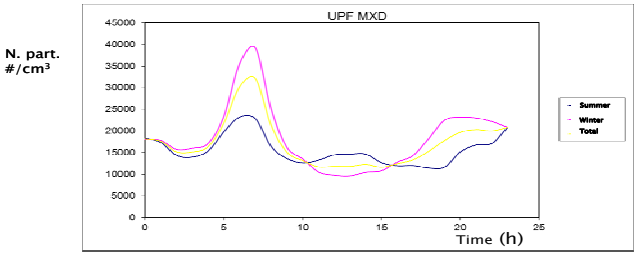

Figure 1. Averaged daily concentration of UFP at one monitored site (MXD): seasonal trend

Consequently, an approach based on cross-correlation functions between the concentration number of UFP and meteorological parameters was developed.

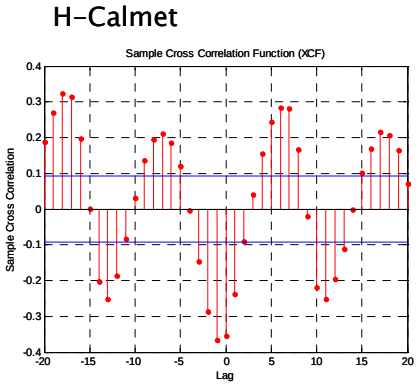

Figure 2: Cross-correlation function of instantanuos UPF concentration and mixing height (H-Calmet)

Analysis indicates that the influence of wind is probably related to stationary sources, which could be one of the contributors to elevated ultrafine particle concentration. Finally a transfer functions model was built, it was able to describe the observed temporal particle concentration. Model performance was evaluated.

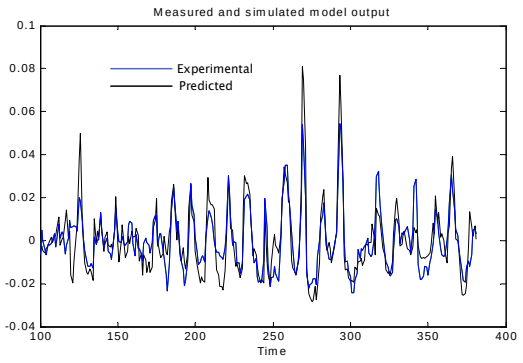

Figure 3. Concentration of UFP at one monitored site (MXD): predicted and experimental data

Attenuation of shock wave from a point blast in a dusty air

A.G. Girin

Odessa National Maritime University, Odessa, 65029, Ukraine
Keywords: aerosol dynamics, dust, aerosol impacts, ambient aerosol.
Presenting author email: club21@ukr.net

The problem of dynamics of shock wave initiated by point blast in a dusty air is solved numerically. Transient internal structure of wave and behavior of dynamic parameters at the wave front are investigated until the distances of hundred dynamic radii. Air is considered as a lean suspension of fine solid particles and equations of motion of two-phase two-velocity, two-temperature continuum are applied. Original three-stage calculation scheme is used, which is based on conservative difference schemes with adaptive grid. The discontinuity of leading shock is fitted and values of jumps of gas phase parameters at the shock are determined. Kinetics of interphase mechanical and thermal relaxation processes in the zone behind the shock are thus calculated with due accuracy. Comparison with known calculations of this problem for the blast in ideal air showed a good agreement.

The investigation shows that in the range of far asymptotics the behavior of blast wave in dusty air differs essentially from that in ideal. Despite small dust concentration, wave profile is transforming gradually under weak, but protracted friction and cooling of a huge amount of fine aerosol particles in the lengthy zone of interphase interaction and in large time interval, while shock propagates at large distances. The effect is most significant at the shock front, so, the jumps of gas-phase parameters bear additional decreasing there, with respect to acoustic in the case of ideal air. Difference of shock attenuation in ideal and heterogeneous air can be seen on fig. 1. Beginning from the length of three dynamic radii R_f, the redundant pressure Δp follows to another regularities in a dusty air, so, at a distances of ten dynamic radii the difference can exceed 60%. ***Blast wave with a front discontinuity disappears at finite distance from its origin and turns into dispersive wave without a shock***. Zone of maximum interphase

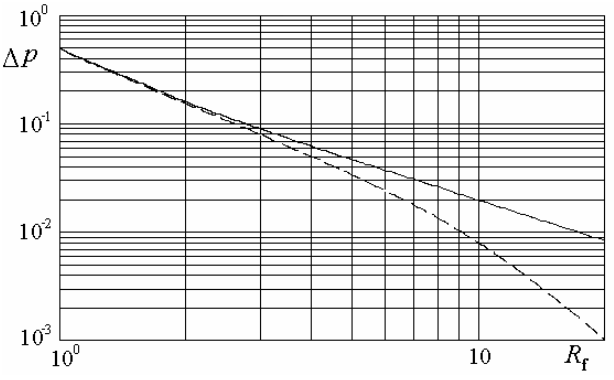

Fig.1. Shock attenuation dynamics as dependences $\Delta p(R_f)$ in ideal (solid) and in dusty (dashed) air.

interactions goes from the front inside wave. As a result, when the heterogeneity of air is taken into account, the ***total impulse of blast wave already cannot be determined by the value of redundant pressure on a distances greater than three dynamic radii***, i.e. over the whole range of far asymptotics.

An additional heterogeneous attenuation of shock wave can be seen on fig. 2, where the dependences $Z(R_f)=\frac{\gamma+1}{2\gamma}\Delta p(R_f)R_f\sqrt{\ln\left(R_f/R^*\right)}$, that were processed as a result of present calculations in accordance with far asymptotics law $\Delta p=\frac{2\gamma}{\gamma+1}\frac{C}{R_f\sqrt{\ln(R_f/R^*)}}$, are given. In ideal air Z must reach the asymptotic value $C\approx 0.270$, when the wave reaches the range of far asymptotics; vise versa, proximity of values Z and C manifests that wave has reached the range. In ideal air (upper curve) this occurs already at $R_f\approx 7\div 8$, which shows that blast wave has come into far asymptotics range. In dusty air (lower curve) blast wave undergoes strong dissipative heterogeneous action over the range $R_f>2$, which additionally diminishes shock amplitude. This curve clearly manifests, that at dust concentrations $\alpha_{d0}>3\cdot 10^{-3}$ ***blast wave never follows far asymptotic law in dusty air***.

If we take into account more strong, with respect to dust action, dissipative effect of rheological viscosity and heat conductivity of real air, the obtained results put doubts as for real blast waves would achieve the known regularities of far asymptotics valid for ideal gas model. The dissipative properties of real air begin to influence namely at early stage of far asymptotics, when the shock wave already has been weakened enough by expansion ($\Delta p<0.1$).

Similar investigation was done for the case of plane shock wave that confirms the conclusions.

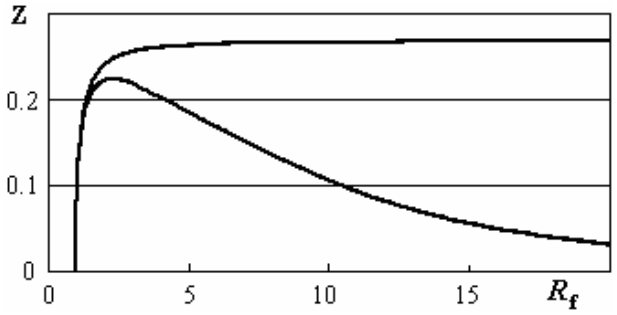

Fig.2. Additional heterogeneous attenuation of shock as dependencies $Z_3(R_f)$; $a_d=4\cdot 10^{-6}m$, $\alpha_{d0}=10^{-2}$.

The Variation of Aerosol Number Concentrations in Relation with 3-D Wind Components in the Ieodo Ocean Research Station

Sung-Hwa Park[1], Sang-Min Jang[2], Dong-In Lee[2*], Woon-Seon Jung[2] and Jong-Hoon Jeong[2]

To investigate variation of aerosol number concentration at each different size with three-dimensional (3D) wind components in ocean area, aerosol particles and 3D wind components were measured in the Ieodo Ocean Research Station, which is located to 419 km southwest from Marado, the southernmost island of Korea, from 25 June to 8 July 2010(Fig. 1).

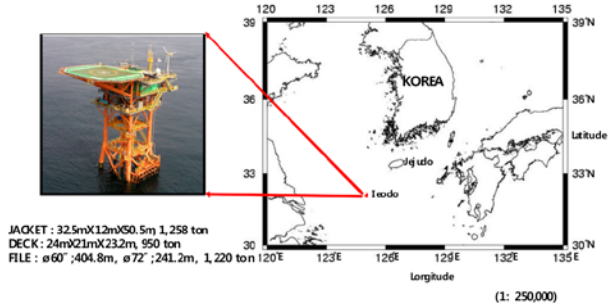

Figure 1. The location of study area.

The Laser Particle Counter (LPC) and ultrasonic anemometer were used to measure the size of aerosol particles and 3D wind components (zonal (u), meridional (v), and vertical (w) wind) respectively. Surface weather chart, NCEP/NCAR reanalysis data and sounding data were used to analyze the synoptic condition.

The distribution of aerosol number concentration had a large variation from bigger particles more than 1.0 ㎛ in diameter by wind direction during precipitation. In the number concentration of aerosol particles with respect to the weather conditions, particles larger than 1.0 ㎛ in size were decreased and sustained to the similar concentration at smaller particles during precipitation (Fig 2.).

The increase in aerosol number concentration was due to the sea-salt particles which was suspended by southwesterly and upward winds. In addition, the aerosol number concentration with vertical wind flow could be related with the occurrence and increasing mechanism of aerosol in marine boundary layer.

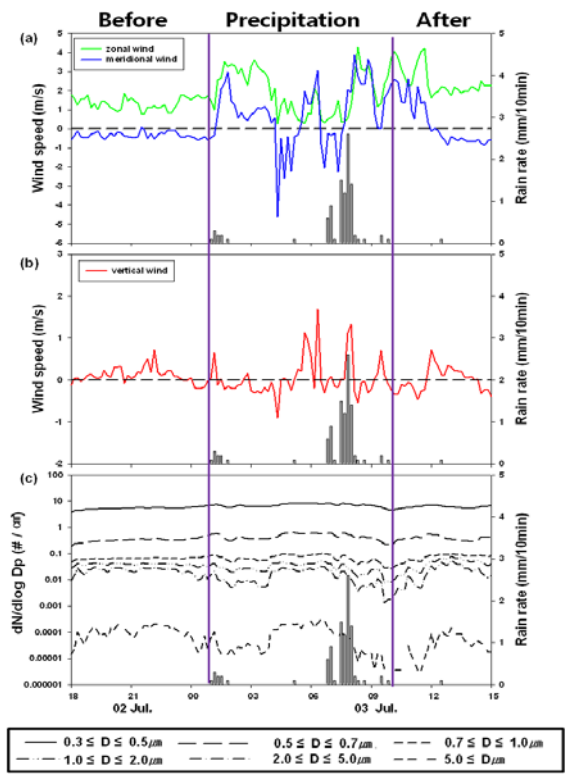

Figure 2. Time variation of (a) zonal and meridional wind speed, (b) vertical wind speed, and (c) the number concentration of aerosol particles at each channel and rain rate from 1800 LST and 1500 LST on 3 July 2010.

Time lag between the tropopause height and ^{7}Be activity concentrations on surface air

A. Ioannidou[1], A. Vasileiadis[1] and D.Melas[2]

[1]Aristotle University of Thessaloniki, Physics Department, Nuclear Physics & Elementary Particle Physics Division, Thessaloniki 54124, Greece.
[2] Aristotle University of Thessaloniki, Physics Department, Applied and Environmental Physics Division, Laboratory of Atmospheric Physics, Thessaloniki 54124, Greece.
Keywords: radioactive aerosols, ^{7}Be, tropopause height, time lag, 11-year solar cycle
Presenting author email: anta@physics.auth.gr, anta@auth.gr

The objective of this study is to define the time-lag between the elevation of tropopause and the concentration of ^{7}Be in near surface air. The concentration of ^{7}Be at surface air has been determined in the region of Thessaloniki, Greece at 40°N, over 52 weekly measurements covering the year 2009, a year of a deep solar minimum and of maximum concentration of ^{7}Be, where any fluctuation due to meteorological and seasonal variations are easily revealed.

Sampling of ^{7}Be aerosols was carried out by Staplex high-volume air sampler with glass-fiber filters, and a regulated airflow rate of 1.7-1.92 m^3 min^{-1} (60-68 ft^3 min^{-1}). The length of each collection period was 24 h. All samples were measured for ^{7}Be activity using an HPGe detector (42% relative efficiency). The tropopause height time series of daily values was obtained from the NCEP/NCAR Reanalysis data (Kalnay et al., 1996).

The positive correlations between the monthly activity concentrations of ^{7}Be and the tropopause height (0.94, $p<0.0001$) and also between ^{7}Be concentrations and the temperature T (°C) ($R=0.97$, $p<0.001$), confirm that the increased rate of vertical transport within the troposphere, has as a result the descent to surface of air masses enriched in ^{7}Be (Ioannidou, 2005; Zanis, 1999). However, the ^{7}Be concentration levels in near surface air are not expected to respond immediately to the change of elevation of the tropopause. The calculation of time lag is the next step in understanding the atmospheric procedures behind the correlation. This step will also reveal information about radioactive aerosols movement in the atmosphere's transfer cycles.

The time lag was found by holding the same column of data for ^{7}Be and calculating the correlation coefficient (R) for each new column of daily data of the tropopause height. The new columns are created by going back in time with a step of one day waiting for the best correlation in order to find how many days we have to wait until the concentration of ^{7}Be responds to the elevation of the tropopause height.

The correlation coefficient (R) between ^{7}Be and the tropopause height was successively calculated for different time lags starting with lag equal to zero (Figure 1). The analysis of the daily data revealed that the time delay between the elevation of tropopause and ^{7}Be concentrations in surface air is about 3days. The most striking feature of the data is the four day plateau (including the day of the measurement and the three previous days) revealing persistence in the state of the atmosphere.

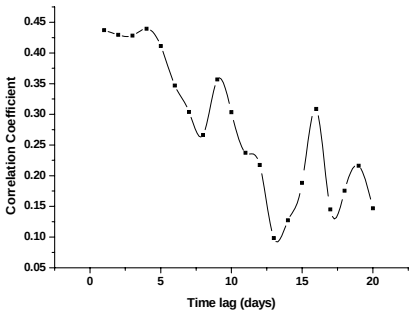

Figure 1. Correlogram between ^{7}Be surface concentration and tropopause height

In order to test our results and confirm that the correlation depends on the successive waves of air masses of a four day period a cumulative index should be calculated (Figure 2).

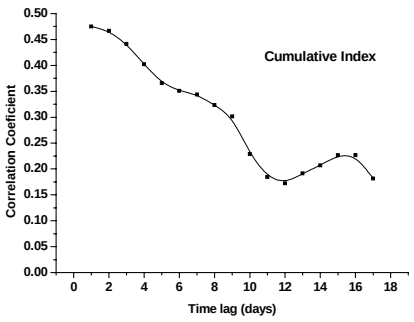

Figure 2. Cumulative index between ^{7}Be surface concentration and tropopause height

The results improved as the correlation coefficient hits a peak in the first calculation at 0.47 and 0.46 in the second one. This indicates that the time lag is 2 to 3 days as the first two calculations refer to the correlation between the ^{7}Be concentrations and 4day average (3 previous days and the day we measured ^{7}Be) measurements of tropopause heights.

Aerosol Measurements Evaluating the Effects of the Red Mud Disaster in Hungary

A. Nagy, A. Czitrovszky, D. Oszetzky and A. Kerekes
Department of Laser Applications, Institute for Solid State Physics and Optics, Wigner Research Centre for Physics, Budapest, 1121, Hungary
Keywords: Red Mud Disaster, air pollution, size distribution
Presenting author email: oszetzky.daniel@wigner.mta.hu

As a result of the Red Mud Disaster in Devecser and Kolontár (Hungary) on October 4, 2010, the aerosol concentration -air pollution- increased at the region derived by the red mud sludge that flooded the area. Samples were collected and aerosol concentration and size distribution measurements were performed with a mobile environmental laboratory at the site right after the catastrophe. The results have been evaluated by different methods such as light scattering, airborne particle counting and sizing, optical- and electron-microscopy, micro Raman- and fluorescence-spectroscopy and EDAX micro analysis. The analysis of the composition, morphology and spectroscopy results show that the red mud dust under certain conditions causes health risk especially because of the high concentration of aerosols.

Figure 1. Image of the red mud spread over villages Kolontár and Devecser.

On October 4, 2010 a breach in the wall of the waste containment reservoir at the Ajka alumina plant in western Hungary sent a caustic flood of "red mud" pouring downhill. The villages of Kolontár and Devecser were caught in the path, and the ensuing deluge of alkaline waste spread over more than 40 square kilometres. Beside the death of 10 persons this disaster produced a considerable contamination of the area. After dehydration the re-suspending red mud dust exceeded the health limit and caused a long term health risk for the inhabitancies. Our aim was to determine the air contamination concentration on site and the physical and chemical parameters of the collected samples.

For the measurements at the site a mobile environmental laboratory was used, which had been developed previously for in situ measurements at different locations. The laboratory is installed in a van, has its own power supply system and is equipped with a wide range of optical particle counters such as the dual wavelength optical particle spectrometer developed by our department. This brode selection of instruments provides a variety of aerosol distribution and concentration measurements in a wide size range.

Both number- and mass distribution were measured at the site in two different measurement series. Mass distribution results are shown in Figure.2.

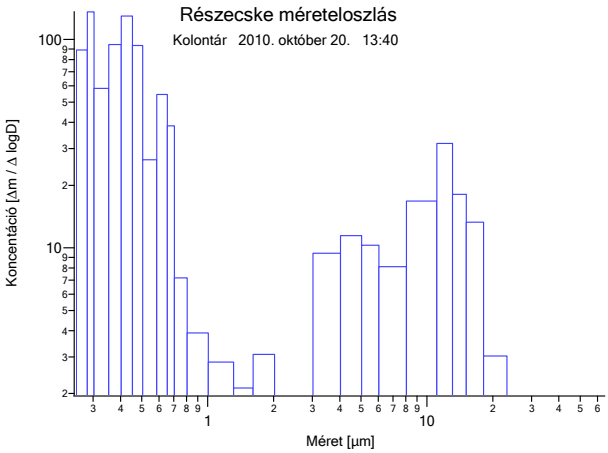

Figure 2. Mass distribution measurements

As we can see in the mass concentration diagram a peak near 10 µm is observable. Taking into account our other measurements at the site this peak is probably connected to the red mud aerosol. This peak is even more significant in measurements inside the mobile laboratory, where the red mud after dehydration was re-suspended and its concentration was high. In both cases the concentration values exceeded the health limit (50µg/m3). Because of the high concentration in indoor environment ventilation and washing is suggested to avoid health risk.

Correlation between measurement results for three-type portable air purifiers: filter, ionizer and wet ones

Bangwoo Han, Hak-Joon Kim and Yong-Jin Kim

Environmental and Energy Systems Research Division, Korea Institute of Machinery and Materials, Daejoen, 305-343, Korea
Keywords: Clean air delivery rate (CADR), Particle collection efficiency, Gas reduction ratio, Ozone, Noise
Presenting author email: bhan@kimm.re.kr

The air purifiers can be classified to filter, ionizer and wet ones depending on their purification mechanism. Filter ones usually removes fine particles and harmful gases by using both fabric particle filters and gas-absorption activated carbon filters. Ionizer ones use a corona discharge to generate air ions and lead to the electrostatic effects on fine particles and harmful gases. Wet ones are water spraying scrubbers which lead to collision of sprayed water droplets with fine particles and gas molecules to collect the particles and absorb gas molecules in the water. Other type ones such as non-thermal plasma or photo catalytic oxidation have been disappeared in the portable air purifier markets probably due to their low performances. The correlation between the performances based on the type of air purifiers has not been understood clearly until now. In this study, the performances such as air flow rate (Q), particle collection efficiency (η), clean air delivery rate (CADR), gas reduction ratio of harmful gases and odors were tested for three-type air purifiers composed of 32 filter, 9 ionizer and 3 wet ones. Noise level and ozone emission were also compared based on the type of the purifiers. Their correlative relationship was then investigated. Filter air purifiers have much higher air flow rates compared to ionizer and wet ones and thus clean air delivery rates (CADRs) of filter air purifiers showed about 30-55 times higher than those of ionizer and wet ones when compared by their averaged values. Significant levels of ozone were emitted from the several ionizer air purifiers. Noises of filter ones were far higher than the other ones due to higher air flow rates. Gas reduction ratio of filter ones were around 50-85 % depending on the gas species. CADR was linearly increased with air flow rate, which indicates that air purifiers having higher air flow rates exhibit higher air purifying performances. Noise level was a little linear relationship with air flow rate and thus noise was slightly increased with air flow rate. Gas reduction ratios were also more than 60% for most filter ones irrespectively of air flow rate. CADR was very linearly correlated (R=0.94) with air flow rate and noise was also somewhat correlated (R=0.66) with the air flow rate. Particle collection efficiency and other gas reduction ratios were little correlated (R <0.35) with the air flow rate. Particle collection efficiency showed a relatively poor linear correlation (R=0.52) with the CADR compared to air flow rate. The product of air flow rate and particle collection efficiency was highly well correlated (R=0.99) with CADR as described in Fig. 1. Short-circuit factor, the ratio between CADR and the product of air flow rate and particle collection efficiency was about 0.85 in our study while it should be 1 for well mixed conditions. Acetic acid was considerably correlated with ammonia (R=0.76) and toluene gases (R=0.75) and somewhat with formaldehyde (R=0.61). Toluene was also somewhat correlated with formaldehyde gas (R=0.68). Acetaldehyde was little correlated with ammonia, formaldehyde and acetic acid (R<0.4). Ammonia was also little correlated with formaldehyde (R<0.4). Acetic acid seems to be the better indication gas for representing gas reduction performance for filter purifiers relatively compared to other gases.

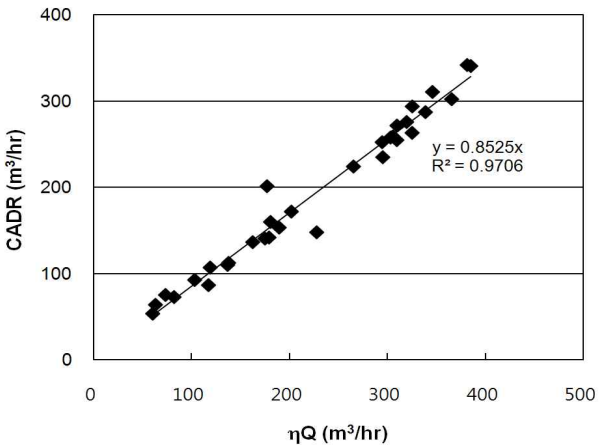

Figure 1. Clean air delivery rate (CADR) with the product of particle collection efficiency, η and air flow rate, Q.

Table 1. Correlation coefficient (R) between reduction ratios of different gases

	Ammonia	Acetaldehyde	Acetic acid	Toluene	Formaldehyde

Drug-resistance and heavy metal tolerance of airborne microbes

O. Nikiforou[1], A. Kikna[1], M. Lazaridis[2], and E. Katsivela[1]

[1]Department of Natural Resources and Environment, Technological Educational Institute of Crete, Romanou 3, P.O. Box 89, 73103 Chania, Crete, Creece
[2]Department of Environmental Engineering, Technical University of Crete, Polytechneioupolis, 73100 Chania, Crete, Greece
Keywords: bioaerosols, bacteria, fungi, Indoor/outdoor particles, heavy metals, antimicrobial
Presenting author email: katsivela@chania.teicrete.gr

The growth and persistence of natural, airborne, viable microbes (heterotrophic bacteria and mesophilic fungi) was studied indoors/outdoors in the presence of drugs (streptomycin or cycloheximide) and heavy metals (mercury or lead).

Air samples were collected using a MAS 100 sampler for the determination of microbial concentrations. Duplicates of samples were collected during each campaign (15 campaigns in total) in a suburban, residential site of the coastal Mediterranean city of Chania (Crete, Greece). The sampling period was from December 2010 to June 2011. The heterotrophic bacteria were grown in Tryptone Soy Agar at 37^{o}C for 48 h, whereas the mesophilic fungi were cultivated in Malt Extract Agar at 20^{o}C for 72 h. The microbial resistance to heavy metal toxicity was studied using, separately, lead chloride or mercury chloride in concentrations varying from 200 to 1,500 μM and from 5 to 20 μM per growth medium, respectively. On the other hand, antibiotic and fungicide resistance was studied using, separately, Streptomycin or Cycloheximide in concentrations from 5 to 20 μg per mL growth medium. Respirable PM_{10} mass concentration and meteorological conditions were determined using portable monitors. The mean values of the ambient meteorological conditions during the measurement period were as follows: Temperature: 20.8 ± 5.3 ^{o}C; relative humidity: 49.7 ± 6.9 %; local wind speed: 0.25 ± 0.24 m/s; PM_{10}: 61 ± 33 μg/m^3. In parallel, the mean values of the meteorological conditions indoors (library; 384 m^3) were as follows: Temperature: 21.9 ± 1.8 ^{o}C; relative humidity: 50.9 ± 4.1 %; local wind speed: 0.04 ± 0.06 m/s; PM_{10}: 47 ± 23 μg/m^3.

Differences between heterotrophic bacteria and fungi were observed in relation to their abundance indoors/outdoors, heavy metal tolerance and drug resistance. Although, heterotrophic bacteria (433 ± 65 CFU/m^3) were more abundant than fungi (210 ± 212 CFU/m^3) indoors, airborne fungi showed significant higher concentrations (352 ± 370 CFU/m^3) than the airborne heterotrophic bacteria (106 ± 93 CFU/m^3) outdoors. In accordance, a higher heavy metal tolerance was observed for the heterotrophic bacteria indoors, whereas fungi possessed higher heavy metal resistance outdoors (Figures 1 and 2).

The highest heavy metal resistance was measured for lead in both taxonomic groups of microbes. However, heterotrophic bacteria were more tolerant to mercury (bacterial resistance to 20 μM Hg^{+2}: 64% indoors and 28% outdoors) than fungi (50% and 28%, respectively). In contrast, fungi were determined to be more tolerant to lead concentrations (fungal resistance to 1,500 μM Pb^{+2}: 100% indoors and 91% outdoors) in comparison to heterotrophic bacteria (28% and 24%, respectively).

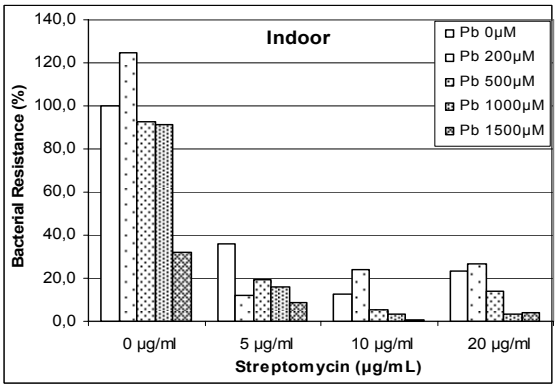

Figure 1: Percentage of viable, airborne heterotrophic bacteria, resistant to Pb^{+2} and Streptomycin indoors.

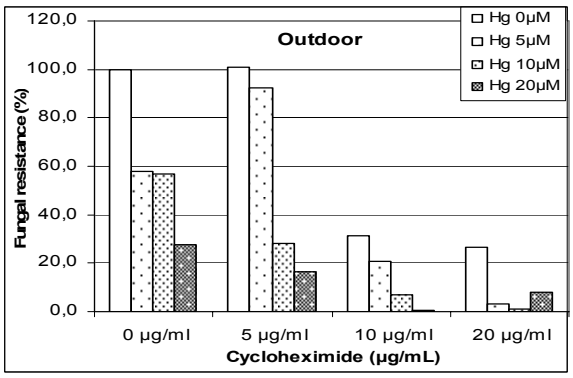

Figure 2: Percentage of viable, airborne mesophilic fungi resistant to Hg^{+2} and Cycloheximide outdoors.

A high percentage of drug and heavy metal tolerance, in the airborne, cultivable microbial community was obtained both indoors and outdoors (Figures 1 and 2). A percentage of 31% indoors and 9% outdoors of the heterotrophic bacteria were resistant, simultaneously, to 20 μM Hg^{+2} and 20 μg/mL Streptomycin. In addition, 18% indoors and 40% outdoors of the mesophilic fungi were resistant, simultaneously, to 20 μM Pb^{+2} and 20 μg/mL Cycloheximide.

Investigation of bioaerosols distribution in greenhouse for orchid growth

Greenhouse provides physical environments suitable for the survival and growth for plants. The high density of biomass, including plant and soil inside the greenhouse is expected cause bioaerosols accumulation and dissemination; result in the distortion of environmental quality. Bioaerosols exposure in greenhouses among workers may lead various respiratory symptoms. (Hansen *et al*., 2012) In Taiwan, Orchid has the high economic value and becomes import commercial export in past decades. The growing process of Orchid depends on greenhouse facility to maintain the best quality. The objective of this study is investigating the bioaerosols distribution in the greenhouses designed for growing orchids.

Two greenhouses were selected as the target facility in the study. Greenhouse 1 was equipped with fan and pad system but different in area. In addition, Greenhouse 2 was fully-enclosed and equipped air conditioner without fresh air-intake. Sampling sites were set based on covering plant growing beds, aisles, near-pad fresh (sampling sites A~J for greenhouse 1) and outdoor (sampling sites K for greenhouse 1) to monitoring the bioaerosols distribution inside the space.

Viable bacteria and fungus were collected with collected in accordance with Taiwan Environmental Analysis Laboratory guideline (NIEA E301.11C). The BioStage single-stage viable cascade impactor (SKC Inc., USA), loaded with tryptic soya agar and melt extract agar were used to collect bioaerosols. The BioSatge impactor was operated at flow rate 28.3 L/minute for 30 seconds to obtain sample. For each sample, three replicates were performed. After incubation, the colonies formed on the plate samples were manually counted and convert to airborne bacterial concentration in CFU/m^3. The temperature and relative humidity was monitored with Q-trak (Model 8550, TSI Inc., USA).

Figure .1 shows the fungal bioaerosols distribution in the greenhouse 1. The concentration of indoor fungal bioaerosols is higher than outdoor can be found. In addition, higher fungal bioaerosols concentration reveal in the afternoon sampling section. It might be due to the increasing of relative humidity and plants irritation. Figure.2 shows the bacterial bioaerosols distribution in the greenhouse 1. No statically significantly difference was found between indoor and outdoor bacterial bioaerosols. The results can be explained by a generally more fungus was presented in the soil materials used for plant growth.

High concentration of fungus bioaerosols presented in the greenhouse indicates that workers' exposure should be further studies. Besides, Personal protecting equipments were also recommended to be used for protecting the respiratory systems of workers.

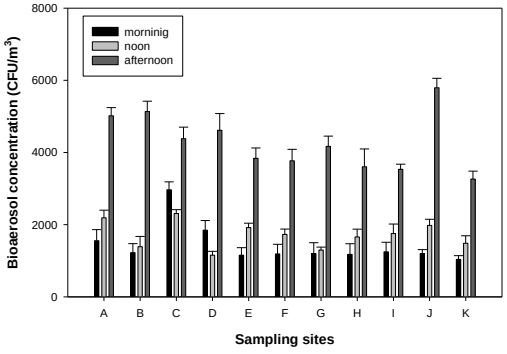

Figure 1. The fungal bioaerosols distribution in greenhouse 1.

Autofluorescence of atmospheric bioaerosols – fluorescent biomolecules, biological standard particles and potential interferences

C. Pöhlker[1], J. A. Huffman[1,2], U. Pöschl[1]

[1]Biogeochemistry Department, Max Planck Institute for Chemistry, Mainz 55020, Germany
[2]Department of Chemistry and Biochemistry, University of Denver, Denver, Colorado 80208, USA
Keywords: Bioaerosols, Fluorescence, Bacteria, Fungal spores, Pollen.
Presenting author email: c.pohlker@mpic.de

Primary biological aerosol particles (PBAP) such as pollen, fungal spores, bacteria, biogenic polymers and debris from larger organisms are known to influence atmospheric chemistry and physics, the biosphere and public health. PBAP account for up to ~30% of fine and up to ~70% of coarse particulate matter in urban, rural and pristine environment and are released with estimated emission rates of up to ~1000 Tg/a (Elbert et al. 2007).

Continuous measurements of the abundance, variability and diversity of PBAP have been difficult until recently, however. The application of on-line instruments able to detect autofluorescence from biological particles in real-time has been a promising development for the measurement of PBAP concentrations and fluxes in different environments (Huffman et al. 2010; Pöschl et al. 2010). The detected fluorescent biological aerosol particles (FBAP) can be regarded as a subset of PBAP, although the exact relationship between PBAP and FBAP is still being investigated.

Autofluorescence of FBAP is usually a superposition of fluorescence from a mixture of individual fluorescent molecules (fluorophores). Numerous biogenic fluorophores such as amino acids (e.g., tryptophan, tyrosine), coenzymes (e.g., NAD(P)H, riboflavin) and biopolymers (e.g., cellulose) emit fluorescent light due to heterocyclic aromatic rings or conjugated double bonds within their molecular structures. The tryptophan emission peak is a common feature of most bioparticles because the amino acid is a constituent of many proteins and peptides. The influence of the coenzymes NAD(P)H and riboflavin on the autofluorescence of bacteria can be regarded as an indicator for bacterial metabolism and has been utilized to discriminate between viable and non-viable organisms (Lakowicz 1999). However, very little information is available about other essential biofluorophores in fungal spores and pollen.

In order to better understand the autofluorescence behavior of FBAP, we have used fluorescence spectroscopy and fluorescence microscopy to analyze standard bioparticles (pollen, fungal spores, and bacteria), atmospherically relevant chemical substances and ambient aerosol samples (Fig. 1). We found varying levels of fluorescent emission and significant differences in the spectral properties of major PBAP classes. The combination will support the quantitative interpretation of data obtained by real-time FBAP instrumentation (Pöhlker et al. 2012).

Fluorescent Biological Aerosol Particle (FBAP) Number Concentrations & Size Distributions Measured by the Waveband Integrated Bioaerosol Sensor (WIBS-4) at Environmental Research Station Schneefernerhaus (UFS)

Emre Toprak[1] and Martin Schnaiter[1]

Institute for Meteorology and Climate Research (IMK-AAF), Karlsruhe Institute of Technology (KIT), Karlsruhe, 76344, Germany
Keywords: Bioaerosols - monitoring, On-line measurements
Presenting author email: emre.toprak@kit.edu

Biological aerosol is one of the most important classes of the atmospheric aerosol. The occurrence and the abundance of the biological particles play a very important role in atmospheric processes. Diehl et al. (2001; 2002) investigated the ice nucleation (IN) ability of different pollens and found the IN activity up to -2°C temperatures. Although the potential relevance of biological aerosol has already been investigated by several groups (Matthias-Maser and Jaenicke, 2000; Matthias-Maser et al., 2000), there is still a lack of information about its regional abundance and release mechanisms.

In this study, we used the Wave Band Integrated Bioaerosol Sensor (WIBS-4) to detect and differentiate the biological aerosol at the high-altitude research station Schneefernerhaus (UFS) in Germany. The detection principle of the WIBS-4 is based on the UV Light-Induced Fluorescence (LIF) method (Kaye et al., 2005; Gabey et al., 2010; Huffman et al., 2010; Gabey et al., 2011). The LIF method assumes that all biological substances contain common fluorophores like tryptophan and NADH, which are used for detection and identification of biological aerosols. After excitation of the aerosol, emitted fluorescence signals from biological substances are stored as single particle data and used to identify biological aerosols. In addition to the fluorescence data the instrument also measures the optical particle size between 0.5 and 18 µm and performs a particle shape analysis based on the single particle scattering pattern.

WIBS-4 measures the emitted fluorescence signals in three channels: the emission following a 280 nm excitation is recorded at 310-400 nm (channel F1, tryptophan) and 420-650 nm (channel F2, NADH), and a 370 nm excitation is recorded at 420-650 nm (channel F3, NADH). The particles showing a simultaneous fluorescence signal in the F1 and F3 channels are accepted as fluorescent biological aerosol particles (FBAP).

As part of the UFS02 field campaign, we measured the biological aerosol at the UFS station, located 300m below the Zugspitze summit. A one week measurement period is presented in Fig. 1 to give an impression about the FBAP number concentrations and size distributions at UFS. Two distinct modes at ~ 3 µm and at ≥ 18 µm were essentially observed for all measurement periods. The ratio of the N_{FBAP} to the total aerosol number concentration N_T was found to be around 5.64% (median) and 7.67% (mean). Particle shape analysis for specific measurement periods was performed and two different trends were identified that are discussed in the contribution.

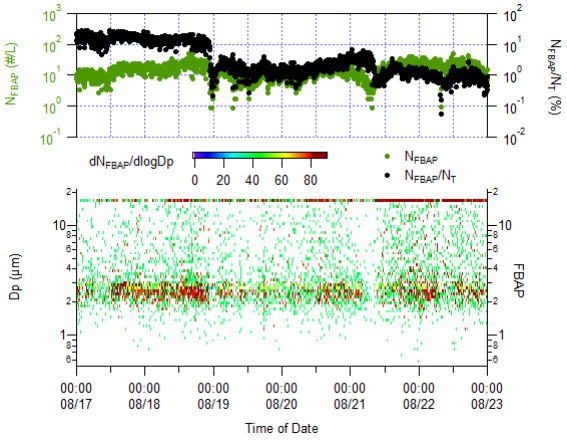

Figure 1. Upper panel: number concentration of fluorescent biological aerosol particles between 0.8 – 18 µm (green, left axis). Ratio of fluorescent particles to total aerosol particles (black, right axis). Lower panel: optical particle size distribution (dN/dlogDp) of the FBAP aerosol.

Keywords: Fungi, Ice nuclei
j.frohlich@mpic.de

Primary biological aerosol particles (PBAP) are ubiquitous in the atmosphere (Fröhlich-Nowoisky, *et al* 2009). Several types of PBAP, including bacteria, fungi, pollen and lichen, have been identified as ice nuclei (IN) that can initiate the formation of ice at relatively high temperatures (e.g.; Pouleur et al., 1992; Georgakopoulos, *et al* 2009). The best-known biological IN are common plant-associated bacteria. The IN activity of these bacteria is due to a surface protein on the outer cell membrane that catalyzes ice formation, for which the corresponding gene has been identified and detected by DNA analysis (Georgakopoulos, *et al* 2009).

Fungal spores or hyphae can also act as IN, but the biological structures responsible for their IN activity have not yet been elucidated. So far, however, the abundance, diversity, sources, properties, and effects of fungal IN in the atmosphere have not yet been well characterized and quantified.

Recent studies have shown that airborne fungi are highly diverse (Fröhlich-Nowoisky, *et al* 2009), and that atmospheric transport leads to efficient exchange of species among different ecosystems (Burrows, *et al* 2009a/b). The results presented in Fröhlich-Nowoisky *et al* 2011 clearly demonstrate the presence of geographic boundaries in the global distribution of microbial taxa in air, and indicate that regional differences may be important for the effects of microorganisms on climate and public health (Figure 1).

Thus, the objective of this study is the identification and quantification of ice nuclei-active fungi and the unraveling of IN-active structures in fungi, including identification of relevant proteins and genes. Results will be essential for improving our understanding of the effects of microorganisms on climate and the hydrological cycle.

Results obtained from the analysis of various soil and air samples and the presence of new fungal ice active species will be revealed.

Characterization and validation of an easy-to-assemble kit of visible LED lights employed for inactivation of environmental bioaerosols

C.H. Luo[1*] and H.K. Chang[1]

[1]Department of Safety, Health and Environmental Engineering, Hungkuang University, Taichung, 43302, Taiwan

Keywords: LED, bacteria, bioaerosols, indoor air quality.

Presenting author email: andyluo@hk.edu.tw

The bactericidal and wound healing effects of visible lights with specific wavelengths have been identified by several researches (Lipovsky *et al*, 2010; Papageorgiou *et al*, 2000; Perricone, 2003). Light-induced phototoxicity was used to explain the inhibition of bacterial growth under the illumination exposure. Airborne bacteria are the major bio-pollutants in indoor environment. Furthermore, light-emitting diodes (LED) with visible wavelengths have become a popular and stable light source because of their high brightness, low energy consumption, small size and long lifetime. The relationship between light-induced inhibition of bacterial growth and visible wavelengths of commercial LED should be useful for bioaerosol control and lighting design of occupational workplaces and leisure facilities. An easy-to-assemble kit of LED arrays with visible wavelengths has been established in this study to evaluate inactivation of airborne bioaerosols (*E. coli* and *B. subtilis*) that are frequently bacterial species indoors.

LED wavelengths (visual colour) in the visible range, including 405nm (violet), 470nm (blue), 520nm (green), 589nm (yellow), and 640nm (red) were used for light exposure experiments. Domesticated bacteria in medium dishes were illuminated by LED arrays assembled on the powered kit. An array unit (10×10 cm) were installed by 100 5mm-sized LEDs of single or two-mixed wavelengths. Total light intensity of a unit is around 1—9 W/m^2 at the measurement distance. The setup is shown in Figure 1. Bacteria were illuminated for 24 hours at 37 ℃ until reaching a logarithmic phase. Controlled bacteria were kept under dark conditions.

The inactivation effect of illumination with individual colour LEDs of 405, 470, 520, 589, and 640nm on *E. coli* (*B. subtilis*) is 70.78±4.00% (12.30±4.16%), 12.34±6.24% (6.95±3.46%), 18.94±3.21% (8.43±2.52%), 8.81±2.65% (9.84±5.29%), and 7.96±6.34% (1.07±7.64%), respectively. The best sterilization for two kinds of bacteria was provided by the violet LEDs. There is a potential advantage of using violet light over antibiotic treatment for indoor spaces with high population density and infection risks. For five individual colour LEDs, the viability of *E. coli* was more inhibited than that of *B. subtilis*. Sometimes the growth of *B. subtilis* might be accelerated after illumination of red LEDs.

The inactivation effect of illumination with mixed LED arrays with two individual colours, violet/blue and yellow/red, on *E. coli* is 45.61±5.69% and 10.53±4.58%, respectively. The violet/blue mixed LEDs was more effective than the yellow/red mixed LEDs. Furthermore, a better inactivation of *E. coli* by the yellow/red mixed LEDs was than those by yellow or red individual LEDs. Moreover, the individual violet LEDs presented a better bactericidal effect than the violet/blue mixed LEDs.

Molecular genetic analysis of biological aerosol particles from African dust storms

Cristina Ruzene-Nespoli[1, 2], Janine Fröhlich-Nowoisky[1], T. Nunes[3], J. Cardoso[3, 4], S. M. Almeida[5] & Ulrich Pöschl[1, 2]

Keywords: African dust, Bioaerosol, DNA
c.ruzene@mpic.de

There is a need to expand our knowledge of the diversity and biogeography of airborne microorganisms, since air connects all ecosystems at the Earth's surface. One of the most important phenomenon which can illustrate the role of the atmosphere as a dispersal mechanism for particulate matter is dust storms, that happen when the top soils from large deserts become airborne, and they can travel great distances through the atmosphere (Goudie and Middleton, 2001). More than half of the dust being transported in the atmosphere is believed to have originated from the Sahara-Sahel region in Africa (Kellog and Griffin, 2006). These dust storms are carrying microorganisms, some of them pathogens, along with the mineral particles (Griffin, 2007).

Studies have shown that the global microbial taxa are not homogeneously distributed in the air, and the regional differences and how they come to be needs to be further understood (Fröhlich-Nowoisky *et al*, 2011). It has been shown that atmospheric transport leads to efficient exchange of species among different ecosystems (Burrows *et al*, 2009a/b). In order to better understand the relationship between microorganism transport and dust, the present study aims to seek for a rhythm in the airborne contents found in African dust events.

Samples were collected between January 2011 and January 2012 in the Santiago Island from the Cape Verde archipelago. The sampling was done with a Hi-Vol with a PM10 head inlet (flow rate of 1,13 m^3min^{-1}). The sampling period was dictated by the data given by a continuous dust analyser (Grimm size dust analyser with 18 channels), with sampling periods ranging from less than 24 hours to 3 days.

Deoxyribonucleic acid (DNA) of filter sample aliquots were extracted, amplified and cloned according to protocol already established (Fröhlich-Nowoisky *et al*, 2009). The DNA extracts were used in several polymerase chain reaction (PCR) runs, using primer pairs targeting fungi and *Archaea*. For some samples, the colony PCR was followed by restriction fragment length polymorphism (RFLP) analysis to observe diversity in the clones. Selected positive products from the colony PCR were then sent to for sequencing, and the obtained DNA sequences were blasted in the National Center for Biotechnology Information (NCBI) database for taxonomic attribution to different phyla, classes, and species (Després *et al*, 2007, Fröhlich-Nowoisky *et al*, 2009).

Preliminary results for *Archaea* show a high diversity and the presence of members from the *Crenoarcheaota*, *Thaumarchaeota* and *Euryarchaeota*. It is also worth mentioning the finding of archeon clones belonging to the *Halobacteria*. As for the fungi, members of the *Agaricomycetes* are predominant for the *Basidiomycota*, with *Dothideomycetes* and *Sordariomycetes* appearing more often for the *Ascomycota*.

Further results will be obtained from sequences that are still being analysed, as well as new samples that will be processed, to expand the present data set.

Survival of airborne influenza on surfaces

Cordonnier[1,2], Florian[1,2], Ha[1],Thi-Lan[1], Robine[1], Enric[1] and Gehin[2], Evelyne[2]

[1]Université Paris-Est, Centre Scientifique et Technique du Bâtiment (CSTB), Laboratoire de Recherche et d'Innovation pour l'Hygiène des Bâtiments, 84, avenue Jean Jaurès - Champs-sur-Marne, 77447 Marne-la-Vallée, France

[2]Université Paris Est,Centre d'Études et de Recherche en Thermique, Environnement et Systèmes (CERTES),; 61, avenue du Général de Gaulle, 94010 Créteil Cedex

Keywords: Airborne virus, influenza, virus survival, fomites

Florian.cordonnier@cstb.fr

In indoor environments, 80% of respiratory infections,have viral origin. Flu caused by *Myxovirus influenzae*, an unspecific virus of human, belongs to human pathologies with important morbidity and mortality rates. The transmission of the pathogenic agent is mainly interhuman : it occurs by direct contact with an infected person or through droplets expelled when coughing, sneezing or talking towardthe respiratory tract of a new host. The environment role (air and surfaces) in virus transmission remains unknown.

This research study aims to improve the knowledge of environmental mechanisms involved in the transport and the survival of flu viruses, and more particularly, the role played by fomites. In this context, an experimental device was set up in order to reproduce support contamination by an Influenza aerosol and to study survival of the flu virus.

The experimental device (Figure 1) is composed of an aerosol production line, a mixing chamber with hygrometry and temperature controlled, associated with a specific equipment to determine aerosol size, concentration and infectivity of airborne viruses. The device is also equipped with a contamination setup: different indoor typical media (office furniture, door handle, IPE…) are placed in a Single-stage Bioaerosol Impactor and contaminated by airborne viruses.

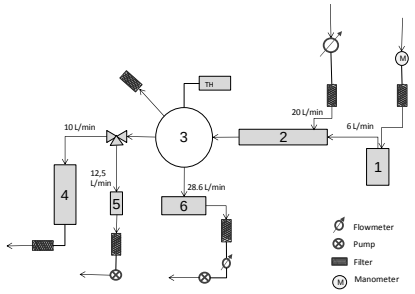

Figure 1. Representation of the experimental device

(1) Collison nebulizer, (2) Drying Column,(3)Mixing Chamber, (4) Electrical Low Pressure Impactor, (5)SKC Biosampler, (6)Single-stage Bioaerosol Impactor

The system produces, from the virus in a saliva substitute solution, a polydispersed aerosol (σ_g= 1.6) centered on 0.08 µm. The virus presence in aerosol was revealed by quantitative Polymerase Chain Reaction (quantification of total ARN) and Viral Plaque Assay (infectivity quantification) performed on particles collected on ELPI stages. The viral particle size ranges from 0.1 to 2 µm, with a bimodal distribution (modes at 0.25 and 0.8 µm) (Figure 2).

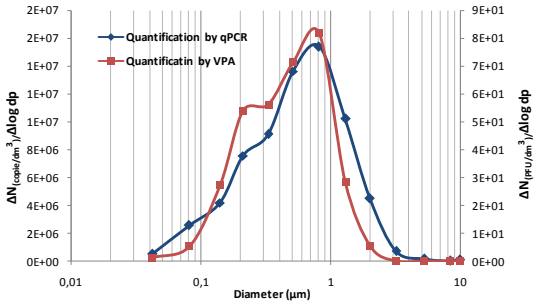

Figure 2. Virus size distribution

The experimental device permits to contaminate materials by airborne viruses and study effects of these materials on virus survival.

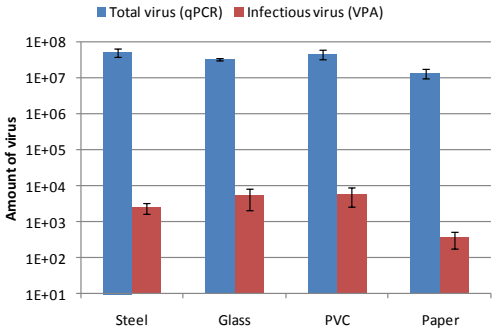

Figure 3. Virus survival just after material contamination

First results show (Figure 3) a viral contamination between materials comprised between 1.5×10^7 and 4.2×10^7 amount of virus/material. After contamination, virus survival is included between 2.5×10^3 and 5.8×10^3 infectious virus for steel, glass and PVC. The virus survival on paper is less of 1 log (3.7×10^2) compared to the other materials. These results of survival after contamination tend to be similar with Bean et *al.*,(1982) works on porous and non porous surfaces.

Bean, B., B. M. Moor, *et al.* (1982). "Survival of Influenza Viruses on Environmental Surfaces." The Journal of Infectious Diseases**146**(1): 47-51.

Internally controlled multiplex bioaerosol detection procedure

E.V. Usachev and I.E. Agranovski

Griffith School of Engineering, Griffith University, Brisbane, 4111 QLD, Australia
Keywords: Bioaerosol detection, personal sampler, internal control, multiplex real-time PCR.
Presenting author email: i.agranovski@griffith.edu.au

Detection of airborne pathogens has a crucial importance from health and safety prospects in many areas, including food industry, environmental quality, clinical diagnosis and others. Amongst growing areas of interest, usage of rapid methods for defense applications could be emphasized. Effective detection of biothreat agents requires a fast response with high sensitivity and specificity. More importantly, a detection system ought to be capable for simultaneous disclosure of many analytes in a sample, and have the ability of integration into a portable, miniaturized instrumentation.

Recently, we suggested a concept of portable fully automated "first alert" device combining personal bioaerosol sampler with miniature real-time PCR machine. The technology meets all requirements suggested for POC systems; it is portable (all modules could be located on a belt of security staff member), fully automated (consisting of sampling triggering devices, air sample collector, pumping station for aliquot delivery to a PCR machine, real time PCR/RT-PCR machine, and personnel alerting system), and capable of simultaneous detection of a range of targeted microorganisms in one reaction tube. In addition, a special PCR system, which does not require nucleic acid purification step has been developed and utilised by the new technology. This system enabled to eliminate bulky modules making the technology truly portable.

The aim of the current study was to develop an internally controlled system for bioaerosol detection by real-time PCR device combined with personal bioaerosol sampler. A recombinant phage fd (M13) was suggested for utilisation as internal amplification control (IAC). The main objective of this project was development of highly reliable and sensitive internally controlled on site detection of airborne viral strains.

The IAC was designed and optimized for use in multiplexed PCR with the aim to exclude false-negative results and to detect the presence of PCR inhibitors. Live virus based IAC has been chosen to match the sampling protocol for target microorganisms as the suggested "first-alert" concept presumes elimination of nucleic acids isolation and purification steps from the entire analytical procedure. The main advantages of this approach are related to low cost, simple maintenance and possibility of customising within wide spectrum of parameters. The IAC virus is simple to maintain, as it can be transfected or its double stranded phagemid transformed into appropriate bacterial strain. Then the virus can be easily recovered and harvested up to required titre. The fluorescence probe for the IAC detection can be synthesized with any fluorescent dye and appropriately paired quencher for particular optical settings of a PCR device used. Besides, the use of IAC in a format of full virion allows adding it directly into sampling liquid during aerosol collection and maintaining it along with a target pathogen at the same physical and biological conditions prior PCR amplification.

The IAC was tested individually in singleplex TaqMan reactions and also in multiplex reactions along with targeted T4 phage (commonly used virus surrogate for aerosol related studies) detection TaqMan assay. Amplification effects as a result of both high and low concentrations of T4 templates in the multiplexed assays were investigated to ensure that the IAC and the assay-specific reactions would not out-compete each other. No competitive effects were observed for target or IAC amplification within the concentration ranges from 3×10^1 to 3×10^6 PFU per reaction of T4 and 6.5×10^1 - 6.5×10^5 PFU per reaction of IAC. This demonstrated that the addition of IAC with concentrations of at least five orders of magnitude did not affect the amplification of as few as 30 copies (PFU) of T4 target. This outcome clearly shows the robustness of the amplification of our

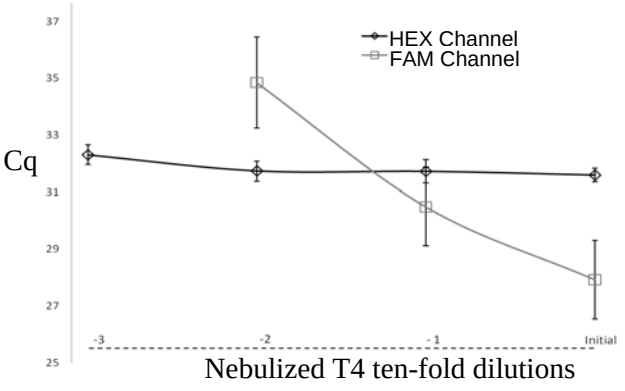

Figure 1. Internally controlled amplification of aerosolised T4 serial ten-fold dilutions. Error bars represent standard deviations of at least three measurements..

suggested IAC across wide range of target nucleic acid concentrations and the efficiency in which it can also be used to detect PCR inhibitors. The evaluation of use IAC in bioaerosol detection of T4 phage (Fig. 1) proves that it can be successfully utilised in real-time "first-alert" devices with multiple target detection, because of its non-competitive nature.

Could BFFB mode breath aerosol play a role in H5N1 transmission?

L. Morawska[1]; G.R. Johnson[1] and S.C. Bell[2,3]

Recent findings concerning exhaled aerosol size distributions and the regions in the respiratory tract in which they are generated could have significant implications for human to human spread of lower respiratory tract-specific infections. Even in healthy people, measurable quantities of aerosol are routinely generated from the Lower Respiratory Tract (LRT) during breathing(1-3).

We have found that there at least three modes in the exhaled aerosol size distribution of healthy adults(4) (see Figure 1). These modes each have a characteristic size and arise from different parts of the respiratory tract. The respiratory bronchioles produce aerosol during breathing, the larynx during speech and the oral cavity also during speech. The model of the resulting droplet size distribution is therefore called the Bronchial Laryngeal Oral (B.L.O.) tri-modal model of expired aerosol.

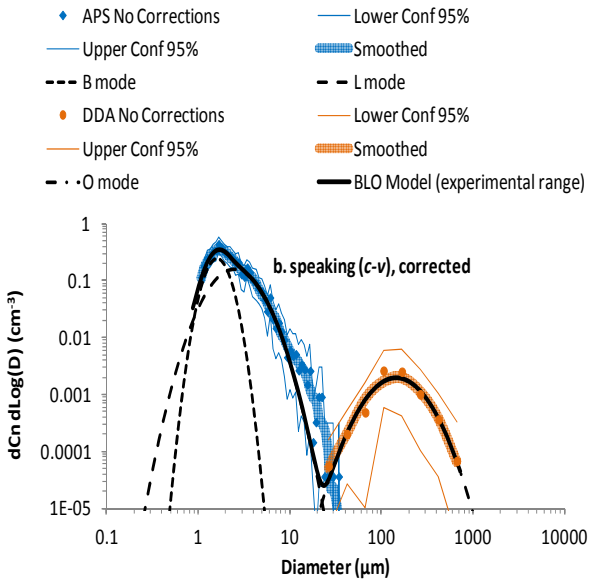

Figure 1: Breath aerosol number contribution compared to other modes during speech.

The bronchiolar fluid film burst (BFFB) mechanism (or simply B) mode is produced from fluid lining the respiratory bronchioles(1-3). The B mode droplets are produced in very large numbers by some individuals (see Figure 2). The small size of the B mode droplets means that they can remain in the air for prolonged periods, giving them the potential to travel large distances.

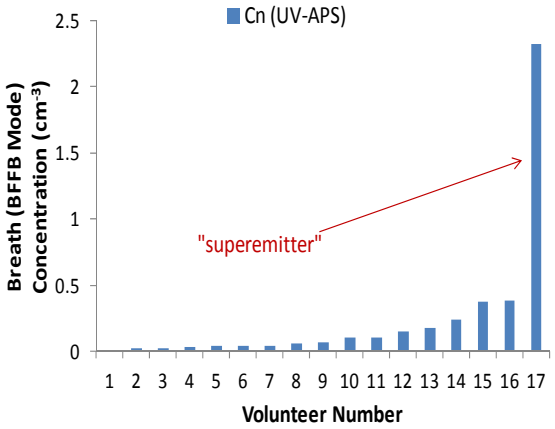

Figure 2: Example of super emitter of breath aerosol BFFB mode aerosol.

For a virus to be spread effectively between humans by aerosolisation, it must acquire the ability to infect cells in the upper respiratory tract and proliferate there so that high viral load can exist in the fluid that is aerosolised by sneezing and coughing(5).

We examine what role the B mode might play in the context of the news of the two research groups, who have independently demonstrated that H5 viruses including the much-hyped H5N1 avian influenza, can easily be modified to transmit between mammals (ferrets) and suggesting the potential in humans via exhaled aerosol.

Recent advances in bioaerosol control methods

Byung Uk Lee[1]

[1]Department of Mechanical Engineering, Konkuk University, Seoul, Republic of Korea
Keywords: bioaerosols, control.
Presenting author email: leebu@konkuk.ac.kr

Bioaerosols are defined as aerosols of biological origin. Bioaerosols are one kind of aerosols, however they are different from non-biological aerosols in terms of viabilty and biological activity.

Historically, bioaerosols were studied as a part of researches for finding out the origin of life by the great French scientist, Louis Pasteur (1822-1895).

Currently, most of bioaerosol researches were conducted due to health effects of bioaerosols. There are three mechanisms regarding the health effects of bioaerosols, which are hypersensitivity, toxic reaction, and infection. These mechanisms are related to choosing correct methods for sampling, analyzing, and controlling bioaerosols.

As air infection outbreaks have received public attention, there are strong demands of studying of sampling and controlling of bioaerosols.

In controlling bioaerosols, there are several steps. First, the air flow containg bioaerosols should be controlled by fluid machineries. Second, aerosol particles inside the air flow should be controlled by typical aerosol control methods such as filters, impactors, and electrostatic precipitators. For bioaerosols, they can survive in the typical aerosol control devices, and somtimes they grow with producing rank odors and offsprings inside the aerosol control devices. Therefore, we need third step, which is to control bioaerosols in the control devices. Thermal energy, ultraviolet irradiation, unipolar ion emission, and hybrid methods have been studied for controlling bioaerosols (Lee, 2011).

Here, recent advances in bioaerosol control methods are reviewed and these methods are compared with each other. Each control method has advantages and weakness points. For example, a thermal energy system can be easily installed inside any ventilation system for controlling bioaerosols, however, thermal energy systems usally consume significant amount of energy which is an economical weakness point of the control method. To decrease the weakness points with maintaining advantages of an individual method is a key of hybrid control methods for bioaerosols.

Bioaerosol control methods have great potential to be applied in various research areas. Bioaerosol control methods with electrospraying have been studied for analysis tools for biological materials. Artificial generation of biological particles with bioaerosol control methods can be applied in articultural industry and health care medical industry.

This work was supported by a National Research Foundation of Korea (NRF) grant (‘Measurement of airborne microorganisms in public facilities and development of control methods against airborne pathogenic microorganisms’, No. 2012-0002857) funded by the Ministry of Education, Science, and Technology.

Study on the ventilation and air dispersion in a hospital Intensive Care Unit (ICU) using simulation techniques

J.H. Song, J.Y. Jang, M.Y. Cho, D.S. Park and S.-B. Kwon

[1]Subway IAQ Research Corp., Korea Railroad Research Institute, Uiwang-si, Gyeonggi-do, 437-757, Korea

Presenting author email: songjihan@krri.re.kr

Infectious diseases such as influenza can be transmitted through respiratory droplets expelled from coughing or sneezing in indoor locations. Wan *et al.*, (2007) reported that the location of exhaust vents have significant impact on the dispersion pattern of expiratory droplets indicating that the airborne particles can be effectively controlled by air extraction from the exhaust air stream. There has been limited research on the air distribution system to improve the indoor environment (Tang *et al.*, 2007; Yau *et al.*, 2011). In this study, three possible types of ventilation systems in an intensive care unit (ICU) are tested using CFD simulation (Version 13.0) and the air flow pattern associated with the type of ventilation are discussed.

The isometric view of the simulated ICU room ($30m^3$) with a patient's bed is described in Figure 1. There are seven possible ventilation units that can be used for either supply or exhaust ventilation; ceiling-center, ceiling-division, ceiling-slit, side-center, side-division, Floor-center, Floor-division. Three cases of ventilation are considered for the simulation and the location of ventilation units for each case is described in Figure 2 (left). The ventilation rate for both inlet and outlet units are 0.1169 kg/s with the use of 12 ACH.

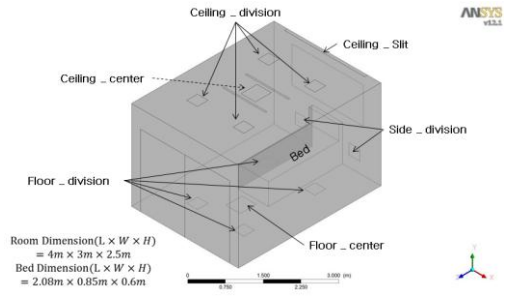

Figure 1. The isometric view of the simulated ICU room including interior bed location and ventilation systems.

The air flow vectors for three cases resulting from the CFD modelling are shown in Figure 2 (right) and the major air stream inside the room is described by a solid arrow. For both Case 1 and 2, the supply air flows from the slit at the side of the ceiling. It is less likely to have higher ventilation efficiency with the use of Case 1, since the exhaust units of Case 2 are at different four positions at the ceiling where air stream is distributed well than that of Case 1. For Case 3, rapid change in air speed is shown at the center part of the room and the air stream slows down near the bed to exit to the outlet located at the side wall. With the consideration of all values evaluated in this study such as air flow pattern, wind vectors, and mean age of air, Case 3 is chosen to be the most effective ventilation type in the simulated ICU room.

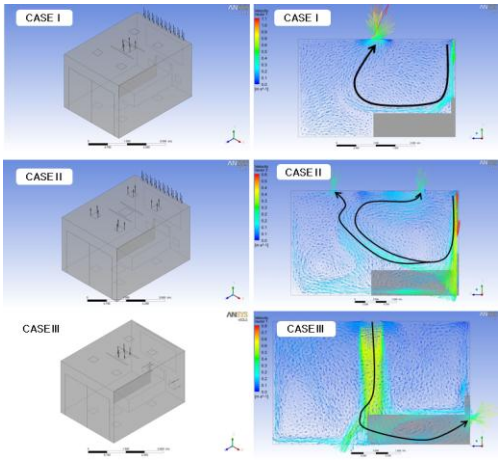

Figure 2. The geometry of model domain (left) and air flow vectors (right) for three cases of ventilation used in this study.

For further studies, environment variables such as the movement of a patient and the space of the room will be considered to study the air flow pattern inside the ICU room. Also, the dispersion and transmission mechanism of infectious particles expelled from the patient's cough in an ICU will be studied using CFD simulation based on the parameters obtained from previous study (Kwon *et al.*, 2012). Finally, ventilation performance will be tested depending on the various locations of supply and exhaust ventilation units to control the bio aerosol inside the ICU room effectively.

Airborne particles, primarily bacteria, virus, and fungi, are a primary means of disease transmission in humans and other animals. Due to renewed concerns over biological airborne contaminants such as new strains of flu or anthrax, many researchers have investigated the real-time technique that can be continuously monitored for potentially harmful biological aerosols.

Recently, the focus on fluorescence-based optical sensors has been to improve characterization by individual fluorescence spectral analysis. The fluorescence spectrum varies from material to material, and the evidence obtained from laboratory measurements indicates that effective differentiation from likely interferents should be possible with broadband spectral differentiation (Pan *et al*., 2011; Kaye et al., 2005). There has also been a focus on developing simpler, more robust, and lower-cost real-time sensors for intelligent network deployments.

The aerosol fluorescence sensor (AFS; Biral, Bristol, UK) is a promising monitoring device for the continuous real-time detection of airborne microorganisms, which is based upon the principle of Ultra-violet light induced fluorescence (UV-LIF) targeting the intrinsic fluorescence response from common amino acids found in living matter. The sensor uses an UV optical excitation source of 280 (+20/-40) nm to illuminate an airstream flowing drawn continuously through the sensor detection volume. Fluorescence from all particles instantaneously present within a sensing volume is measured using two photomultiplier detectors optically filtered to detect radiation in the bands 305-385 nm (UV) and 415-550 nm (Vis), enabling a generic discrimination between different aerosol populations.

This study describes the continuous real-time fluorescence characteristics of bacterial bioaerosols (*E. coli, B. subtilis and S. epiderdmids*) with various cell viabilities using the AFS. To control cell viability, the test bacterial bioaerosols were continuously exposed at various surrounding temperature with very short-time in the thermal electric tube furnace and passed into the AFS (Jung *et al*., .2009).

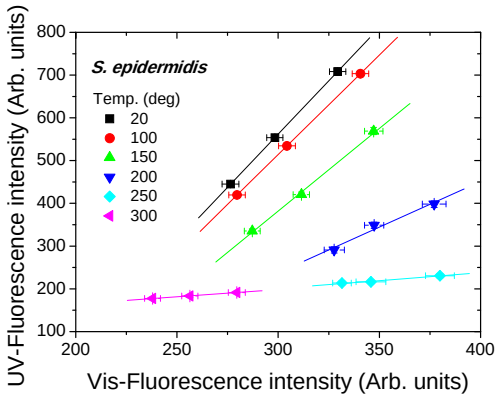

Figure 1. Variation of fluorescence characteristics of *S. epidermidis* bioaerosols under various thermal conditions.

Laboratory data show that these UV- and Vis-fluorescence intensities from the bacterial bioaerosols were decreased with increasing surrounding temperature following the decrease of bacteria viability.

In particular, this slope reduction value has statistically significant relationship ($p<0.05$) with the bacterial cell viability reduction. These experimental results provide basic information about the feasibility of AFS for real-time cell viability assessment of bacterial bioaerosols and may contribute in various applications such as indoor air quality, public health, and military defense against bioterrorism.

This research was supported by the Converging Research Center funded by the Ministry of Education, Science and Technology (2011K000750).

In Europe, about 15% of the population suffer from pollinosis. Pollen forecasts are a helpful tool for medical doctors to advise their patients. In addition, pollen forecasts can assist allergy sufferers to plan their leisure time and the medicine intake which reduces the symptoms. This highlights the need for regionally and temporally detailed pollen forecasts.

Model design of COSMO-ART

Numerical pollen dispersion models such as COSMO-ART (COnsortium for SMall-scale Modeling - Aerosols and Reactive Trace gases; Vogel *et al*, 2009) can provide spatially and temporally highly resolved pollen forecasts. COSMO is a non-hydrostatic mesoscale model that is used in operational weather forecasts in a number of European weather services including those of Switzerland and Germany. The ART module describes the chemical reactions and the aerosol dynamics as well as the pollen emission and dispersion processes.

We present the main features of the pollen module of COSMO-ART. A phenological heat sum model is used to predict the start and the end of the pollen season. This model performed very well in the verification process with an average accuracy of 2-3 days. The pollen season is described by various sigmoidal functions. The parameterization of the pollen emission is superposed on these seasonal factors and depends strongly on the meteorological conditions. The calculation of the settling velocity takes into account that the pollen grains can hydrate or dehydrate.

An important input to COSMO-ART is the source distribution. However, this input is not available for the allergy-relevant species such as hazel, alder, birch, grass or ragweed. Hence, plant distribution datasets need to be derived from suitable sources. For birch and grass we used the dataset by Pauling *et al* (2011). The source distribution for grass pollen was produced using a similar method.

Pollen forecasts using COSMO-ART

During the birch pollen season 2011, COSMO-ART was operational at MeteoSwiss for the first time using horizontal resolution of 7km. Figure 1 shows the observations at Zusmarshausen, Germany, and the modelled time series of the nearest grid point. Good agreement with the observations was achieved at many, though not all, observation sites. In addition, grass pollen were in a test phase in the same year.

We will present the results of the birch and grass pollen season 2012. Verification is done through rigorous comparison with observations and the calculation of skill scores. Moreover, the results of COSMO-ART are compared with statistically based pollen models and traditional man-made forecasts.

Future developments of COSMO-ART include the increase of the spatial resolution to 2km. This will significantly improve the results especially in complex terrains such as the Alps. Additionally, further allergy-relevant species such as ragweed will be modelled on a operational basis.

Abstract

Here, non-thermal plasma generated by a dielectric barrier discharge(DBD) system was applied to inactivating aerosolized *Bacillus subtilis* cells and *Pseudomonas fluorescens* as well as indoor and outdoor

bioaerosols. The culturability, viability, and diversity losses of the microorganisms in air samples treated by the plasma for 0.06-0.12 seconds were studied using culturing, DNA stain as well as polymerase chain reaction-denaturing gradient gel electrophoresis (PCR–DGGE) methods. In addition, the viable fraction of bacterial aerosols with and without the plasma treatment was also quantified using qPCR coupled with ethidium monoazide (EMA).

It was shown that less than 2% of *B. subtilis* aerosols survived the plasma treatment of 0.12 s, while none of *P. fluorescens* aerosols survived. Viability tests, EMA-qPCR results and Scanning Electron Microscopy (SEM) images demonstrated that both bacterial species suffered significant viability loss, membrane and DNA damages. Exposure of environmental bacterial and fungal aerosols to the plasma for 0.06 s also resulted in their significant inactivations, more than 95 % for bacteria and 85-98 % for fungal species. PCR-DGGE analysis showed that plasma exposure of 0.06 s resulted in culturable bacterial aerosol diversity loss for both environments, especially pronounced for indoor environment. The results here demonstrate that non-thermal plasma exposure could offer a highly efficient air decontamination technology.

Single-particle fluorescence spectroscopy of atmospheric relevant fungal spores and bacteria and potential interferences

S. Saari[1], M. Putkiranta[1] and J. Keskinen[1]

[1]Department of Physics, Tampere University of Technology, P.O. Box 692, FI-33101 Tampere, Finland
Keywords: fluorescence, bioaerosols, fungal spores, bacteria
Presenting author email: sampo.saari@tut.fi

Bioaerosols such as fungal spores and bacteria can act as CCN and IN in the atmosphere, so they have an impact on the global climate and precipitation. Bioaerosols contain usually alive micro-organism, which can have various health effects for humans and animals. For these reasons, information on the concentration, size distribution, sources and types of bioaerosols are needed in various environments. The development of real time measurement techniques is important for reliable bioaerosol classification.

Recently, laser induced fluorescence (LIF) has become a common way to detect bioaerosols. The LIF technique is an effective method for detecting biological molecules such as tryptophan, NADH and flavins that are present in bacterial cells and fungal spores. The focus on our previous studies was developing LIF based real time measurement technique for biological weapons detection (Manninen et al. 2008, 2009; Putkiranta et al. 2010). The idea is processed to use similar measurement technique for atmospheric relevant fungal spores and bacteria detection.

The idea in this study is to get information for effective fluorescence measurement parameters of airborne fungal spores and bacteria and also some fluorescent chemicals that can act as potential interferences in the atmosphere. The most important parameters are excitation wavelength and fluorescence emission spectrum and the best way to present these parameters is a fluorescence map. The fluorescence parameters depend on the state of biological origin and its environment. So it is important to measure fluorescence parameters in the natural aerosol phase. The fluorescence parameter studies are important for further instrumentation.

The experimental setup is represented by Manninen et al. (2008, 2009). The biological aerosol are generated with the ultrasonic nozzle (SNAG) and dried with the tube furnace and silica gel. The fluorescence spectrum is measured in the optical chamber and the size distribution of aerosol is measured with UVAPS (TSI Model 3314). A wavelength-tunable, pulsed solid-state optical parametric oscillator (OPO) laser (NT342/1/UVE, Ekspla UAB, Vilnius, Lithuania) is used to excite the fluorescence of individual aerosol particles. An image-intensified CCD (ICCD) camera (4 Quik E, Stanford Computer Optics, Berkeley, CA, USA). The ICCD camera acquires the fluorescence spectrum of individual aerosol particle through a grating spectrograph (250IS, Bruker Optics, Billerica, Massachusetts, USA). With this setup the fluorescence maps for single airborne bacteria and fungal spores and chemical particles can be measured.

The results of this study indicate that the fungal spores and bacteria have dissimilar fluorescence maps and the potential interference particles seems to have the similar fluorescence maps to common biological molecules. The bacteria and fungal spores are the common primary biological aerosol particles (PBAP) in the atmosphere. They have different emission sources and may have dissimilar properties when acting as CCN and IN. It may be possible to classify atmospheric bacteria and fungal spores through the dissimilar fluorescence properties, but influence of the potential interferences must be taken into account.

Microbial and fungal bioaerosol concentrations in Lithuanian schools

I. Radziuniene, D. Martuzevicius, D. Ciuzas, E. Krugly, and T. Prasauskas

Department of Environmental Engineering, Kaunas University of Technology, Kaunas, LT-50254, Lithuania
Keywords: bioaerosol, indoor air quality, sedimentation method, microorganisms.
Presenting author email: inga.radziuniene@ktu.lt

Introduction

Indoor air quality is influenced by many different pollution factors, such as chemical components (e.g. carbon dioxide, formaldehyde, organic substances, radon), particles (asbestos, pollen, other particulate matter, etc.) and microbial contaminants (Jones, AP, 1999). It affects human health, comfort, performance and productivity. Since the majority of people spend most of their time in the indoor environment, it is very important to evaluate different risk factors' influence on people's health.

School children are very susceptible to adverse effects. They spend up to 30% of their day time in the school environment and are more sensitive to environmental pollutants (Kulkarni and Grigg, 2008). Large number of pupils generate high pollutants load inside the school buildings, therefore schools very often fail to comply with the indoor air quality standards (van Dijken, F., 2006).

In this study, microbial contamination in schools was investigated with respect to total viable microorganisms (TVM), fungal and Gram negative bacteria concentration in bioaerosol.

Methods

Five schools situated in Kaunas municipality, Lithuania, were participating in this study. Three classes in each of the schools were selected for this study. Measurements were performed during November and December of 2011. Microbial contamination in schools was measured using sedimentation method. The exposure time was one hour. Standard Petri plates (85x15 mm) loaded with Plate Count Agar (PCA), MacConkey agar and Sabouraud agar were used to indicate different bioaerosol contents. PCA was used to quantify TVM in bioaerosol, MacConkey agar – Gram-negative bacteria and Sabouraud agar – fungal contamination. A minimum of three sampling plates for each agar were taking simultaneously in each sampling place. Recorded concentrations of bacteria and fungi in bioaerosol were expressed as colony forming units per plate per hour (CFU/plate/h).

Results

Distribution of the mean concentrations of TVM and fungi are presented in Figure 1. The bacteria and fungi were not speciated. Number of Gram-negative bacteria (potential intestinal pathogens) colonies on the MacConkey agar was below reliable limit. The recorded CFU varied from 0 to 9 CFU/plate/h. Therefore these results were not evaluated. The presented results show microbial contamination, detected in the schools during classes. The observed contamination after the classes' period was considerably lower.

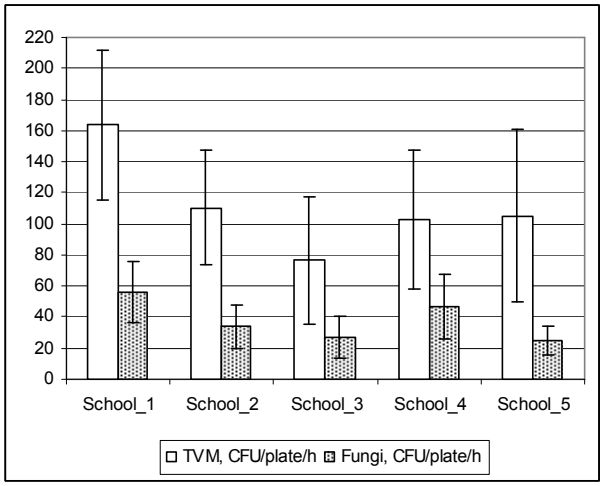

Figure 1. Average concentrations of TVM and fungi in schools, CFU/plate/h.

The results show that the observed microbial TVM contamination was above 100 CFU/plate/h in most of the schools. In each case the variation of the results was considerable. Recorded amount of total viable microorganisms cfu was varying from 14 CFU/plate/h (School_3) up to 224 CFU/plate/h (School_1), having average of 111,72±45,20 CFU/plate/h. Number of fungal CFU was lower in each case and was varying from 5 CFU/plate/h (School_3) to 90 CFU/plate/h (School_1), with an average 37,65±15,45 CFU/plate/h. The quality of indoor air varies depending on school. In each case the results are considerably dispersed, meaning that the bioaerosol concentration in the rooms varies depending on time and place. In summary it can be noted, that the bioaerosols concentration in the classrooms is relatively high. Fungi amounts about one third of the overall microbial contamination in schools.

More studies involving differentiation of bioaerosol concentration during different room occupation time and the results comparison with buildings parameters are needed (currently ongoing) to evaluate and find out the possible sources of indoor air contamination..

Airborne bacterial deposition in Sierra Nevada National Park

G. D´Orta [1], N. Mladenov [2] and I. Reche[1]

[1]Department of Ecology, Faculty of Sciences, University of Granada, Granada, 18071, Spain
[2]Department of Civil Engineering, Kansas State University, Manhattan, KS 66506, USA
Keywords: bioaerosols, African dust, dry and wet deposition
Presenting author email: ireche@ugr.es

The Sahara-Sahel region of Africa is the largest source of aerosolized soil dust on Earth, contributing as much as one billion metric tons of dust per year to the global atmosphere. Every year, massive airborne plumes of this Saharan dust are exported to the Mediterranean region influenced by the presence of cyclones mostly during spring and summer. These dust intrusions have a relevant impact on the chemistry and biology of the downwind ecosystems, in particular on the most pristine ones (Reche et al. 2009).

Bacteria are one of the many types of biogenic aerosol particles that are ubiquitous in the atmosphere. Airborne bacteria are typically transported <1 km from their source, however, dust-associated bacteria can be transported over 5000 km from Africa to the Caribbean coasts or Europe (Kellogg and Griffin, 2006). Therefore, these African dust intrusions could also have a role in expanding the biogeographical range of some microorganisms. Different approaches have been used to characterize the dust-associated microbial community. However, the total loading and the specific microbes associated with the dust intrusions remains poorly explored and highly imprecise.

Here, we tested a different procedure based on chemical and physical treatments to detach bacteria from the aerosol particles, similar to the technique proposed by Amalfitano and Fazi (2008) for benthonic bacteria. We determined the bacterial loadings in wet and dry collectors in Sierra Nevada National Park. This location is an ideal site to collect these aerosols because is close to the Sahara desert and has altitudes above 3000 m above sea level (asl) considering that the mainstream of Saharan dust transport occurs between 1500 and 4000 m asl. In Sierra Nevada National Park, there are also many pristine high mountain lakes submitted to this influence of Saharan dust intrusions.

Separate samples of dry and wet atmospheric deposition were collected, during the summers of 2007 and 2008, using two MTX1 ARS 1010 automatic deposition samplers located at about 2896 m asl at the Sierra Nevada Observatory (OSN) and at about 3000 m asl at Veleta peak. The bacterial loading in deposition samples were quantified in treated (detached) samples and in untreated samples (controls) using a flow cytometer. We examined the source of air masses over the Sierra Nevada, Spain, by computing daily backward trajectories (http://www.arl.noaa.gov/ready.html) using the HYSPLIT model with 120 h run time.

Detached bacteria from dust particles ranged from 2,77 x10^6 to 5,12 x10^7 with an average of 1,31 x10^7 cells m^{-2} day^{-1} (n = 51) whereas bacteria in the untreated samples ranged from 1,61 x10^4 to 3,03 x10^6 with an average of 1,58 x 10^5 cells m^{-2} day^{-1} (n= 49).

When data-set was split by the type (wet vs. dry) of deposition, a significant correlation ($p< 0.05$, $r = 0,57$) was found between the particulate matter (PM) and the bacterial loading in wet deposition whereas we did not obtain significant values for dry deposition.

Similarly, when PM deposition with a predominant Saharan source was related to the bacterial loadings, a significant correlation ($p <0.05$, $r=0,42$) was found (Figure 1). A non-significant relationship was found between PM with a predominant marine source and bacterial loading (not shown).

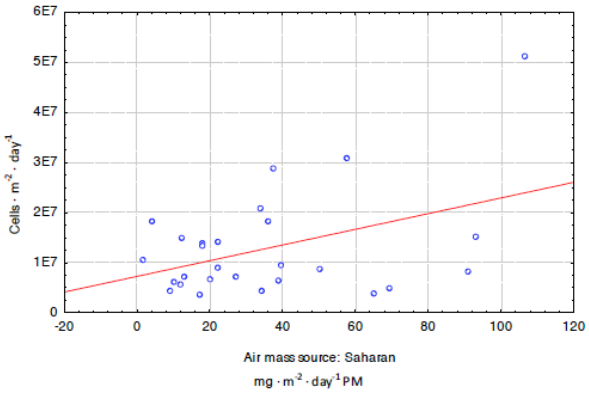

Figure 1. Relationship between Particulate Matter (PM) (mg m^{-2} d^{-1}) with a predominant Saharan source and bacterial loadings (cells $m^{-2}d^{-1}$).

Overall, we positively tested a bacterial detach procedure for aerosol deposition samples and we detected a high bacterial loading associated mostly with Saharan dust intrusions that should be taken into account to address ecological and biogeographical questions in the microbial realm.

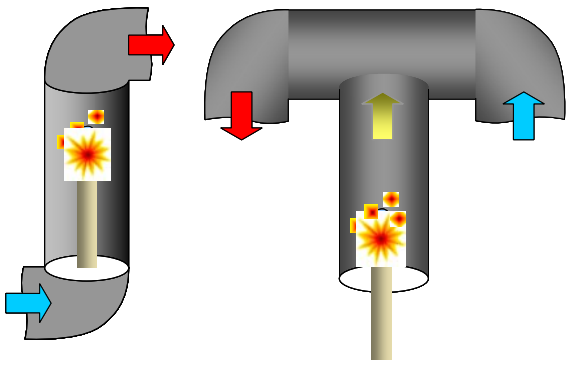
Neutralization of highly pathogenic aerosolized bio-threat agents is an important objective of bio-defense research programs. If a bio-weapon facility is accidentally or intentionally targeted, the bio-agent release should be prevented as some microorganisms (e.g., bacterial spores) may survive considerable heat and chemical stresses and, while remaining airborne, can represent a major health hazard. Various reactive materials are being currently developed with the added capability to "kill" (neutralize) viable microorganisms during their release to the atmosphere. A laboratory evaluation of these materials requires adequate experimental facilities and protocols. The main disadvantage of existing evaluation methods is that they do not differentiate between the effects caused by heat stress and by combustion products.

To address this gap, we have developed a two-configuration experimental approach, which allows establishing two sets of conditions for the bioaerosol exposure. In the first one, the challenge bioaerosol is supplied directly through the combustion zone so that the microorganisms are exposed to both the thermal and chemical inactivation. In the second one, the bioaerosol is supplied downstream from the combustion zone where the air temperature decreases to the levels, which do not cause significant thermal "killing" (Grinshpun et al., 2010), and thus the viability loss occurs primarily due to exposure to combustion products. Figure 1 schematically shows these configurations.



Configuration 1 **Configuration 2**

Figure 1. Exposure of a challenge bioaerosol to heat and chemical stresses associated with the combustion of reactive materials: two experimental configurations.

Two experimental setups were designed and built to implement these configurations. A hydrocarbon fuel flame seeded with three fuel additives, which were delivered to the burner from a powder disperser, represented the tested combustion environments. One of the powders contained aluminum with embedded iodine that was designed to be released at the aluminum melting temperature.

In experiments performed with both setups, endospores of *Bacillus subtilis var. niger* (also referred to as *Bacillus atrophaeus* or BG spores) as well as *Bacillus thuringiensis* (Bt spores) were exposed to the combustion environments, and the spore viability loss was quantitatively characterized using a culture-based enumeration of the exposed and non-exposed bioaerosol samples. Additionally, the first configuration was utilized to perform the tests, in which the burner was replaced with an axial heater providing specific temperature conditions for the challenge bioaerosol with no release of combustion products.

A separate set of experiments was conducted to evaluate different sampling techniques for collecting the aerosolized spores. These included four filter materials (Teflon, polycarbonate, membrane and gelatin) as well as a BioSampler (SKC, Eighty Four, PA, USA) with deionized water. The bioaerosol collection on the gelatin filter and into the BioSampler were found to be the most favorable sampling techniques for this study.

It was determined that the spore neutralization levels associated with the heat and chemical stresses may be comparable. It is anticipated that these factors may produce a synergistic effect, as a heat-induced damage of protein coats is likely to affect the spore outer membrane, cortex, and subsequently inner membrane, which enhances the penetration of the combustion-associated "lethal" chemical products. A systematic investigation is needed to test the above hypothesis.

The study was supported by the U.S. Defense Threat Reduction Agency (DTRA) and the U.S. Office of Naval Research. The authors are grateful for this support.

Keywords: Biomass combustion, PM_{10}, OC, EC, chemical composition, emission factor
celia.alves@ua.pt

As in many other countries, biomass burning is a common practice in Portugal in order to obtain energy, especially for domestic heating. It has been estimated an annual wood consumption of 1.950 kton in domestic equipments in Portugal (Gonçalves et al. 2011). Besides gas emissions, biomass burning releases an important particulate matter fraction to the atmosphere that can represent up to 70% of particulate organic matter in rural regions of Europe during winter time (Puxbaum et al. 2007). This particulate emission is a major concern due to its impact on public health, indoor and outdoor air quality as well as its contribution to greenhouse gas (GHG) emissions. Emission factors (EF; $g_{\text{pollutant}}\,kg^{-1}_{\text{dry biomass burned}}$) for European biomass burning are scarce; the available EF were obtained for US, Alpine and Scandinavian biofuels (Fine et al., 2004, Johansson et al., 2004, Schmidl et al., 2004), which are uncommon in southern Europe. To better estimate the emissions of certain countries, it is necessary to burn biomass fuels commonly used in the country of study, as well as to use typical domestic heating equipments.

A set of tests was carried out to determine the gas and chemical composition of PM_{10} emitted from the combustion of three typical wood species in a stove and a fireplace. The species selected for this study were pine (*Pinus pinaster*), eucalyptus (*Eucalyptus globulus*) and Cork oak (*Quercus suber*) from Portuguese forest; common in Iberian Peninsula forests. The burning experiments were carried out in a fireplace and a wood stove; typical equipments used in Portugal for domestic heating.

The logs were cut in four small parts with weight variation between 0.3 and 0.7 kg and 0.3 and 0.4 m of length. The fireplace and woodstove were operated manually in batch mode. They heat the room air by a combination of natural convection and radiation. The woodstove has a combustion chamber with 0.093 m^3 of volume, while that of the fireplace has 0.15 m^3. Both equipments have a vertical exhaust duct with 0.2 m internal diameter and 3.3 m height. Each combustion cycle lasted between 45 and 60 minutes. The O_2 source was atmospheric air at a temperature between 20ºC to 25ºC and pressure from 101 kPa to 102 kPa.

The flue gas composition was monitored continuously at the exit of the chimney: i) total volatile hydrocarbons were determined using an automatic analyser with flame-ionisation detector and ii) CO_2 and CO were determined using a non-dispersive infrared analyser.

Particles (PM_{10}) were collected, under isokinetic conditions, on quartz filters using a low volume sampler in the dilution tunnel that was directly coupled to the chimney. Filters were analysed in order to determine the carbonaceous content (elemental - EC - and organic carbon - OC) by a thermal-optical transmission technique.

Higher EFs were obtained for the fireplace than for the wood stove, for the three tree species studied (Table 1). Carbonaceous compounds represent an important fraction of PM_{10}, with OC always remaining higher than EC.

This study points out the strong influence of the surrounding environmental conditions on fireplace emissions due to the open combustion chamber of this equipment. Changes in these conditions will influence the combustion process, affecting the combustion speed, temperatures and, hence, the emission profiles.

Table 1 - Emission factors for PM_{10}, OC and EC ($g.kg^{-1}$ biomass, dry basis).

		Pine	Eucalyptus	Cork oak
Woodstove	PM	4.42±1.89	7.75±3.30	6.96±2.12
	OC	1.93±0.78	4.05±2.08	3.68±1.38
	EC	1.54±0.56	0.58±0.23	0.53±0.06
Fireplace	PM	20.0±9.3	23.2±2.7	17.5±1.6
	OC	12.5±6.0	13.3±1.6	10.6±1.1
	EC	1.55±0.74	0.43±0.08	0.72±0.11

Inventory of emissions from residential wood combustion in Portugal

C. Gonçalves, C. Alves and C. Pio

Centre for Environmental and Marine Studies (CESAM), Department of Environment, University of Aveiro, 3810-193 Aveiro, Portugal.

Keywords: Survey questionnaire, wood species, burning appliances, emission factors, inventory.

catiagoncalves@ua.pt

Nowadays, most developed countries suffer from a nearly total dependence on fossil fuels for energy production, in economic and social activities. With the emergence of environmental politics and the imminent depletion of fossil fuels, there is a strong encouragement to change to renewable energy sources. The use of biomass for energy production is being promoted to decrease the dependence on fossil fuels. However, residential wood combustion (RWC) is one of the largest sources of fine particle emissions to the atmosphere in Portugal. Since wood burning practices and activities can vary geographically, residential wood combustion chemical composition profiles also differ by region.

In this study, data from a number of source burning tests conducted with several Portuguese wood species (Fernandes et al., 2011; Gonçalves et al., 2011) were used to assemble a national inventory of emissions. These emissions include $PM_{2.5}$, OC and EC, CO and CO_2 and various individual organic compounds (for example levoglucosan) that are released from RWC (fireplaces and woodstoves) in Portugal.

In addition to the emission factors, a comprehensive knowledge of RWC activity data and its spatial distribution, which are not available in national statistical databases, is required. The survey questionnaire was conducted by telephone calls between 21 September and 11 October 2010 by a market research company, working under contract for the University of Aveiro. The survey was based on 2387 effective respondents, from which a total of 806 positive answers were obtained, i.e., house owners who have declared the use of RWC.

The total amount of wood consumed in Portugal in the year 2010 was around 2 Mt for both heating (83%) and cooking (17%) purposes. In the households where wood is frequently burned, 43% use fireplaces, while 6% of respondents said that burn wood in barbecues fireplaces. Woodstoves and traditional ovens represent about 24% of the total number of appliances (Table 1). The largest percentage of wood (51%) is burned in fireplaces, while the lowest percentage of wood (0.30 %) is burned in furnaces (Table 1). The results of the questionnaire indicated an average of 1.3 wood combustion appliances per household.

Regarding wood species used, Holm oak and cork oak are the most common woods for residential combustion in the southern districts; maritime pine, Portuguese oak and eucalypt present a larger share in northern districts. Around 20% of the house owners burn mixtures of different types of woods.

The use of different appliances and wood species is of great importance because both affect the amount and type of emissions ($PM_{2.5}$, OC, EC and organic compounds).

Table 1 Appliance distribution (%) and wood consumption by appliance in mainland Portugal.

	(%) distribution	Wood Consumption (%)	Wood Consumption (t y^{-1})
Fireplace	43	51	954 652
Woodstove	20	22	411 646
Wood burning furnace	11	12	218 631
Salamander stove	7.8	7.6	143 125
Boiler	7.2	3.3	61 646
Barbecue	5.8	1.5	28 027
Oven	4.3	2.5	46 785
Wood burning water heater	0.57	0.58	10 839
Furnace	0.38	0.30	5 631

The emissions of $PM_{2.5}$ were estimated to be between 0.09 kt y^{-1} (Portalegre) and 1.30 kt y^{-1} (Aveiro), totalising 10.96 kt y^{-1} in Portugal. The national emissions of OC and EC were estimated to be 5.32 and 0.53 kt y^{-1}, respectively. It was estimated that the total CO_2 emissions from RWC in Portugal are 1.7 Mt y^{-1}. The levoglucosan emissions contribute with between 7.8% (Beja) and 16.1% (Vila Real) of $PM_{2.5}$ emissions from RWC. PAHs from RWC in Portugal represent approximately 6.5% of the total emissions from the main activity sectors.

Keywords: aerosol chemistry, biomass burning aerosol, aerosol transport, aerosol aging tracer.
Presenting author email: ctlee@cc.ncu.edu.tw

The transport of biomass burning (BB) aerosol from Indochina may affect climate change in the downstream Southeast Asia, East Asia, and West Pacific. Up to now, the investigation on BB aerosol aging during long-range transport is still very limited due to the lack of observation data. In this study, atmospheric aerosols were collected at the Suthep mountain site in Chiangmai, Thailand and the Lulin mountain site in central Taiwan from March to April 2010.

During the study period, five-day backward trajectories showed that the air masses originated from Indochina would transport to Taiwan. Therefore, these two sites (2,400 Km apart from each other) can be considered as the upstream and downstream sites under the prevailing westerlies. Comprehensive aerosol properties were resolved for $PM_{2.5}$ water-soluble ions (WSIs), carbonaceous content (from the U.S. IMPROVE protocol), water-soluble/insoluble organic carbons (WSOC/WIOC), low-molecular-weight dicarboxylic acids (C2-C5), and monosaccharide anhydrides.

By employing non-sea-salt potassium ion (nss-K^+) or low-temperature elemental carbon (EC1) after the correction for pyrolized organic carbon (OP) as the BB aerosol tracer, the aerosol is considered to be aged when the Aging Ratio (AR_X) exceeding unity as follows:

$$AR_{nss\text{-}K^+} = \frac{(\frac{C_i}{nss\text{-}K^+})_{Lulin}}{(\frac{C_i}{nss\text{-}K^+})_{Suthep}}$$

Table 1. Selected values of aerosol WSIs normalized to nss-K^+ or EC1-OP (in parenthesis) and the resulted AR_X values at the Suthep and Lulin sites.

	$\frac{NH_4^+}{nss\text{-}K^+}$	$\frac{NO_3^-}{nss\text{-}K^+}$	$\frac{nss\text{-}SO_4^{2-}}{nss\text{-}K^+}$
	$\frac{NH_4^+}{EC1\text{-}OP}$	$\frac{NO_3^-}{EC1\text{-}OP}$	$\frac{nss\text{-}SO_4^{2-}}{EC1\text{-}OP}$
Suthep (N=15)	0.96±0.20 (0.39±0.12)	0.49±0.16 (0.19±0.05)	3.92±0.99 (1.59±0.53)
Lulin (N=19)	3.17±1.15 (1.81±1.87)	1.78±0.88 (1.02±1.19)	8.12±2.83 (4.66±4.73)
$AR_{nss\text{-}K^+}$ ($AR_{EC1\text{-}OP}$)	3.31 (4.67)	3.61 (5.33)	2.07 (2.93)

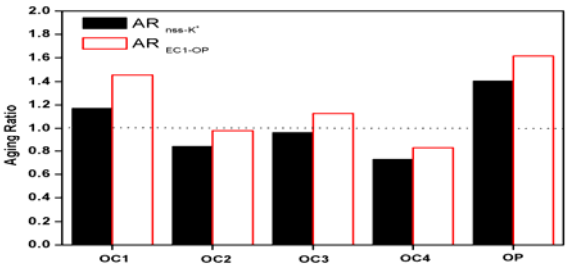

Figure 1. Aerosol AR_X values ($AR_{nss\text{-}K^+}$ or $AR_{EC1\text{-}OP}$) for the resolved OC fractions from the U.S. IMPROVE protocol.

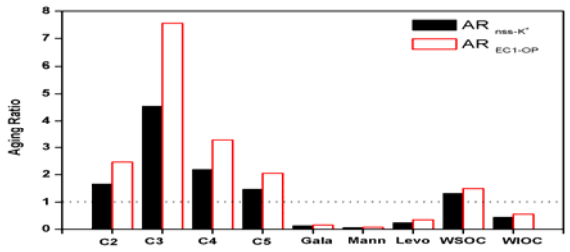

Figure 2. Aerosol AR_X values ($AR_{nss\text{-}K^+}$ or $AR_{EC1\text{-}OP}$) for the resolved organic fractions.

The computed AR_X values show that NH_4^+, NO_3^-, nss-SO_4^{2-}, the lowest volatility organic carbon (OC1), OP, C2-C5, and WSOC are all above unity which indicates that these fractions or species were enhanced and thus aged during transport. In contrast, the AR_X values of levoglucosan, galactosan, and mannosan are only in the range of 0.1 to 0.3 which indicates monosaccharide anhydrides would degrade during transport. Therefore, by comparing aerosol properties at the upstream and downstream sites, aerosol aging effect for different species or fractions can be evaluated.

With the observation of aerosol comprehensive compositions at the Suthep and Lulin sites and the development of an AR_X value, this study provides a quantitative method to assess the aging of BB aerosol species or fractions during long-range transport.

Summer 2010 forest fires in central Portugal: characterisation of trace gases and aerosol emissions

A.M. Vicente[1], C.A. Alves[1], A.I. Calvo[1], A.P. Fernandes[1], T. Nunes[1], A.C. Monteiro[1], M. Evtyugina[1], L.A. Tarelho[1] and C.A. Pio[1]

[1]Centre for Environmental and Marine Studies, Department of Environment, University of Aveiro, 3810-193 Aveiro, Portugal

Trace gases and aerosol particle emissions from several wildfires occurring in Portugal were sampled in summer 2010 (Table 1).

Table 1. Wildfires episodes over Portugal in summer 2010, where smoke samples were collected.

Sampling locations	Date	Number of samples ($PM_{2.5}$+$PM_{2.5-10}$)	MCE(*)
Dornelas	26 Jul.	2	0.87
Rebordelo	27 Jul.	6	0.83-0.94
Albergaria-a-Velha	4 Aug.	2	0.92
Albergaria-a-Velha	6 Aug.	2	0.89
Junqueira (Vale de Cambra)	11 Aug.	4	0.87-0.91
Vila Nova de Tazem	13 Aug.	12	0.64-0.84

(*) modified combustion efficiency

Coarse ($PM_{2.5-10}$) and fine ($PM_{2.5}$) smoke particles were collected sequentially on pre-fired quartz fibre filters, using a portable high-volume sampler. Sampling was performed at 1.5 m above ground, downwind from the burning area, at distances of 10 e 200 m from the flame. Tedlar bags were used for the collection of gas samples in parallel with aerosol sampling. Total volatile hydrocarbons (THC) and carbon oxides (CO_2 and CO) in the Tedlar bags were measured using automatic analysers with flame ionisation and non-dispersive infrared detectors, respectively. The organic and elemental carbon content of particulate matter was analysed by a thermal-optical transmission technique (Alves et al., 2011a). The detailed speciation of organic compounds in smoke samples was carried out by gas chromatography-mass spectrometry. The water-soluble ions were obtained by ion chromatography.

Emission factors (EF) for some gaseous compounds and particulate matter were calculated. This parameter is usually defined as the amount of a compound released per amount of dry fuel consumed, expressed in units of g kg^{-1} (Alves et al., 2011a; Reid et al., 2005).

The CO emission factor (EF_{CO}) ranged between 67.1 and 364 g kg^{-1} biomass (dry basis) burned. The EF_{CO} obtained for wildfires in summer 2010 in Portugal (159±84 g kg^{-1}) are similar to those obtained in 2009, with values of 231±177 g kg^{-1} (Alves et. al. 2011b). The EF_{CO_2} obtained for wildfires in Portugal (2010) ranged between 1029 and a maximum of 1655 g kg^{-1} biomass (dry basis) burned. Total hydrocarbon emission factors (EF_{THC}) reached a maximum of 28.1 g kg^{-1} (dry basis), averaging 12.1±9.98 g kg^{-1}. $PM_{2.5}$ and PM_{10} particulate matter concentrations reached 11.6 mg m^{-3} and 12.2 mg m^{-3}, with average values of 3.72±3.60 mg m^{-3} and 4.01±3.80 mg m^{-3}, respectively. The EF ranged between 4.40 and 67.5 g kg^{-1} for $PM_{2.5}$ and between 4.80 and 72.1 g kg^{-1} (dry basis) for PM_{10}. A clear predominance of carbonaceous aerosol was observed, with OC concentrations always remaining much higher than EC in both size fractions. The EF_{OC}, on average, were 11.0±9.72 g kg^{-1} and 11.4±9.97 g kg^{-1}(dry basis) for fine and coarse particles, respectively. The EC emission factors (EF_{EC}) obtained for $PM_{2.5}$ and PM_{10} ranged between 0.07 and 2.26 g kg^{-1} (dry basis).

The concentration of water-soluble inorganic ions represented, on average, 3.9% and 2.8% of $PM_{2.5}$ and $PM_{2.5-10}$ mass, respectively. Focusing on average concentrations, highest values were registered for Cl^-, NH_4^+, K^+, SO_4^{2-} and Ca^{2+} in $PM_{2.5}$, and SO_4^{2-}, Ca^{2+} and K^+ in $PM_{2.5-10}$.

The chromatographically resolved organics included *n*-alkanes, *n*-alkenes, *n*-alkanoic acids, *n*-di-acids, unsaturated fatty acids, phenolic compounds, ketones, steroids, di- and triterpenoids, PAHs and anhydrosugars.

Levoglucosan was always present at higher concentrations than those of galactosan and mannosan. Ratios of OC to levoglucosan, galactosan and mannosan were similar to those registered during summer 2009 wildfires in Portugal (Alves, et al., 2011a; Vicente et al., 2011).

This work was supported by the Portuguese Science Foundation (FCT), through the project PTDC/AMB/65706/2006 (BIOEMI). Ana Vicente acknowledges the PhD grant SFRH/BD/48535/2008.

Contribution to $PM_{2.5}$ from domestic wood burning in a small community in Sweden

P. Molnár[1] and G. Sallsten[1]

[1]Occupational and Environmental Medicine, Sahlgrenska Academy at University of Gothenburg, Gothenburg, SE 405 30, Sweden

Keywords: Wood smoke, PM and source apportionment, PMF, XRF. Black carbon

Presenting author email: peter.molnar@amm.gu.se

Background: The use of wood stoves and fireplaces for heating is quite common in homes in many countries with cold climates. Biomass burning produces a number of gaseous and particulate pollutants which when released affects the ambient air (Fine et al., 2001; Hedberg et al., 2002; Lee et al., 2005; McDonald et al., 2000). The rising importance of biomass emissions in ambient air increases the demand to quantify the contribution in local settings.

The aim was to investigate and quantify the contribution to ambient air from domestic biomass burning for space heating in a residential area.

Methods: Daily 24 hours $PM_{2.5}$ samples during 151 days in the winter season 2007-08 were collected using the IVL weekly $PM_{2.5}$ sampler (IVL Swedish Environmental Research Institute, Gothenburg, Sweden) on 25 mm TF (PTFE) Membrane filters (Pall Corporation, USA) at two sampling places, one in a wood burning area and the other at a reference station without any houses with domestic wood burning nearby.

After determination of mass concentration, a subset of the filters (56 filters paired from 28 days) was selected for chemical analysis. Black carbon, BC, was analysed using Model OT21 Optical Transmissometer Magee Scientific Corporation, USA and elemental concentrations were determined using EDXRF. The 28 days were chosen based on trajectory analysis to be days with low regional contribution.

Source apportionment analysis was carried out by Positive Matrix Factorisation (PMF) technique using the US EPA software EPA-PMF 3.0.

Results: Statistically significant higher concentrations were found in the wood burning area compared to the reference area for the following variables; $PM_{2.5}$, BC, K, Zn, and Br. The concentrations for these variables were 22, 55, 58, 44, and 24 per cent higher in the wood burning area.

For the PMF analysis the two data sets from the wood burning and the reference area was put together into one data set. A five factor model was used for the PMF analysis and the following sources were identified; Long range transported (LRT), Biomass, Sea salt, Soil, and Traffic (Table 1).

The Biomass factor profile was identified by high percentage of the variables BC, K, Zn, and Cu being attributed to the factor.

Table1. Factor contributions and the ratios in the wood burning area and the reference area from the PMF analysis.

Factor	Wood burning area ($\mu g/m^3$)	Reference area ($\mu g/m^3$)	Ratio
LRT	1.65	1.57	0.93
Biomass	1.41	0.77	**1.84**
Sea Salt	0.90	0.85	1.06
Soil	0.47	0.51	1.10
Traffic	0.16	0.15	1.06

Discussion: All factors, besides the Biomass burning, are very similar in source strength at both places, indicating that the only real difference between the two areas was the presence of biomass burning. The reference area was not devoid of any biomass influence, but the contribution is only about half compared to the wood burning area.

The contribution from LRT in the current PMF model is smaller than in reality for the winter season since the analysis is performed only on a subset of the data without any influence from the more polluted regions of Europe. For all the other sources, including domestic biomass burning, the contribution is representative for the winter season.

No evidence for a regional additional source of secondary organic aerosol (SOA) has been identified in measurements of biomass burning-influenced ambient air masses. Measurements included in this study were obtained from the deployment of an Aerodyne Quadrupole Aerosol Mass Spectrometer during four field campaigns, involving both research aircraft flights and ground-based measurements. OA concentrations normalised to excess CO (OA/ΔCO) show strong regional and local scale variability, with a difference of almost a factor of five across fresh OA emissions between campaigns. Average OA/ΔCO is typically higher in the near-field than at a greater distance from source, indicating an absence of significant SOA formation, despite evidence to suggest OA becomes increasingly oxidized with age. This trend is in contrast with observations of anthropogenic OA in urban environments, where OA/ΔCO is consistently shown to increase with distance from source. There is no such agreement in the case of biomass burning OA (BBOA) amongst the literature base, with conflicting examples relating to the influence of SOA on aerosol loadings. A wide range of average initial emission ratios (ERs) close to source are observed both within the datasets analysed here and within the literature, together with considerable variability in individual OA/ΔCO values throughout fresh biomass burning plumes. The extent of this variability far outweighs any increase in OA/ΔCO in the few instances it is observed here, suggesting that source conditions are of greater importance for the propagation of BBOA loadings within the ambient atmosphere. However, the implications of ageing on OA/ΔCO variability appear to be highly uncertain, with little consistency between observed trends for different locations. Furthermore, the exact effects of the fire conditions influencing emissions from biomass burning events remain poorly constrained. These uncertainties regarding the evolution of biomass burning emissions emphasise the need for improved characterisation of BBOA to ensure accurate representation in global climate models.

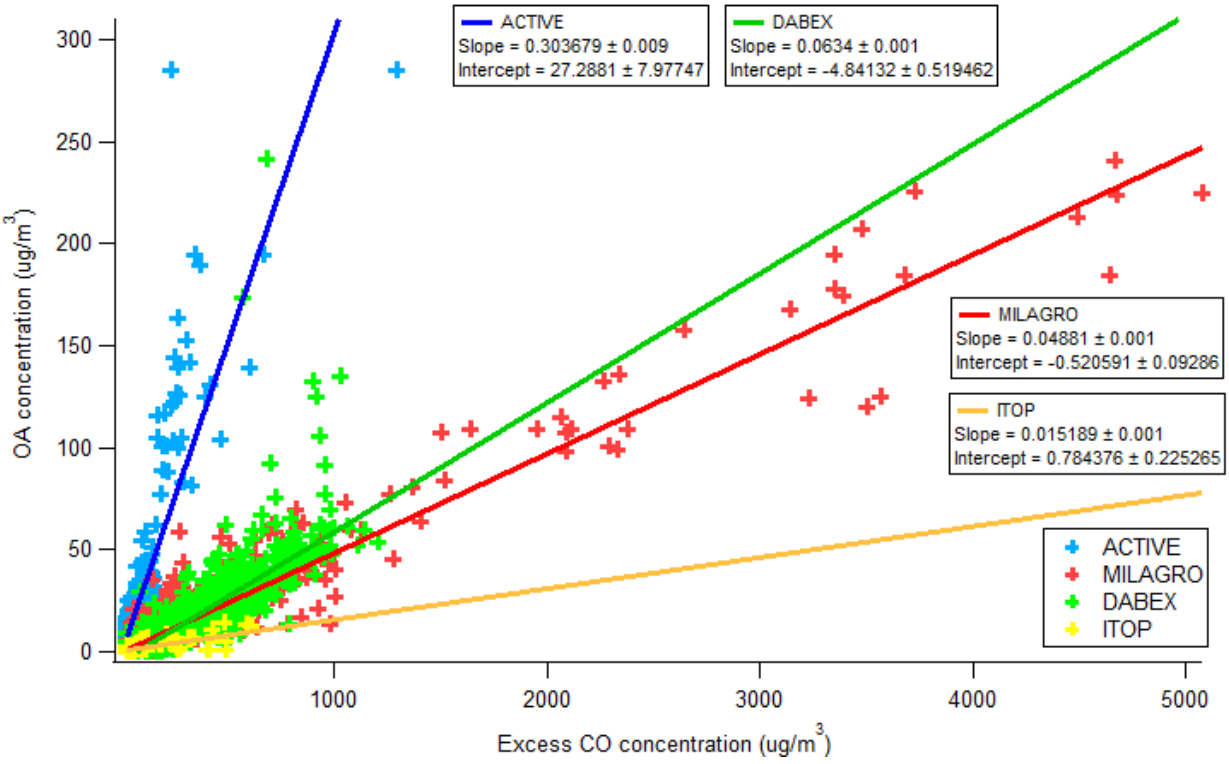

Figure 1. Organic aerosol mass concentration versus excess CO for all data meeting selection criteria throughout each campaign included in this study. Coefficients are for linear regressions applied to datasets, with uncertainties of ± 1σ.

Large use of wood combustion for domestic heating in France: impacts on the air quality in rural environments

C. Piot[1,2], J. Cozic[2], J.-L. Besombes[1] and J.-L. Jaffrezo[2]

[1]Université de Savoie-LCME, Le Bourget du Lac, France

Presenting author email: christine.piot@lgge.obs.ujf-grenoble.fr

France is the leading consumer of wood energy in Europe for domestic heating with an annual consumption of 7.3 million PET. This consumption is being increased due to the use of wood burning for domestic heating often considered by policy makers as an interesting source of renewable energy. Therefore, an increased impact of residential wood burning emissions on air pollution can be expected and a growing number of scientific studies have recently focused on the influence of these emissions on the ambient aerosol concentration. Indeed, biomass burning can represent an important source of Particulate Matter (PM) and carcinogenic compounds like Polycyclic Aromatic Hydrocarbons (PAH).

For example, biomass burning was found to account for 42% of PM2.5 in Grenoble during winter (Favez *et al.*, 2010) and for 41% of the organic aerosol in Zurich (Szidat *et al.*, 2006). However, there are few studies in the literature on the impacts of wood combustion on the air quality in rural environments in France. The need to study contributions of this source to the air quality in rural sites is increased since this type of emissions is very dependent of local fuel and practices (e.g. type of wood burned).

The Particul'Air program was proposed to investigate the chemical composition and sources of PM during one year: 9 week-long campaigns, from March 2009 to February 2010 simultaneously in 9 rural sites (3 rural background sites and 6 rural exposed sites) located along a West-East transect. A focus was put on the determination of biomass burning chemical tracers (levoglucosan and its isomers) and on the apportionment of this source. Additionally, detailed chemical composition of PM10 and source apportionment were also studied in 2 other rural background sites from the EMEP network (as part of the CAMERA program) since January 2011 (1 daily sample per week). In both programs, PM10 were collected by French air quality networks on quartz filters with high-vol. samplers (Digitel DA-80).

On average, levoglucosan represents a large part of organic matter (OM) in winter for rural sites, and its fraction tends to increase from West to East of France (Fig.1). It represents only a minor fraction in the summer season. For the two background sites from the EMEP network (BACK 4 and 5 on Fig.1), the concentrations are much lower than in other rural sites, indicative of a lower impact of biomass burning emissions in remote areas. Conversely, the contribution of biomass burning tracer to OM is very high for the exposed rural site "EXP5" located in an Alpine valley. This is valid both for winter and summer, and the contributions to OM are even larger than that measured by Favez et al. (2010) in Grenoble in winter (50 $mg.g^{-1}_{OM}$).

Source apportionment using the Chemical Mass Balance (CMB) method was performed for all these sites. It shows that in winter, biomass burning emissions accounts for between 10 and 60 % of PM10 in these rural sites. The presentation will discuss these results in detail, including limitations and uncertainties.

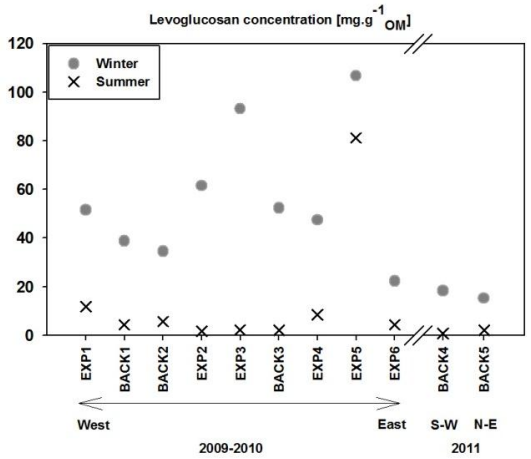

Figure 1. Average levoglucosan concentrations in rural sites background (BACK) and exposed (EXP) in winter and in summer in $mg.g^{-1}_{OM}$.

Burning of Olive Tree Branches: A Major Organic Aerosol Emission Source in the Mediterranean

E. Kostenidou[1], C. Kaltsonoudis[1,2], E. Louvaris[1,2], M. Tsiflikiotou[1,2], and S.N. Pandis[1,2,3]

Presenting author email: v_kostenidou@chemeng.upatras.gr

Burning of olive tree branches is a common agricultural waste management technique after the pruning of the olive trees during the months November to February. Almost 90% of the global olive trees are located around the Mediterranean Basin, so the emissions of olive tree branches burning in this area can be a significant source of fine aerosols during the cold months.

Organic aerosol produced by olive tree branches burning was characterized with both directed source-sampling (using the ICEHT smog chamber) and with ambient measurements during the burning season. A thermodenuder coupled with a High Resolution Aerosol Mass Spectrometer (HR-AMS) and a Scanning Mobility Particle Sizer (SMPS) were used for the particulate phase characterization, while the gas phase emissions were measured by a Proton Transfer Reaction Mass Spectrometer (PTR-MS), NO_x O_3, CO and CO_2 monitors.

The organic AMS mass spectrum changes with aging as the f_{44} increases while the f_{43} decreases (Figure 1). After the thermodenuder the organic mass fraction remaining at 80°C is around 50%, implying that the olive tree branches burning aerosol is semi-volatile. The thermodenuded mass spectrum is different from the original mainly at *m/z's* 44 and 43 which increase and decrease correspondingly for the less volatile OA components.

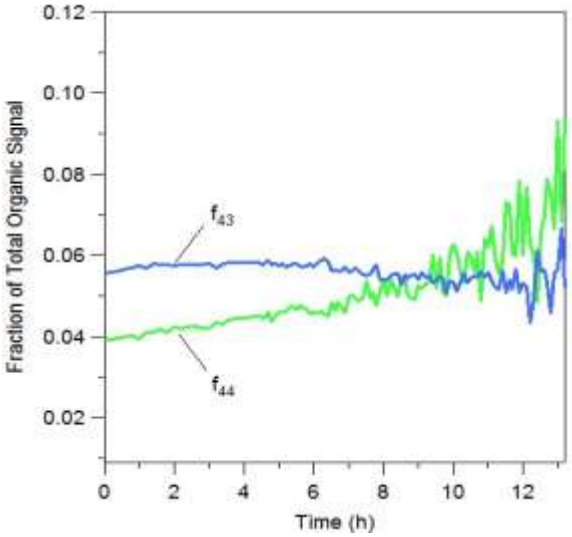

Figure 1. f_{44} and f_{43} of olive tree branches burning organic aerosol during aging.

The chamber organic AMS spectrum resembles the ambient mass spectrum during olive tree branches burning events (Figure 2).

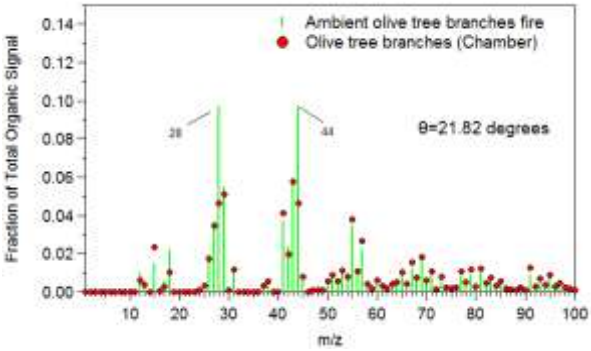

Figure 2. Mass spectrum of olive tree branches burning compared with ambient mass spectrum during olive tree branches fires event

The AMS mass spectrum of the olive tree branches burning differs from the other published biomass spectra. The levoglucosan tracer at *m/z* 60 is lower than in the most biomass burning sources. This may lead to an underestimation of the biomass burning in the Mediterranean Area, where the emissions of olive tree branches burning are high and levoglucosan is being used as a wood burning tracer.

Our estimates for the emissions from olive branch burning suggest that this is the most important fine aerosol emission source during the winter months in the Mediterranean countries in which this activity is prevalent.

Airborne measurements in the lower atmosphere in Finland during Russian wildfires in the summer 2010

Introduction

Atmospheric aerosol particles have both climate (IPCC, 2007) and health related effects (Vaclavik Bräuner et al., 2007). Particles are emitted into the atmosphere a multitude of sources. This study attends to wildfires in Russian forests and peat bogs and precisely emissions transported to Finland in summer 2010. In the end of July were made 4 flights overall to East and Central Finland because of Russian wildfire emissions. We measured total particle concentration and carbon dioxide as a function of altitude.

Methods and experimental setup

The flights were carried out in 29-30 of July 2010. We made profiles in the lower atmosphere from the ground level up to the 3.8 km altitude. The measurement flights were made using a small aircraft, Cessna FR172F. The plane was modified to a two-seater. Behind the pilot and operator there was a measurement rack with instruments. The measurement flights were operated from and to Tampere-Pirkkala airport. The flights were flown with 80 kn airspeed.

The particle concentrations were measured by TSI-3776 Ultrafine Condensation Particle Counter (UCPC) tuned and calibrated for 3 nm cut-off size (Mordas et al., 2008) and CO_2 concentration by CO2/H2O –gas analyzer (Li-COR LI-840). UCPC provided us the total number concentration of the sub-micron particles. The location was coordinated by GPS receiver. Backward airmass trajectories at two altitudes (in the boundary layer and free troposphere) were calculated using the Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT4) model (Draxler, 1999).

Results and discussion

In the preliminary result of this study we observed total number concentrations were high ($8 \cdot 10^3$ cm^{-3}) at the altitudes of 2.5 – 3.8 km over the Jämsä area. Air masses came to Finland from Southeast at the altitude of 3000 m and from Southeast or East at the altitude of 500 m. The particle total concentration was less than ($3 \cdot 10^3$ cm^{-3}) elsewhere. At July 30th we did not detected significant emissions any more. The CO_2 concentration was about 380-390 ppm during the flights. Even at the first flight in the smoky layers we did observed nothing of the ordinary.

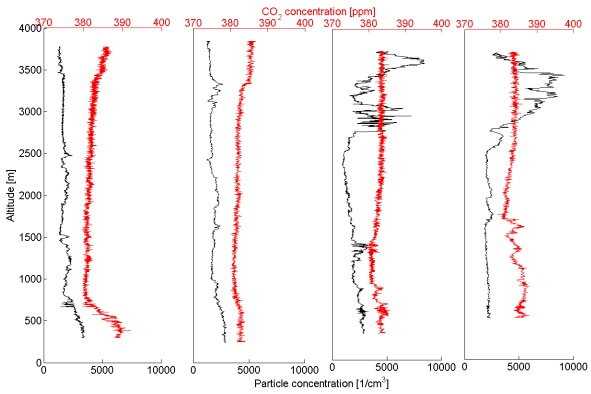

Figure 1. The total number concentration and CO_2 concentration during four altitudeprofiles on July 29th.

Keywords: fluorescence, particle shape, atmospheric aerosol.
Presenting author email: taketani@jamstec.go.jp

Among various optical techniques applied for the atmospheric particle detection, fluorescence is useful for detecting certain types of organic particles, especially those of biological origin. In this study, we employed a single-particle fluorescence sensor, WIBS-4 (Kaye et al, 2005), for the detection of fluorescence particles, to demonstrate the capability of the classification of organic particles in the ambient air.

The single-particle fluorescence sensor utilizes a continuous-wave 635 nm diode laser for the detection of particles and the determination of particle size. A quadrant photomultiplier tube (PMT) is used to detect spatial patterns of the forward scattering that can be related to the particle shape information. The scattering light signal derived from a single particle upon crossing the 635 nm-CW laser triggers two pulsed xenon UV lights (280 nm and 370 nm) for the excitation of compounds contained in the pertinent single particle. The fluorescence signals emitted from the particle are then detected by two PMTs, separately for the 310–400 nm and 420–650 nm wavelength windows.

We conducted ambient air measurements from April 21 to May 11, 2011 using the WIBS-4 instrument at our campus in Yokosuka city, facing Tokyo bay in Japan (35.32°N, 139.65°E). Figure 1 shows the temporal variations in the number concentrations of detected particles (ca. >0.8 μm, black line) and fluorescent particles (FL-particles, blue line). The "fluorescent particles" include those emitted fluorescence in either or both of the two wavelength windows. During the observation period, the ratio of the fluorescent particles to the total varied in the range of 3–53%. During May 2–4, high number concentrations were observed. From the features of the particle size and shape information, it was suggested that dust particles were mainly observed. From the fluorescence signals from individual particles, we found that some dust particles contain fluorescent compounds.

Figure 2 shows time series of number concentrations of FL-particles for different sizes. On April 26, fine particles (diameter < 2.5 μm) and coarse particles (diameter > 2.5 μm) showed peaks at different timings (in the morning and evening, respectively). The coarse particles emitted fluorescence only in the 420–650 nm wavelength range. These results suggested that the fluorescent species are different for the two cases. Further analysis (e.g., with respect to shape information) will be given in the presentation.

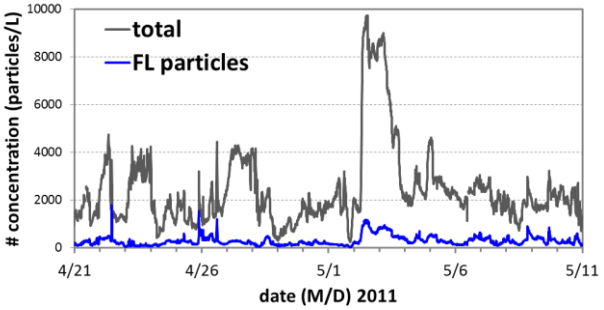

Figure 1. Temporal variations in the number concentrations (#/L) of particles measured by WIBS-4 instrument. Black and blue lines indicate total detected and florescent particles, respectively.

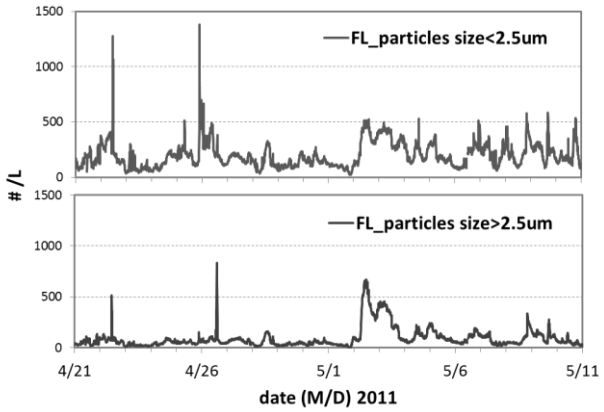

Figure 2. Temporal variations in the number concentrations (#/L) of fluorescent particles measured by WIBS-4 instrument. Upper panel shows concentration of detected fluorescent particles whose diameter is less than 2.5 μm. Lower panel shows concentration of detected fluorescent particles whose diameter is larger than 2.5 μm.

Keywords: biomass burning, levoglucosan, HPAEC-PAD, organic carbon, elemental carbon, water soluble organic compounds
Presenting author email: teresa.latorretta@enea.it

Biomass burning contributes considerably to the atmospheric aerosol composition. As biomass burning markers both Potassium and Levoglucosan can be used.

It's undisputed fact that only the last one can be considered as biogenic univocal marker.

Levoglucosan and its isomers Mannosan and Galactosan are produced by cellulose and emicellulose degradation respectively. In addiction Levoglucosan has a good stability in atmosphere and it is detectable in fine fraction of particulate (Simoneit *et al*.,1999).

In order to assess the biomass burning contribute to the atmospheric pollution a measurements campaign was performed collecting PM10 and PM2.5 particulate samples. This campaign was conducted in winter, on February 2011, in an urban site situated in Bologna (44°31'30",63 N 11°20'40",92 E), in the Po Valley, one of the most polluted region in Europe.

Concentrations of PM, OC, EC, WSOC and anhydrosugars were compared.

Levoglucosan and its isomer concentrations were determined by Dionex ICS3000 instrument using High Performance Anion Exchange Chromatography (HPAEC) with Pulsed Amperometric Detection (PAD) (Piazzalunga *et al*.); WSOC was determined by TOC 5000-a Shimadzu; OC and EC concentrations were determined by OC/EC analyser (Sunset Lab.) using EUSAAR_2 thermal optical transmittance protocol (Cavalli *et al*., 2010).

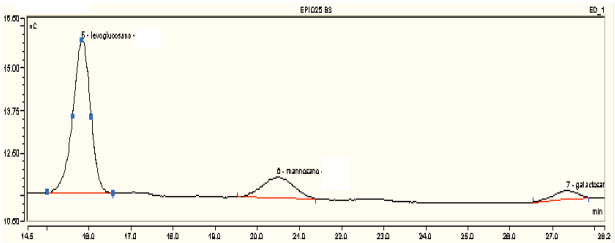

Figure 1. HPAEC-PAD chromatogram obtained from the analysis of winter PM2.5 sample collected on 19th February 2011

WSOC contributes for about 56% to OC in the fraction PM2.5 and for about 52% to OC in the fraction PM10. In the fraction PM2.5 the contribution of Levoglucosan-C to OC, of Levoglucosan-C to WSOC and of Levoglucosan-C to PM is respectively about 4% , 6.5 % and 0.7%. In the fraction PM10 the contribution of Levoglucosan-C to OC, of Levoglucosan-C to WSOC and of Levoglucosan-C to PM is respectively about 3%, 6.4% and 0.4%, confirming the most part of biomass burning is in the fine fraction.

Temporal variations of carbonaceous species and anhydrosugars contributions to fine and coarse aerosols are discussed.

Mobile measurements for the detection of wood combustion: a case study in a rural environment

M. Van Poppel, N. Bleux, J. Peters, J. Van den Bossche P. Berghmans

VITO - Flemish Institute for Technological Research, 2400 Mol, Belgium

Presenting author email: martine.vanpoppel@vito.be

Wood combustion is a growing concern in rural environments. Recent studies show that wood combustion has a significant impact on PM concentrations and can result in increased numbers of exceedence of the PM_{10} limit value. In Flanders, residential wood combustion is responsible for 7 % of the PM_{10} emissions. Source apportionment studies suggest that wood combustion in rural areas is a larger contributor to PM_{10} as compared to traffic (Vercauteren et al., 2011). In addition, health impact might be significant since incomplete combustion can result in ultrafine particles (UFP), BC (black carbon) and other compounds such as benzene and PAHs (Tapanainen et al., 2011).
Local combustion sources will impact the local air quality. However, this implies knowledge of the exact location of the sources and this knowledge is limited so far. The feasibility of using time-resolved instruments installed at a mobile platform to identify hot spots of combustion aerosols in a rural residential setting is evaluated.

At VITO, a measuring bike – called Aeroflex – was developed for mobile measurements and mapping of UFP (P-trak, TSI), PM (Grimm Dust monitor) and BC (µ-Aethalometer, AethLabs). The tool is already extensively used in urban environments and industrial locations for respectively hot spot identification and source identification. In this study, a case study is presented to evaluate the tool for the detection of hot spots related to wood combustion, and to differentiate this from traffic related emissions.

A mapping was performed in a rural area where the use of wood combustion at different houses was known. Figure 1 shows an example of the mapping for UFP. Most peaks with high concentrations could be linked to wood combustion. Time profiles for BC, UFP and PM_{10} are presented in Figure 2. For BC a similar profile was observed. In this study, BC (1s) raw data were first processed using the Optimized Noise-reduction (ONA) algorithm to reduce noise (Hagler et al., 2011). PM_{10} concentrations were also observed to increase in the vicinity of wood combustion sources.

From this preliminary study, significant spatial heterogeneity both in BC and UFP concentrations was observed, due the presence of residential wood combustion particles. A further analysis of currently running experiments will be shown. hereby focussing on the correlations between different pollutants in order to distinguish between traffic related pollution and wood combustion.

Forest and vegetation fires are a relevant atmospheric source of both trace gases and aerosols (Crutzen and Andreae, 1990; Andreae and Merlet, 2001). Biomass burning has an important impact on the atmospheric chemistry, air quality, climate and on global biogeochemical cycles. Europe, and specially the Mediterranean area, is a region that suffers, mostly in warm seasons, the effects of wildfires. The aim of this work has been to study the relation between the wildfires occurred in summer 2006, which affected both Galicia (Spanish northwest) and the north of Portugal and an exceptional air pollution event observed in the southwest of the Iberian Peninsula (IP) which produced the increase of air pollutants to historical levels in some air quality stations of this region (Adame et al., 2012).

The air pollution event was recorded by several air quality stations located in this region, both inland and coastal zones. These stations belong to the Air Quality Network of the Environmental Council, Andalusia Government. Three stations are suburban background (San Fernando, Aljarafe and Santa Clara), two urban backgrounds (El Carmen and Jerez) and one rural background (El Arenosillo). Three are located close to the coastal line (El Carmen, El Arenosillo and San Fernando) and three inland (Jerez, Aljarafe and Santa Clara). In the stations mentioned have been recorded surface ozone, NO_2, CO, particle number concentration and PM10, but in all the stations not all the species are measured. To know the trajectory performed by the air masses that reach the event area, HYSPLIT model has been used whereas the WRF-ARW model has been used to achieve a detailed understanding of the mesoscale meteorological conditions.

The fires start on 2 August and were extinguished on 16 August. Air pollution event occurred in the southwest of the IP from 12 to 13 August. The air pollution event in the southwest starts approximately at 17:00 UTC on 12 August when an unexpected increase on surface ozone was observed in the two coastal stations of El Arenosillo and El Carmen. From 18:00 to 21:00 UTC, the 200 μg m^{-3} as hourly values of surface ozone in both monitoring sites are exceeded, with peaks of 271 and 200 μg m^{-3} at 19:00 UTC at El Arenosillo and El Carmen, respectively. At this time, particle number concentration in the accumulation mode, which was monitored at El Arenosillo, was 8380 cm^{-3}.

At El Carmen station a remarkable increase of CO was also measured. From 17:00 UTC on 12 August to 3:00 UTC on 13 August the 1500 μg m^{-3} was exceeded continuously, with a peak of 1870 μg m^{-3} at 23:00 UTC. PM10 concentrations were also increased at El Carmen from 18:00 UTC on 12 August with a peak of 243 μg m^{-3} at 23:00 UTC.

From 23:00 UTC on 12 August, surface ozone starts to increase at San Fernando and Jerez stations, remaining during the night with values up to 140 μg m^{-3}. At 00:00 UTC on 13 August, peaks of 157 and 191 μg m^{-3} are measured at Jerez and San Fernando respectively. Regards to the CO, at San Fernando a peak of 1558 μg m^{-3} was registered at 23:00 UTC on 12 August, while at Jerez 167 μg m^{-3} were collected at 2:00 UTC on 13 August.

From 00:00 to 13:00 UTC on 13 August the PM10 in both monitoring sites remain at 100 μg m^{-3}, with maximums of 184 μg m^{-3} at 00:00 and 162 μg m^{-3} at 08:00 UTC at San Fernando and Jerez respectively.
Thanks to the modelling tools, have been known that after travelling approximately 1000 kilometres along the Atlantic coast of Portugal, the fire plume went parallel to the Gulf of Cadiz, affecting from the coast line to almost 40-50 km inland. However, the urban stations located in the metropolitan area of Seville were not affected, since air masses from the north didn't reach this area.

Acknowledgements: Thanks to the Environmental Council of the Junta de Andalucía for supplying the air quality data from the Air Quality Network to perform this work. We acknowledge NOAA ARL for provision of the HYSPLIT transport. Mar Sorribas thanks Ministerio de Economía y Sostenibilidad (MICINN) for the award of a Juan de la Cierva post-doctoral grant.

Identification of African dust influence to PM_{10} concentrations at the Athens air quality monitoring network during 2010

V. Aleksandropoulou and M. Lazaridis

Department of Environmental Engineering, Technical University of Crete, Chania, Polytechneioupolis, 73100, Greece

Keywords: urban aerosols, mineral dust, legislation and policy.

Presenting author email: vic.aleksandropoulou@enveng.tuc.gr

In the current study we analyse the concentrations of PM_{10} during 2010 at the Athens monitoring network with the objective to identify high PM_{10} events, exceeding the PM_{10} daily limit values (Air Quality Standard - AQS of 50μg/m^3), caused by natural particulate inputs produced by Sahara air mass intrusions. The day averaged PM_{10} concentrations used in the analysis were retrieved from the Hellenic Ministry for the Environment, Energy and Climate Change. In the Athens Metropolitan Area the concentrations of PM_{10} were recorded during 2010 at 3 traffic urban stations (Aristotelous - ARI, Marousi - MAR and Pireaus-1 - PIR-1) and at 4 background suburban stations (Lykovrisi - LYK, Agia Paraskevi - AGP, Thrakomakedones - THR and Koropi - KOR).

The methodology presented in EC (2002) was used to identify possible Saharan dust influences on PM_{10} concentrations. Initially simultaneous time series of different monitoring stations of the network and from a rural background area (Aliartos-ALI station; data were available only for the period 29/7/2010 – 31/12/2010) close to the monitoring sites were compared and coincident peaks in PM_{10} concentration were identified. To confirm the occurrence of desert dust events information were combined from the OMI aerosol index maps, satellite imagery from the NASA SeaWiFS Project (surface level); daily dust load maps over Europe and the Mediterranean (BSC-DREAM8b model, operated by the Barcelona Supercomputing Center), 5-day back-trajectories obtained using the HYSPLIT4 Model (Draxler and Rolph, 2012; at the coordinates of each station at 10 m above ground, at 00, 06, 12 and 18 UTC, isentropic), 6-h 3D trajectory data calculated using Flextra trajectory model for the Aliartos station (available from EMEP/CCC) and synoptic meteorological charts available every 6 h from the NCEP/NCAR Reanalysis Data Composites of the NOAA Earth System Research laboratory. Finally, in order to calculate the daily African PM load during dust outbreaks and estimate how many of the exceedences could be attributed to Saharan dust outbreaks or to anthropogenic sources the methodology presented by Escudero *et al.* (2007) was used (1/8/2010 – 31/12/2010). The daily rural background levels were obtained by applying a monthly moving 30th percentile (Querol *et al*, 2009 for rural background stations in the Mediterranean Basin) to the PM_{10} time series after a prior extraction of the days with African dust influence.

Descriptive statistics of PM_{10} concentrations at Athens monitoring stations and the rural background Aliartos station are shown in Table 1. It is observed that the current annual AQS was exceeded at the traffic urban stations, whereas the daily AQS for PM_{10} concentrations was exceeded at all the stations besides AGP. Most cases of non-attainment to AQS occur during the cold period. In particular, during February, November and December the meteorological conditions favour the transport of air masses loaded with dust from North Africa over the Eastern Mediterranean. Also in Table 1 are depicted the descriptive statistics of PM_{10} concentrations at Athens monitoring stations after prior extraction of the days with not attainment of the AQS coinciding with African dust outbreaks. It is observed that the current annual and daily AQS was still exceeded only at the ARI station. Finally, by subtracting the African net dust load during the period August to December it was found that only 48% to 67% of the exceedences can be attributed to the African dust influence.

Table 1. Daily averaged PM_{10} concentrations and days with not attainment of the AQS during 2010.

Station	Concentration (μg/m^3)*	Days with Exceedences*
MAR	40.6±19.5 (36.0±11.0)	63 (17)
THR	36.7±19.0 (31.8±11.6)	43 (9)
AGP	28.2±16.5 (24.9±9.5)	22 (1)
LYK	38.6±26.2 (32.6±10.4)	56 (12)
PIR-1	44.1±20.2 (37.2±11.7)	62 (18)
KOR	35.5±25.4 (30.0±11.7)	38 (7)
ARI	48.6±29.7 (40.7±12.2)	99 (36)
ALI	29.1±15.4	9

*The values in brackets correspond to the results after excluding the days with not attainment to the AQS coinciding with Saharan dust events.

Identifying desert aerosols episodes in Cáceres (Spain)

M.A. Obregón[1], A. Serrano[1] and M.L. Cancillo[1]

[1]Department of Physics, University of Extremadura, Badajoz, Extremadura, 06006, Spain
Keywords: atmospheric aerosols, African dust, CIMEL, HYSPLIT.
Presenting author email: nines@unex.es

Atmospheric aerosols, in general, act upon cloud formation and modification, can be very harmful for human and animal health (Dockery and Pope, 1994), and play a substantial role in the Earth's radiation balance producing cooling or warming of the atmosphere depending on their physical characteristics. According to the Intergovernmental Panel on Climate Change 2007, the worldwide average aerosol direct radiative forcing is estimated to be about -0.5 [-0.9 to -0.1] W/m^2 and the worldwide indirect forcing about -0.7 [-1.8 to -0.3] W/m^2, thus contributing to the cooling of the planet. Furthermore than these average figures, there is still a large uncertainty concerning their climate effects. Thus, it is of particular interest to identify different types of aerosol and analyze the effects associated to each type. For this aim, the first step to take is to develop methodologies to achieve a reliable classification of aerosols.

One type of aerosol with a remarkable interest in the Iberian Peninsula is the "desert" one, corresponding to desert dust arriving from the near Sahara Desert in the North of Africa. The intrusions of these aerosols show a typical seasonal pattern driven by the annual latitudinal displacement of the general atmospheric circulation (Cachorro et al, 2005).

In order to properly identify desert aerosols reaching Cáceres (Western Spain), in this study a classification criterion is applied to measurements recorded at the Cáceres station by a CIMEL photometer. This station belongs to the AERONET (Aerosol Robotic NETwork) global aerosol network. The applied criterion is based on the analysis of 120-hour back-trajectories arriving at Cáceres during well-defined desert dust episodes. These trajectories were calculated using the HYSPILT (HYbrid Single-Particle Lagrangian Integrated Trajectory) model (Draxler and Hess, 1998). The trajectories calculated for this study correspond to an arriving time of 12:00 UTC and to heights of 1500 and 3000 m a.s.l.

For this purpose, seven well-defined desert episodes were selected analyzing the spectral optical depths, the Ångström α exponent and the air mass trajectories. Additionally, eight areas corresponding to possible origins of the air masses were establised: "Local", "Peninsula", "Rest of Europe", "Mediterranean Sea", "North Africa", "Tropical Atlantic", "Rest of the Atlantic", and "Arctic".

After analyzing the trajectories of air masses for these selected episodes, the number of hours that air masses spend on each region has been calculated. A common situation observed in all desert events is that the trajectories at 1500 or 3000 meters showed more than 40 hours over the region named Africa, and even in the case the trajectories spend less than 40 hours on this region, they circulate over the tropical Atlantic during more than 60 hours. This criterion for identifying desert events was applied to the whole set of trajectories during the period between July 2005 and July 2011, finding 99 trajectories that matched this criterion. More than 60% of these cases occur between April and August, in agreement with the seasonal pattern of desert dust events typical in the Iberian Peninsula. Figure 1 shows the trajectories of these 99 days at 3000 m a.s.l. It can be seen that most trajectories show similar path evidencing the transport of aerosols from Saharan Desert to the Iberian Peninsula. The desert character of the aerosol of the identified cases has been validated by analyzing the τ and α values measured by the CIMEL existing in Cáceres. Results indicate that 92% of cases were positively identified as desert while the remaining 8% correspond to other types. These results support the good performance of the proposed criterion.

Figure 1. 120 h back trajectories at 3000 m a.s.l. arriving at Cáceres during the days identified as desert aerosol according the new criteria proposed in this study.

Mineralogical composition and origin of airborne particles during dust events in the Eastern Mediterranean

I. Kopanakis[1], T. Glytsos[1], D. Pentari[2], V. Perdikatsis[2] and M. Lazaridis[1]

[1]Department of Environmental Engineering, Technical University of Crete, Chania, Greece
[2]Department of Mineral Resources Engineering, Technical University of Crete, Chania, Greece

Keywords: Sahara dust event, mineralogical composition, illite.

Every year, the vast area of Sahara and Sahel deserts, in North part of Africa, produce thousands of tones of airborne particles with considerable consequences in global climate, ecosystems and health. Produced particles from wind erosion can be transferred at long distances such as the Mediterranean Basin, Atlantic Ocean and Scandinavia.

Saharan particulates were found to be composed mainly of oxides and carbonates - principle constituents of the Earth's crust. The main aim of this study was: (1) to examine the origin of the eolian airborne particles during dust events and (2) to determine the mineralogical composition of different airborne Saharan dust samples which were collected during spring time in the period 2004-2009. The sampling of particulate matter took place at the Akrotiri station which is an urban background station on the island of Crete (Greece) (Lazaridis et al., 2008). In the current work, airborne dust samples measured in a period of 5 years were examined.

In total, five airborne dust samples were collected during intense Saharan dust events in canisters. Canisters were used in the sampling, which are a kind of precipitation samplers. The sampling was performed in the spring period during 2004, 2005, 2006 and 2009. The first 3 samples (S1, S2 and S3) were deposited in the canisters during wet deposition. Furthermore, during the year 2009, two other samples were collected (S4 and S5), one from dry deposition and the second, the same day, during wet deposition. The wind direction of the air masses during the sampling was from south directions. The transported air masses stayed at least one day above the African deserts before moving north to the island of Crete. Elevated $PM_{2.5}$ mass concentrations were recorded at the station in comparison to the time periods before and after the Saharan dust event, as it is depicted in Figure 1.

The bulk mineralogy of the collected dust was determined by X-ray powder diffraction (PXRD). Table 1 presents the dates of each sampling and the corresponding mineralogical composition. The results showed that Illite was the most abundant mineral identified in all samples. The mean percentage was 31.8% for the rain-collected samples and 30.0% for the airborne dust sample. It is believed that the percentage of illite is elevated when dust comes from the regions of Chad, compared to the Egyptian and Libyan deserts.

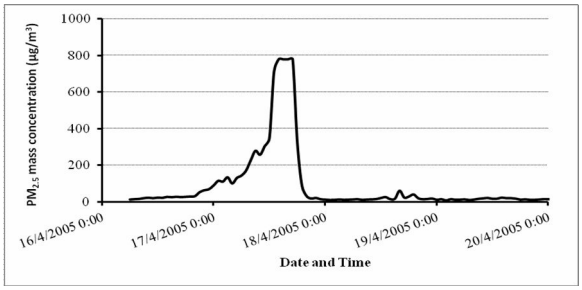

Figure 1: $PM_{2.5}$ mass concentration during an intense Saharan dust event on 17/4/2005.

Illite, quartz and calcite were the main components of mineral dust, in accordance with other XRD measurements on desert-derived dust (Blanco et al., 2003). Furthermore, the kaolinite percentage is much lower, in comparison to other measurements where kaolitine is found to be either the most abundant mineral in dust collected in the eastern Mediterranean Sea or represents a higher fraction (30%) of the minerals found in the dust originated from Libyan and Egypt**.**

Aerosol deposition in the main African dust transport region: establishing a long-term time series at Sao Vicente, Cape Verde

K. Kandler[1], L. Mendes Neves[2], N. Niedermeier[3], and T. Müller[3]

Mineral dust is one of the dominating aerosol species in the atmosphere. Particularly, the tropical North Atlantic Ocean is heavily affected by dust, changing cloudiness, precipitation, nutrient fluxes into the ocean, radiation balance etc. A number of field experiments with different foci recently investigated dust properties (e. g., SAMUM, AMMA, SHADE, PRIDE, GERBILS). However, these experiments usually lasted a short time, usually a few weeks, some a season. As a result, they captured a low number of dust episodes only. Given the highly episodic nature of dust outbreaks and a potential inter-annual variation, the question arises, how these experiments should be rated with respect to an annual average, or how they can be compared to each other. This actual problem arises from the nonexistence of longer time series in the tropical North Atlantic Ocean (except at Barbados; Trapp *et al*, 2010).

While the shortcomings in the past can't be changed, a quasi-continuous measurement of aerosol deposition was installed in the middle of December 2012 at the Cape Verde Atmospheric Observatory (http://ncasweb.leeds.ac.uk/capeverde/), at the Island of Sao Vicente Island, Cape Verde. Aerosol deposition is measured by a passive aerosol sampler, modified from Ott and Peters (2008) "type A – flat plates" by introduction of a liquid trap and lowering the recipient position slightly below the level of the lower plate. 25 mm diameter aluminum stubs coated with standard electron microscopy carbon adhesives were used as sampling surface. The analysis was made with an acceleration voltage of 20 kV and a beam diameter of 2.6 nm. The particles were classified according to their chemical composition into eight classes (Fig. 1). For details on the materials and methods as well as the data processing refer to Kandler *et al* (2011).

Three samples in December 2011 could be analyzed as a start of the time series (total of 1841) particles. Trajectory calculations (HYSPLIT/GDAS) showed that during all period dust was transported straight from Mauritania and South Morocco to Cape Verde (about 24 to 30 h transport time from the coast), so the differences in dust abundance – also seen in the aerosol volume concentrations measured by Scanning Mobility Particle Sizer and Aerodynamic Particle Sizer (74, 33 and 48 cm^3/m^3 for SVS_101/2/3) – are most probably linked to dust emission variation.

The relative abundance of dust increases with the particle size between 1.5 and 10 µm (Fig. 1). The ratio of quartz to the silicate dust varies between 0.1 and 0.3. Sulfate plays a minor role during the more maritime periods and is absent during the dustier phase. Interestingly, the amount of mixed particles (internal mixtures of dust and sea-salt) is largely higher for particles of 5 – 10 µm diameter than for those with 2.5 – 5 µm. This points to an increased deposition flux of dust particles internally mixed with sea-salt, as proposed by Zhang (2008). It indicates that during the observed dust intrusions, larger pure particles have already been removed by sedimentation.

Presenting author email: sonia.castillo@dgeo.uhu.es

The mineral dust deposition, originated from the African dust outbreaks episodes, influences largely in deposition fluxes of metal nutrients in Southern Europe (Avila, 1996) and oceanic regions (Arimoto, 2001). The low precipitation in the Mediterranean basin favours the long residence time of dust in the atmosphere with the consequent impact on air quality and in atmospheric deposition. Recently, more studies are coming out about the impact of dust from deserts on health. An association between the increase of hospital admissions (respiratory and cardiovascular causes) and days with Saharan dust episodes (Perez et al., 2008) shows the evidence of the importance of these natural episodes in areas closely to Sahara desert.

Most studies that quantify the Saharan dust deposition have only measured the soluble fraction. In this study we compare the fluxes both in the soluble and insoluble fractions for the wet and dry deposition at two sites located at different distances from North Africa. One sampling site was in a rural area of the North-eastern of the Iberian Peninsula, in the Montseny Mountains (MSY) at 40km NNE from Barcelona. The other site was in the city of Santa Cruz de Tenerife (SCO) in Canary Islands.

The atmospheric deposition fluxes depend of the concentration of suspended particulate matter (SPM) in the atmosphere. In SCO where SPM levels were 3.3 times higher than in MSY, for the same period, the total annual deposition levels registered was up 29 g/m^2 while in MSY was up 20.9 g/m^2 (Table 1).

Table 1. Annual deposition levels (g/m^2) both in soluble and insoluble fractions in wet and dry deposition.

		soluble	insoluble	Total
MSY	DRY	2.9	4.3	7.2
	WET	8.0	5.7	13.7
	TOT			20.9
SCO	DRY	6.7	10.4	17.1
	WET	6.8	5.1	11.9
	TOT			29.0

It´s highly remarkable the dependence of climatology in the deposition fluxes. In MSY with an annual mean precipitation of 800-1000 l/m^2, 65% of SPM deposited was by wet deposition mode. In SCO with an annual mean precipitation of 200 l/m^2 was 41%. However, total wet deposition amounted to 13.7 g/m^2 in MSY and 11.9 g/m^2 in SCO (Table 1). The relatively high fluxes registered in SCO by wet deposition were accounted largely by the high sea spray contribution at this coastal site (being this 62% of the total mass, Na^+ and Cl^-) and the dust transported from Sahara and Sahel deserts (Ca^{2+} was 20% of the total mass). .

By contrast, dry deposition registered major annual levels in SCO than in MSY by a factor of 2.4, with 17.1 g/m^2 in SCO against 7.2 g/m^2 in MSY (Table 1). This is the result of the sea spray contribution (46% of total mass) and the high influence of the African dust outbreaks above the Islands (Ca^{2+} reaches 32%) under the quasi-permanent dry meteorological conditions in the Canary Islands. The vast amount of dust transported from Sahara and Sahel deserts into Atlantic Ocean generate elevated dry deposition fluxes of mineral dust to the surface.

Calcium presents the highest contribution in MSY and SCO. In MSY, with high precipitation and low levels of SPM, Ca^{2+} contribution is similar in wet and dry deposition and more elevated in the soluble fraction. In SCO, with low precipitation, high SPM levels and an elevated influence of African dust outbreaks, Ca^{2+} dominates in dry deposition, and is higher in the insoluble fraction.

Sodium content (originated by sea spray) is the second highest contribution in SCO (high sea spray emission rate in Atlantic Ocean) but not in MSY (low emission rate in Mediterranean Sea). Moreover, due to the high solubility of this species, the major contribution is in the soluble fraction, which is the dominant fraction (both in wet and dry deposition) at SCO.

Laboratory investigations of contact and immersion freezing of mineral dust using two techniques: vertical wind tunnel and acoustic levitator

K. Diehl, H. Schmithüsen, M. Debertshäuser, S.K. Mitra, and S. Borrmann

Institute of Atmospheric Physics, Johannes-Gutenberg University, 55099 Mainz, Germany
Keywords: laboratory experiments, heterogeneous ice nucleation, mineral dust
Presenting author email: kdiehl@uni-mainz.de

According to model studies (e.g., Storelvmo *et al*., 2008) the type and quantity of atmospheric ice nuclei affect ice cloud microphysical and radiative properties as well as their precipitation efficiency. The role of mineral dust particles as ice nuclei is undoubted, however, information from laboratory experiments are available so far mainly for two mineral dust types, kaolinite and montmorillonite (e.g., Pitter and Pruppacher, 1973). Some most abundant minerals occurring in desert aerosols as e.g., quartz, calcite, mica, hematite, illite, and gypsum have not been investigated so far in immersion and contact freezing modes. New experimental results will serve as base for parameterizations to estimate the effects of new mineral dust types on cloud microphysics (Diehl *et al*., 2006).

Two methods are used in the laboratory: the Mainz vertical wind tunnel (e.g., v. Blohn *et al*., 2005), and an acoustic levitation technique (e.g., Diehl et al., 2009). In both cases drops are freely levitated, either at their terminal velocity in the wind tunnel updraft or around the nodes of a standing ultrasonic wave. Thus, heat transfer conditions are well approximated, and wall contact effects on freezing as well as electrical charges of the drops are avoided. Ambient temperatures reach -30°C in the wind tunnel and -40°C in the cold chamber where the acoustic levitator is placed. Drop radii are 180 to 400 µm and 0.5 to 3 mm, respectively. Immersion freezing is a volume-dependant process so that the results for different drop sizes allow deriving volume-dependant parameterizations for various types of ice nuclei. Contact freezing as it is not drop size dependant is investigated with the levitator technique only.

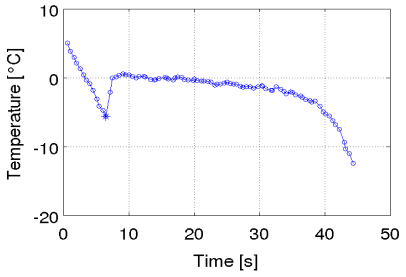

Figure 1. Temporal development of drop surface temperature during freezing in acoustic levitator.

Experiments are carried out either with drops containing a defined amount of ice nuclei (immersion freezing) or with pure water drops colliding with ice nuclei (contact freezing). In the wind tunnel, the onset of freezing is observed directly. The use of the acoustic levitator allows measuring the temperature of the drop surface by an in-situ calibrated Infrared thermometer as the drops are very stationary. Because of the release of latent heat the onset of freezing is indicated by a rapid rise of the drop surface temperature as shown in Figure 1. The time period needed to completely freeze the drops is indicated as the surface temperature again decreases afterwards.

Table 1. Freezing temperatures for various mineral dust types and freezing modes.

mineral dust type	**freezing mode**	T_{min} **(°C)**	T_{median} **(°C)**	T_{max} **(°C)**
montmorillonite	contact	-19.0	-8.7	-2.8
montmorillonite	immersion	-22.8	-18.0	-6.3
mica	contact	-20.0	-12.3	-2.2
mica	immersion	-22.0	-18.7	-4.2
illite	contact	-21.9	-15.4	-2.9
illite	immersion	-23.3	-19.9	-10.6

So far, experiments have been performed with montmorillonite to test the acoustic levitator set-up and with mica and illite as new samples. Results are given in Table 1. The median freezing temperatures of illite and mica are lower than the ones of montmorillonite which stands so far for the most efficient mineral dust type, but they are still somewhat higher than the ones of kaolinite (e.g., Pitter and Pruppacher, 1973) which might represent the lower limit for mineral dust. Additional wind tunnel experiments with illite and mica in the immersion mode will account for smaller drop sizes. Besides that, experiments with both techniques will be continued with hematite and results will be presented at the conference together with parameterizations based on the new data.

Long-term Chemical Characterization of Aerosol at the CVAO

K. Müller, K. W. Fomba, E. Brüggemann, T. Gnauk, G. Spindler, H. Herrmann
Department of Chemistry, Leibniz-Institute of Tropospheric Research, 03418 Leipzig, Germany

Keywords: Saharan dust, long-term observation, chemical constitution
Presenting author email: konrad@tropos.de

The Sahara and the North-East trade winds are responsible for the entry of enormous amounts of dust into the Tropical North Atlantic. The geographical location of the Cape Verde Islands makes the islands suitable for scientific investigations of ocean and atmosphere interactions. Starting during SOPRAN I in 2007, the collection and chemical characterization of PM_{10} particles by a high-volume filter sampler was carried out at a 30m tower near the north-eastern coastline of the island São Vicente. During intensive campaigns, size-segregated sampling of PM took place additionally. Seasonal and inter-annual variations of the transportation of Saharan dust have been observed. The observations show a maximum of Saharan dust entries during winters but episodes of high dust concentration were observed in other seasons, too (Fig. 1).

In the focus of the chemical characterization of PM_{10} aerosols was the iron concentration (Fig. 2) and their seasonal and interannular variation. Iron and other transition metals were analysed from impactor samples taken during intensive campaigns only on polycarbonate foils. Typically, the dust fraction was found in the coarse mode PM but in some samples strongly elevated concentrations were found in the fraction 0.14-0.42 µm.

Secondary inorganic species (non-sea-salt sulphate, nitrate and ammonium) and OC/EC were determined. During dust events highest concentrations of all anthropogenically emitted species were found as well. The transport of secondary ionic species, EC and OC from the African continent is combined with Saharan dust events.

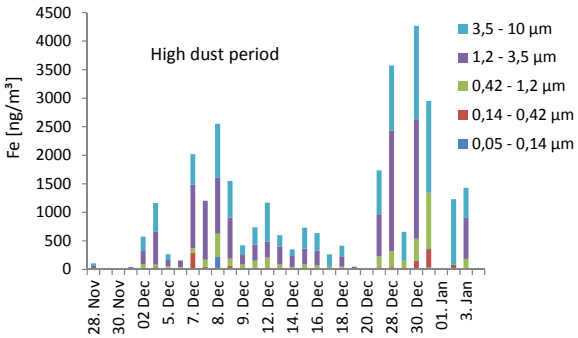

Figure 2. Iron concentration in size fractions of the impactor during dusty season in winter 2007/2008 (From a few samples not all size fraction have been analysed.).

This work was funded by the German BMBF under the grant No. FKZ 03F0611J. The authors have to thank Luis Mendes and Helder Timas from the INMG in Mindelo, CV, for their technical support.

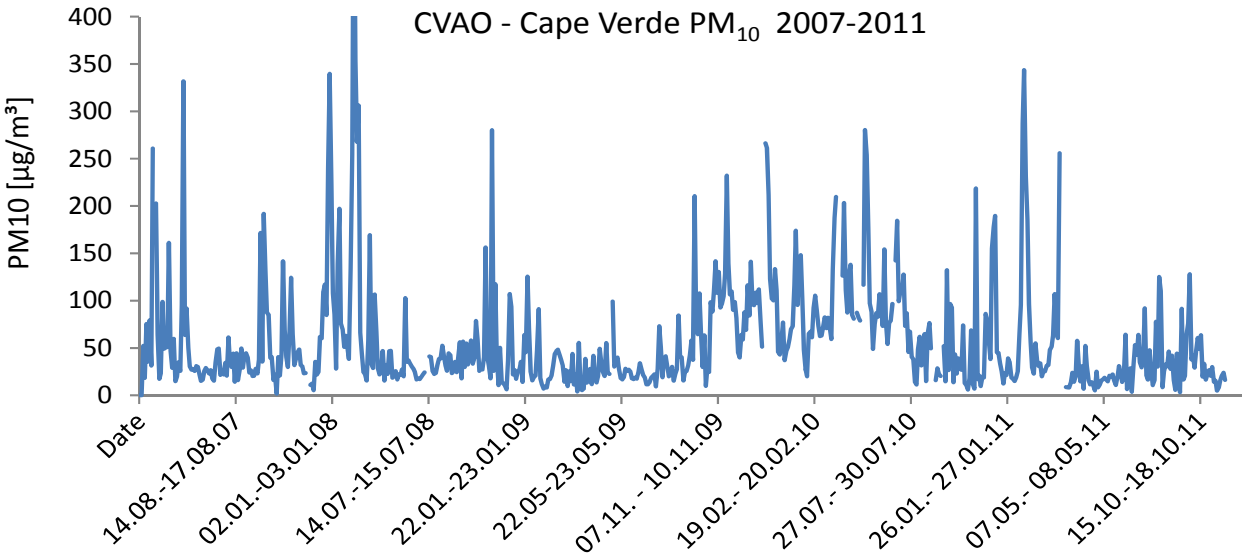

Figure 1. PM_{10} concentration at the research site CVAO at the island São Vicente. From October 2009 till June 2010 the sampler was operated not in 30 m but in 4 m above ground.

Effects of desert dust aerosols on surface UV radiation from OMI satellite instrument at Granada (Spain)

The atmospheric aerosols affect the propagation of solar radiation through the atmosphere, modifying the values reaching the Earth's surface. The largest differences between the satellite and ground-based UV irradiance data are obtained in urban polluted areas, where UV-absorbing aerosols have a great relevance. Thus, it is expected that desert dust particles (with significant absorption properties in the UV range) may also produce large differences between the satellite-derived and experimental UV irradiance. This work focuses on the evaluation of the effects of desert dust intrusions (2006-2010) on surface UV erythemal irradiance (UVER) retrieved from the satellite Ozone Monitoring Instrument (OMI) at Granada (southern Spain).

The inventory of African desert dust events occurred at Granada from 2006 to 2010 is based on a supervised methodology using mixed information from models, back-trajectories analysis, synoptic meteorological charts, satellite and surface data. Detailed information about this desert dust's inventory can be found in the work of Valenzuela et al. (2012a, 2012b) which evaluated its aerosol optical properties and its dependence on source region and transport pathways.

The UVER data derived from the OMI satellite instrument strongly overestimate the ground-based UVER measurements during the desert dust cases (see Fig. 1) with a mean bias of 22%. The analysis of clear-sky cases shows that around eight percentages points of this large difference may be related to the fact that current OMI UV algorithm assumes no absorbing aerosols. Therefore, the effect of desert dust events on the UV irradiance derived from the OMI instrument cannot be neglected in regions like southern Spain, where the intrusions of the desert dust aerosols are frequent.

Those eight percentages points can be corrected by means of an off-line method which is tested using an independent dataset. Thus, the mean OMI bias change from ~21% for operational satellite UVER data to ~13% for corrected data, indicating this value the remaining bias associated with other sources of uncertainty different to the absorbing aerosols.

We would like to point out the great effects of desert dust aerosols over UV data retrieved from OMI, being essential to maintain routinely operative ground-based stations with high-quality instrumentation in order to validate the satellite data.

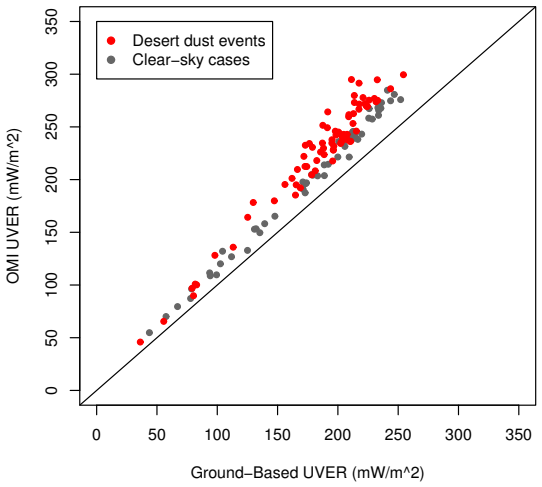

Figure 1. Correlation between OMI and ground-based UVER data for desert dust cases (in red) and clear-sky cases (in grey)

The Sahara desert is a major natural source of global mineral dust emissions, Forster *et al* (2007), through the mobilisation and lifting of dust particles into the atmosphere from dust storms. A significant fraction of this dust is in the aerosol coarse mode, Weinzierl *et al* (2009).

It is highlighted of the difficulty in making accurate and reliable measurements from an aircraft platform, particularly that of coarse mode aerosol, Wendisch *et al* (2004). To achieve the measurement of a representative aerosol sample an aerosol inlet, on an aircraft, is required for the delivery of the sample to the instruments making the measurements. Inlet design can modify aerosol size distribution through either underestimating due to aerosol losses or overestimation due to enhancements.

The Low Turbulence Inlet (LTI) was designed to improve inlet efficiency. This is achieved by reducing turbulence flow within the tip of the inlet, reducing impaction of particles to the walls of the inlet Wilson *et al* (2004). The LTI further maintains isokinetic sampling flow (free stream velocity, U_0 and sampling velocity, U are equal to 1).

Dust aerosol over the Sahara desert provides an excellent environment to test and quantify the capabilities of the LTI on the FAAM BAe 146, whilst enabling in-situ dust measurement. The LTI was operated during the Fennec field campaign in June 2011 with 11 flights during the campaign over Mauritania and Mali.

We are using the LTI to provide critical information on the sampling characteristics of the inlet used by nearly all aerosol instruments inside the aircraft (AMS, Nephelometer, PSAP, and CCN). Inlet experiments were performed with identical Optical Particle Counters (OPC) connected to the Rosemount and LTI with size distribution for each inlet measured and Rosemount enhancements determined. Rosemount inlet enhancements were determined to be 2 to 4.5 times for particles up to 3.0 μm.

A key parameter in aerosol measurement is size distribution, in which the LTI is a critical method of sampling quantifiably coarse mode aerosol up to 12 μm into the FAAM BAe 146 aircraft. Size distributions for the Fennec field campaign will be presented. Size distributions from the LTI are found to compare well with that of the externally mounted aircraft probes.

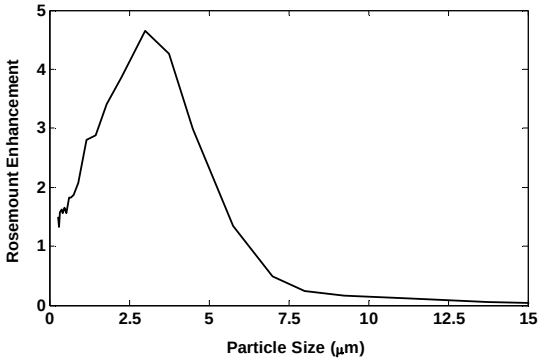

Figure 1. Rosemount inlet enhancement as a function of particle size

A Compact Cascade Impactor (CCI) was incorporated along the sample line and used to collect size segregated particle samples on polyurethane foam (PUF) substrates. X-Ray Diffraction (XRD) analysis is to be used to determine mineralogy of the dust samples. From known dust mineralogy it will be possible to infer the particles optical properties, specifically refractive index.

Dust outflows frequently affect the broader Mediterranean basin, having significant impact on the radiation budget of the Earth-Atmosphere system of the region. The sources of dust outflows are located, primarily, in the North African deserts and secondarily, in the Arabian Peninsula. Given that desert dust episodes (DDEs) affect extended areas of the Mediterranean, implementation of satellite measurements is the appropriate tool to assess them. Their accuracy, however, should be validated and tested against ground measurements, e.g. by the AERONET network, which although being spatially limited are taken as the truth.

The main target of the present study is to describe the optical and radiative properties during DDEs in the Mediterranean. First, the DDEs are identified based on an objective and dynamic algorithm. In brief, the algorithm is based on quality optical properties from the MODerate resolution Imaging Spectroradiometer (MODIS-Terra), Earth Probe (EP) and Ozone Monitoring Instrument (OMI) databases, on a daily basis and upper and lower thresholds, defined according to the existing literature and several sensitivity tests enabled the identification of DDEs for each location and day, for the period 1 March 2000 – 28 February 2007. The optical properties which have been used are: aerosol optical depth (*AOD*), Ångström exponent (α), fine fraction (*FF*), effective radius (r_{eff}) and Aerosol Index (*AI*). The intensity of the DDEs has been calculated based on a methodology which has been presented by Gkikas et al (2009). Second, aerosol extinction profile information based on the CALIPSO satellite measurements is used for the determination of the aerosol layers, and finally the updated version of BSC-DREAM dust model is initiated (http://www.bsc.es/projects/earthscience/DREAM) in order to provide a link to the observed episodes using remote sensing techniques with in situ aerosol information.

Ground-truth data used for the evaluation of the algorithm performance include microphysical, optical and radiative properties from 9 selected AERONET stations across the Mediterranean. During study period, 58 DDEs with collocated satellite and ground measurements, have been sorted out and studied. Here, we present only AERONET retrievals (synergistic retrievals are presented on the EAC-related poster).

In Figure 1-i, the AERONET-resolved mean volume size distribution during DDEs is presented and compared to the general case of all days with common surface and satellite measurements (named as all period). During DDEs, a significant increase, by a factor of ~10, of the coarse mode and a peak of size distribution for particles radius centered at 2.24 μm are depicted. The $\alpha_{0.44\text{-}0.87\mu m}$ values during the DDEs vary between 0.03 and 0.47, and are significantly decreased, in all stations, compared with the all period values. Also, there is an increase, especially at the visible wavelengths, of the AOD (more intense loads), SSA (more scattering) and g (more forward scattering) spectral values. For the days with DDEs, the mean r_{eff} values range from 0.65μm to 1.1μm. Moreover, between 0.44μm and 1.02μm, the real part of the refractive index increases while the imaginary part decreases. Our results, as it concerns aerosol optical properties, are in line with the corresponding ones presented by Kim et al (2011).

The AERONET aerosol radiative forcing (RF) values at the bottom (BOA) and at the top (TOA) of the atmosphere are also given in Fig. 1-ii. During DDEs, there is an average surface radiative cooling equivalent to -92.2±21.2 Wm^{-2} and also a planetary cooling (at TOA) equal to -38±12.2 Wm^{-2}. Compared with the all period case, the DDEs RF values are increased in magnitude by about 150% at BOA and 190% at TOA, implying enhanced surface and planetary cooling over the Mediterranean. It should be noted, however, that this planetary cooling arises just because DDEs occur over sea or other than highly reflecting desert land surfaces, where a planetary warming can occur.

Combination of AERONET and CALIPSO data for the study of Saharan dust outbreaks over Valencia (Spain)

C.R. Marcos[1], R. Pedrós[1], J.L. Gómez-Amo[1], J.A. Martínez-Lozano[1], M.P. Utrillas[1]

In this work a combination of CALIPSO level 1 data and sunphotometer measurements is performed to study the impact of Saharan dust over the metropolitan area of Valencia, in the Mediterranean coast of Spain.

The Cloud-Aerosol Lidar with Orthogonal Polarisation (CALIOP) is the main instrument on board the CALIPSO satellite, launched in April 2006 as part of the NASA A-Train constellation (Winker *et al*., 2007). Comparisons between the aerosol optical depth (AOD) derived by CALIOP and data from AERONET sunphotometers show little correlation (Bréon *et al.* 2011). To avoid the discrepancies found in level 2 data, a synergetic combination can be performed between level 1 data and the values of AOD obtained from an independent source (eg. Royer *et al*, 2010). This combination provides us with more accurate extinction profiles, which can be used to improve our understanding of the direct effect of aerosols in radiative forcing.

The CALIOP total attenuated backscatter at 532 nm (level 1 data) can be written as:

$$\beta'(z) = \left(\beta_m(z) + \beta_a(z)\right) \exp\left[-2\int_0^{r(z)} \left(\sigma_m(r') + \sigma_a(r')\right) dr'\right] \quad (1)$$

where β represents the backscatter coefficient, σ represents the extinction coefficient and the indices m and a point out the molecular and aerosol contribution respectively. The molecular terms can be calculated using atmospheric data from CALIPSO level 1 products. To retrieve the aerosol extinction coefficient from (1), a constant lidar ratio (LR), which is the relationship (σ_a/β_a) between the aerosol extinction and backscatter, is assumed. Finally, the value of LR is set so that the total integrated aerosol extinction coefficient match up the value of the AOD measured by a sunphotometer within a difference of 0.01.

The sunphotometer used in this study, belonging to the AERONET network since April 2007, is located in Burjassot (39.51N, 0.42W), a town of the metropolitan area of Valencia, in the Mediterranean coast of Spain. The values of AOD are averaged along one hour centred in CALIPSO overpass for daytime cases and linearly interpolated for night-time cases. The total attenuated backscatter cloudless data are averaged horizontally over the area within a distance of 25km from the sunphotometer (approximately, the metropolitan area of Valencia) to improve the signal-to-noise ratio.

A total of 57 cases (38 night-time cases and 23 daytime cases) could be used for this study. Among these events, 6 night-time and 2 day-time cases were classified as Saharan dust outbreaks by analysing the air masses backward trajectories given by HYSPLIT model.

The mean value of the lidar ratio obtained using the combination of AERONET and CALIPSO data (Table 1) is in agreement with the one retrieved by Pedrós *et al.* (2010) for Valencia. Remarkable differences can be seen in the mean extinction profile (Figure 1) above 1 km, since the extinction coefficient for the Saharan cases is greater than the one retrieved for the rest of the cases. This result show the notable influence of Saharan dust outbreaks in the vertical distribution of aerosols over Valencia, and the greater values for the extinction coefficient suggest the importance that these events have in the radiative forcing compared to the rest of cases.

Table 1. Mean value of LR (sr^{-1}).

	Saharan	Other
Night-time	45 ± 7	56 ± 24
Day-time	58 ± 10	67 ± 23
Pedrós *et al.* (2010)	55 ± 11	-

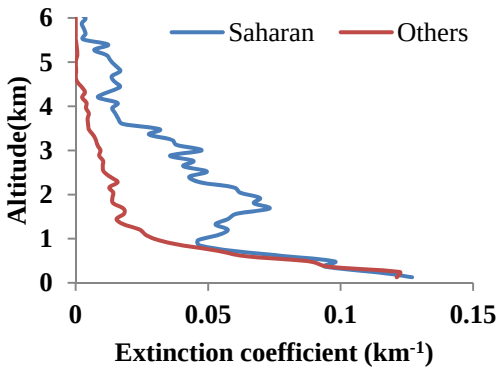

Figure 1. Mean extinction profile for Saharan dust outbreaks and for all other cases.

Experimental study of hygroscopic properties of mineral dust particles.

T.I. Ryshkevich[1], E.F. Mikhailov[1] and S.S. Vlasenko[1]

[1] Institute of Physics, Department of Physics of Atmosphere, Saint-Petersburg State University, Saint-Petersburg, 198504, Russia

Keywords: Arizona test dust, hydroscopic growth, specific surface area.

Presenting author email: Ryshkevich_t@mail.ru

Despite extensive investigation of the processes of cloud formation and significant technological advances in this field the physical mechanisms that control the processes of cloud systems formation still cannot be fully understood (Pruppacher H.R. and Klett J.D., 2000). An important question is how ice forms in mixed-phase clouds. Various atmospheric observations of droplet freezing through heterogeneous ice nucleation show that mineral dust particles act effectively as ice nuclei (IN) (DeMott et al., 2003). Through their ability to nucleate ice, mineral dust particles influence microphysical and dynamical cloud properties, cloud life time, and therefore Earth's climate. As a result of different aging processes, the particle surface and therefore particles' IN ability may change. Several laboratory studies have been performed to investigate the hygroscopic properties of mineral dust particles.

The method of generating the initial particles with specified dispersed characteristics was worked out in the first stage of the experiment. This technique is based on the method of acoustic dispersion. This procedure is mainly used to generate a liquid aerosol. But it was optimized to get a narrow size fraction of Arizona test dust (ATD) particles. The result is shown in the fig.1. The range of particle sizes is the result of merging the measurement data obtained with a scanning mobility analyzer 3080 SMPS (TSI, USA) in the size range 20-800 nm, and the aerodynamic 3321 APS (TSI, USA) spectrometer in the range of 0.5 -20 microns.

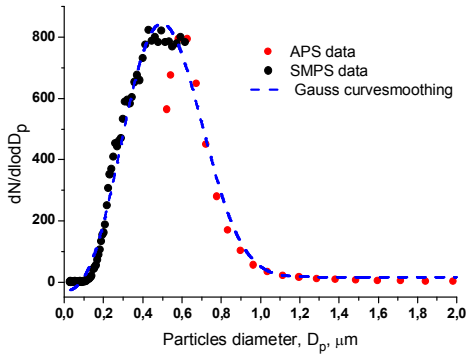

Figure 1. ATD particles size distribution.

Values of specific surface area of mineral dust particles were obtained based on nitrogen and water vapor adsorption using BET theory. These values are: $S_{sp}(N_2) = 5.6 \pm 0.2$ м^2/г and $S_{sp}(H_2O) = 5.6 \pm 0.5$ м^2/г, respectively. Moreover, the adsorption of nitrogen was investigated at a temperature of ~ 77K and the water adsorption at 295K. The effective radius (r) of ATD particles can be calculated as $r=3/S_{sp}\rho_{ATD}$, where ρ_{ATD} =2.65 g/cm^3, so it is equal to 201 nm. This is in agreement with *in-situ* measurements (see fig.1). This means that there are no aggregated clusters and selected ATD sample consist of single elementary particles.

We used a filter-based differential hygroscopicity analyzer for studying the hygroscopic properties of ATD particles based on a katharometric measurement of the amount of water vapor absorbed by an aerosol sample at temperature 295 K (E. F. Mikhailov et al, 2011). The results are shown in fig.2. It is shown that the number of water monolayers is about 6 at RH ~ 70% and a macroscopic liquid film has formed around the particles above this humidity. It is also important that the desorption branch coincides with the direct adsorption, indicating the absence of pores in the particles.

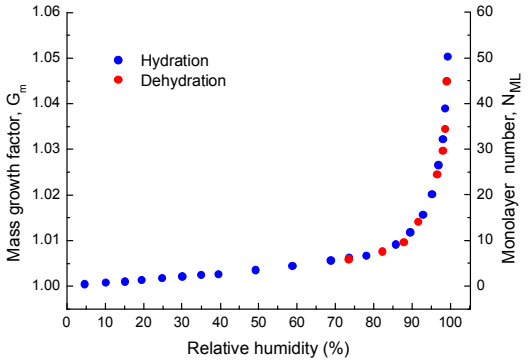

Figure 2. Mass growth factor G_m and the number of monolayers of water molecules N_{ml} depending on relative humidity.

Optical properties of a desert dust cloud after long-range transport using scattering matrix formalism and a polarization Lidar

G. David[1], B. Thomas[1], A. Miffre[1] and P. Rairoux[1]

[1]Laboratoire de Spectrométrie Ionique et Moléculaire, CNRS UMR 5579, Université Lyon 1, Villeurbanne, 69622, France

Keywords: remote sensing, scattering matrix, desert dust, number concentration

Presenting author email: amiffre@lasim.univ-lyon1.fr

Mineral dust particles are incriminated for their role on the Earth climate and radiative forcing. One of the main difficulties arises from the dust particles non-sphericity as Lorenz-Mie formalism is not applicable to highly irregularly-shaped particles (Nousiainen, 2009). Moreover, after advection over several thousands of kilometers, dust particles are highly dispersed and aged and the dust cloud is a complex mixture of both spherical (s) and non-spherical (ns) particles. To face this complexity, we have for the first time developed the scattering matrix formalism for a mixture of s and ns-particles (Miffre et al., 2011). We then applied this new formalism on a Saharan dust episode that occurred at Lyon (France) on 9th July 2010, by performing a polarization Lidar experiment. We hence provided a new methodology to remotely retrieve the dust particles number concentration (Miffre et al., 2011).

Starting from the **F**-scattering matrix definition (Mishchenko et al., 2002), we noticed that for a mixed aerosol cloud (a) = {s, ns}, $\mathbf{F} = \mathbf{F_s} + \mathbf{F_{ns}}$ since **F** is additive. By developing F_{11} and F_{22} matrix elements for s and ns-particles, we showed that, due to the presence of s-particles, the aerosol Lidar depolarization ratio δ_a differs from the ns-particles Lidar depolarization ratio $\delta_{a,ns}$ as follows:

$$1/\delta_a - 1/\delta_{a,ns} = 2F_{11,s}/(F_{11,ns} - F_{22,ns}) \quad (1)$$

Hence, while δ_s is always null, δ_a differs from $\delta_{a,ns}$, and in the presence of s-particles, δ_a is always below $\delta_{a,ns}$.

We then applied this new formalism to a Saharan dust episode that occurred at Lyon on 9th July 2010. Ns-particles were hence mostly attributed to desert dust particles while s-particles were most likely small-sized ammonium sulphates and aged carbonaceous particles (Kaaden et al., 2009). We separated backscattering from s and ns-particles by performing an accurate polarization Lidar experiment (providing the aerosol backscattering coefficient β_a for both {//,⊥}-polarization axes). This {s, ns}-partition is very efficient since laboratory measured polarization cross-talks are below 10^{-7}. Hence, by noting that dust particles are detected on both polarization channels, we retrieved the dust particles backscattering coefficient:

$$\beta_{dust} = \beta_{dust,//} + \beta_{dust,\perp} = \beta_{a,\perp}(1 + 1/\delta_{dust}) \quad (2)$$

The dust particles depolarization ratio [$\delta_{dust} = \delta_{a,ns}$ (dust) = (22.5 ± 2.0) %] is derived from the literature on T-matrix (Veselovskii et al., 2010). By using equation (2), we retrieved the dust particles number concentration N_{dust}, after numerical computation of the dust particles backscattering cross-section, assuming surface-equivalent spheres, or T-matrix computation to further reduce the N_{dust}-uncertainty. Vertical profiles of $\beta_{a,//}$, $\beta_{a,\perp}$, δ_a and N_{dust} are displayed in figure 1. In agreement with the newly developed scattering matrix formalism, at altitudes where the dust cloud is observed (z > 2 km), δ_a is below δ_{dust}, since, after long-range transport, the dust cloud is composed of both s and ns-particles. It is worth noting that the N_{dust}-vertical exhibit a different behavior from the δ_a-vertical profile, the latter being intensive and not dust particles specific, in contrary to $\beta_{a,\perp}$.

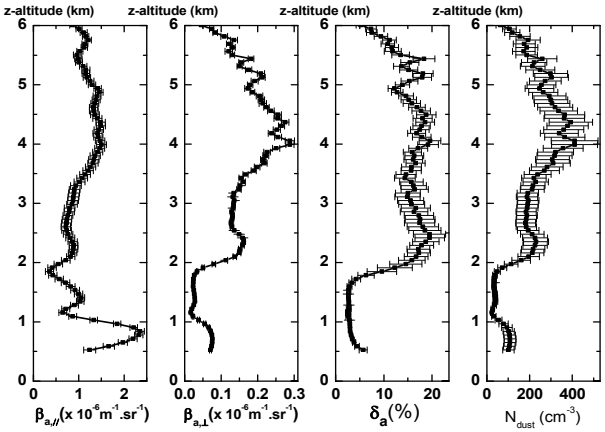

Fig. 1 Optical properties of a Saharan dust cloud at Lyon (France) measured with a UV-polarization Lidar.

The retrieved N_{dust}-values agree with recent in-situ measurements performed on dust particles over central Europe with optical counters (Klein et al., 2010). Moreover, dust particles specificity is here provided. The presentation will point out these new findings (Miffre et al., 2011), which concern the scattering matrix of a {s, ns}-dust cloud as well as its remote observation under real atmospheric conditions.

Desert-dust episodes over a background European environment: relationship between optical and physical properties by in-situ and columnar-integrated techniques

M. Sorribas[1,2,3], J.A. Ogren[4], F.J. Olmo[1,2], R. Fraile[5], B.A. de la Morena[3] and L. Alados- Arboledas[1,2]

The wide variety of aerosol data sets from long-term monitoring programs can be used to analyze trends of aerosol properties and the synergy of aerosol products. Here we discuss the details of the desert-dust plumes (DDPs) aerosol properties in the South-west of Spain for improving the knowledge of aerosol properties and their interaction with solar radiation on regional scale.

The data sets used have been measured in El Arenosillo – Atmospheric Sounding Station (37.1N, 6.7W, 40 m a.s.l) , which is a multi-instrument platform located in a background rural-coastal site. In this observatory, aerosols are studied in great detail, using combinations of in-situ and remote sensing observations (Córdoba-Jabonero et al., 2011). Particle size distribution within (14 - 10000) nm was measured with a SMPS-APS system, scattering (SC) and back-scattering coefficients within PM_1 and PM_{10} size ranges were provided by an integrated nephelometer and optical columnar-integrated properties was monitored by a CIMEL sun-photometer. Levels of PM_{10} were measured in a nearby station 6 km away and they were supplied by the Andalusian Government.

Estimation of particle mass size distribution using a SMPS-APS tandem system was provided thanks to an intercomparison with the real-time monitor of PM10. A particle density was assumed depending on the analyzed period. In case of the desert-dust event which aerosol properties are shown in Figure 1, a particle density of 3.0 g/cm^{-3} was assumed. The correlation coefficient of the comparison was of 0.86.

To evaluate the aerosol effectiveness on solar light radiation, mass scattering coefficient efficiency (MSC), defined as the ratio of 1-hour SC^{550} to 1-hour PM1 or PM10 mass concentration, has been evaluated for several DDP events. In the example shown in Figure 1 (up), MSC for PM1 and PM10 were (0.9 ± 0.03) $m^2\ g^{-1}$ and (1.1 ± 0.04) $m^2\ g^{-1}$ respectively. In both cases high correlation coefficients (R) of 0.93-0.97 were obtained, indicating a good relation between optical and microphysical parameters.

The correlation based on coincident 1-hour PM1, PM10 and (PM1/PM10) mass concentrations from SMPS-APS system and the 1-hour AOD from Cimel during the selected DDP episode is shown in Figure 1 (down). High correlation between the two properties is found with correlation coefficient of 0.85-0.90. The best relationship is observed for AOD & PM10.

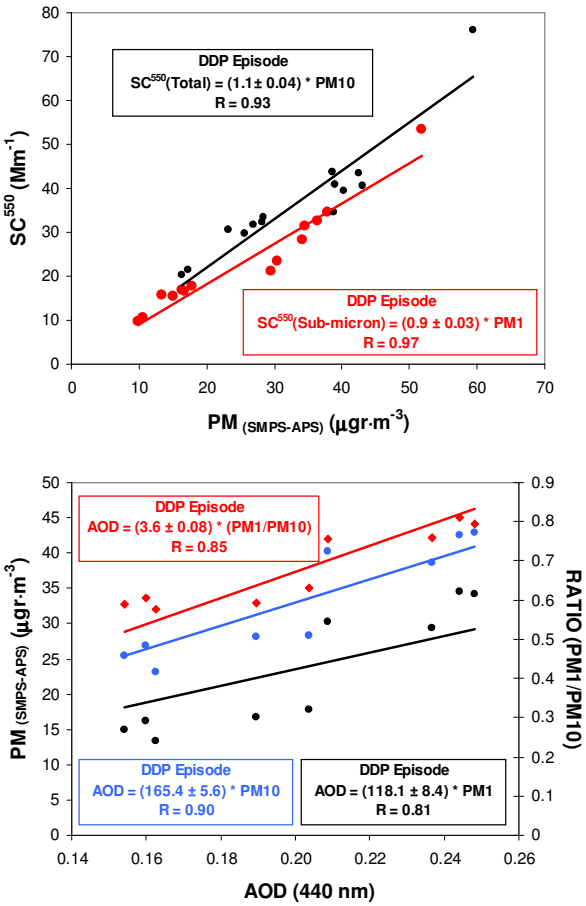

Figure 1. Relationship between (up) SC^{550} & (PM10 and PM1) and (down) AOD & (PM10, PM1 and ratio(PM1/PM10)) during a DDP episode.

Estimation of dust emission amount for spring in East Asia using WRF/Chem

Jung-Yoon Kang[1] and Soon-Chang Yoon[2]

[1]Atmospheric Environment and Applied Meteorology Research Department, Meteorological Research Institute, Tsukuba, Ibaraki, 305-0052, Japan
[2]School of Earth and Environmental Sciences, Seoul National University, Seoul, 151-747, Korea
Keywords: Mineral dust, Asian dust, Emissions, Modelling
Presenting author email: doosan8@snu.ac.kr

Mineral dust is one of the most important aerosols because it affects not only air quality and human health but also radiation budget by scattering and absorbing solar and terrestrial radiation. Taklimakan Desert and Gobi region are known to be one of significant source regions of airborne dust in the world, and dust phenomena frequently occur in the springtime in East Asia. It is important to estimate dust emission amount exactly in understanding the effect of dust particles, and dust model is a good means of obtaining dust emission amount. In this study, a new dust emission scheme proposed by Shao (2004) (hereinafter referred to as S04) was implemented in Weather Research and Forecasting with Chemistry (WRF/Chem) (Kang *et al.*, 2011) and numerical simulations were conducted to estimate dust emission amount for the springtime in East Asia.

The newly implemented dust emission scheme, S04 is a physically-based scheme and it considers two main dust emission mechanisms, called 'saltation bombardment', and 'aggregate disintegration'. The soil texture type data and vegetation cover data for East Asia were newly updated to improve the boundary condition.

A case study for a severe dust event that took place in the spring of 2007 was carried out to evaluate the new dust emission scheme. The model results show that WRF/Chem with S04 scheme has a capability to simulate dust phenomena reasonably; dust plumes are generated by strong wind over Mongolia and Gobi region and then transported to the Korean peninsula and Japan along the low-pressure system. The spatial distribution of dust plumes is also well matched with the Ozone Monitoring Instrument (OMI) Aerosol Index and World Meteorological Organization (WMO) synoptic data. The comparison between modelled dust concentration and observed PM_{10} data for several stations in Korea (Figure 1) reveals that model can capture the onset time of the dust event well and the estimated dust concentrations are quite well comparable to the observed data.

To calculate dust emission amount for the springtime in East Asia, the model simulation was conducted for March, April, and May from 2006 to 2010 for 5 years. The vegetation cover was updated every month and the horizontal grid size of the model domain was set to 100 km.

Figure 2 shows the 5-year-averaged dust emission amounts for the springtime for several regions. The Gobi region occupies the largest area and shows the highest dust emission amount. The dust emission amount per area is the highest for Badain Jaran Desert. The monthly and yearly changes of dust emission amount were also examined, and Taklimakan desert shows less variability than other regions while Loess region shows high variability because of the change of vegetation cover.

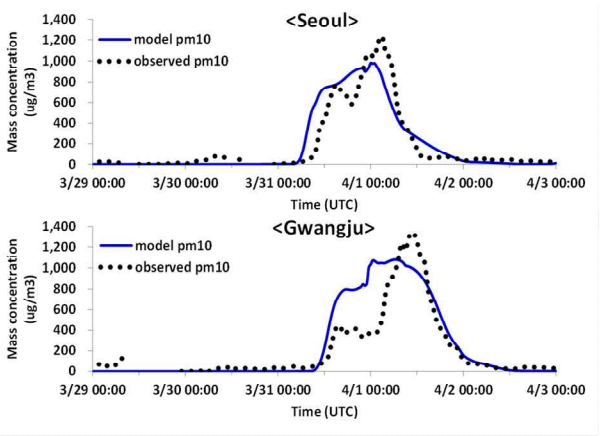

Figure 1. Comparison between model dust concentration (blue line) and observed PM_{10} concentration (black dot) at Seoul and Gwangju.

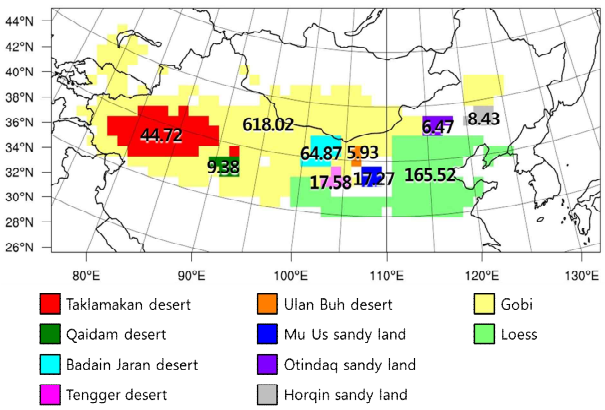

Figure 2. Total averaged dust emission amounts [Tg] for the springtime for several regions.

Keywords: Saharan dust, Carbonaceous aerosol, Sea salt
tnunes@ua.pt

The position of Cape Verde Islands in the Atlantic Ocean represents an important area to study and characterize Saharan/Sahel mineral dust transported over West Africa and the adjacent Tropical Atlantic Ocean. Sahara and Sahel regions are the most important contributors to the global dust emission (Goudi and Middleton, 2001). The atmosphere of Cape Verde Island is deeply marked by the contribution of these dust emission sources. At local level even the native population recognize the importance of this contribution, that occur mainly in the dry season (November / February), using a suggestive name "bruma seca" (dry haze). At Cape Verde islands, significant mixing of aerosols is expected due to the presence of desert mineral dust, sea salt and anthropogenic aerosol emissions. Uncertainties exist in the quantification of the highly variable distribution of this modified aerosol. In order to contribute for a better understanding and impact of mineral dust source, a year measurement campaign was performed at Santiago Island in the scope of CV-Dust Project. A surface field station was implemented in the surroundings of Praia City (14°55' N e 23°29' W, 98 m at sea level), where aerosol sampling, throughout different samplers, was performed.

Particulate matter were collected simultaneously with a Hi-Volume sampler (Tisch) and a low-volume sampler (Partisol), both with standard PM_{10} inlet heads, between January 2011 and January 2012, performing 115 parallel samples. Teflon filters with 0.45 µm pore size and quartz filters were used with low and high volume samplers, respectively. Teflon filters samples were used to quantify water inorganic soluble species by ion chromatography; instead quartz filter samples were used to quantify carbonaceous species. PM_{10} mass concentrations were quantified by gravimetric method. Carbonate fraction was determined by sample acidification with phosphoric acid and the CO_2 evolved measured with a NDIR gas analyzer. Organic and elemental carbon was determined by using a thermal-optical transmission technique after removing carbonate fraction by exposing the filters to HCl vapour (Castro et al., 1999). Complementary to PM_{10} samples, a set of 11 samples were performed along the year with a five stage cascade impactor and PM collected in quartz filters. The different species referred above were as well as quantified in these filters.

PM10 concentrations at Cape Verde Island shows a high variation, with concentrations ranging between <15µg m^{-3} up to more than 500 µg m^{-3}.

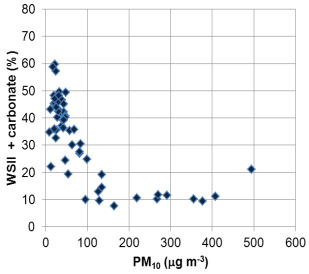

Figure 1 – Percentage contribution of WSII and carbonates for PM10.

Water soluble inorganic ions and carbonates, during mineral dust events, contribute around 10% of the PM10 mass concentration (Fig. 1), while out of this influence could increase up to 60%.

Carbonaceous particles, organic and elemental carbon account in average less than 1.02±0.82% of PM10, while Ca+Carbonates contribute with 2.47±1.60 %. Chloride, sodium and magnesium ions showed a high correlation among them (R^2>0.95), which denotes the strong sea salt source for the local observed aerosol. In average Na+Cl ions account 22.4±12.1 of the total PM mass.

Usually coarse particles, dominates the mass concentration of PM10 in Cape Verde, with the prevalence of particles between 3-7.2 µm (Fig. 2).

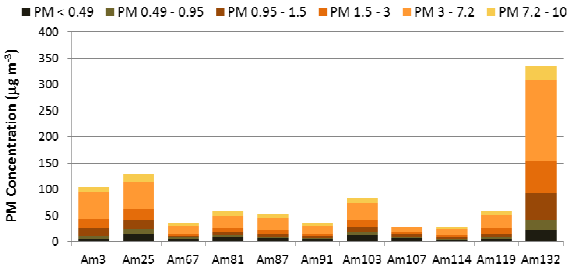

Figure 2 – Size distributions of PM mass concentration

Presenting author email: sibylle@vedur.is

In the evening of the 21st May 2011 an eruption started in Grímsvötn volcano, a sub-glacial volcano beneath the Vatnajökull glacier ice sheet in Southeast Iceland. The eruption plume exceeded 20 km in altitude during the first hours but decreased in the early hours of 22 May to 10-15 km altitude (Bjornsson, 2012). The eruption plume was observed until 25 May and the eruption was defined as deceased at 07 UTC 28 May. During the first hours of the eruption, ash fall was observed to the south and west of Vatnajökull glacier.

In the evening of the 22nd of May the volcanic ash cloud was advected over the South and Southwest part of Iceland due to strong north-easterly and easterly winds. Local ash fall was observed as well as severe reduced visibility and air quality.

The particle number concentrations were measured with optical particle counters at two different locations in South Iceland, in Skógar, 145 km southeast of Grímsvötn volcano, and in Hvolsvöllur, 160 km southeast of the volcano. The particle number concentrations were converted to mass concentrations assuming a density of volcanic ash of approximately 2600 kg/m^3.

During this event, high number concentrations were measured at both stations. The calculated mass concentrations are shown in Figure 1.

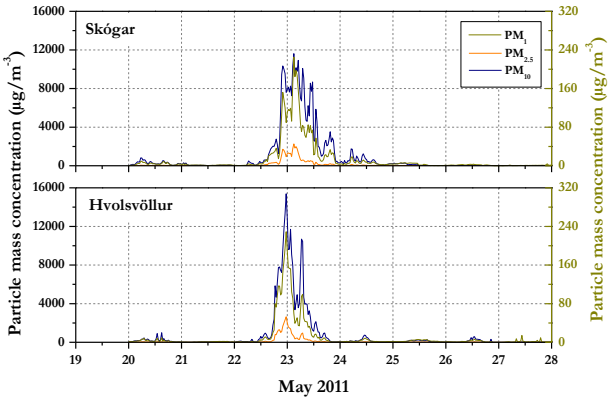

Figure 1. Calculated PM_1, $PM_{2.5}$ and PM_{10} mass concentrations of measured particle number concentrations (30 min average) at two different locations in S-Iceland.

In the aftermath of the eruption in Eyjafjallajökull volcano in 2010, volcanic ash was frequently remobilised by wind (Thorsteinsson, 2012). Those events were observed especially in South-Iceland and continued to occur into 2011 (Leadbetter et al., 2012). The Grímsvötn eruption added volcanic material in nearly the same region as the eruption one year before. And volcanic ash and dust resuspension was occasionally observed in summer and autumn 2011.

In September 2011, during a period of several days, heavy dust and sand storms were observed in the south part of Iceland. The dust cloud can clearly be seen on MODIS images of this time period. The PM_{10} concentrations, measured in Southeast Iceland, exceeded the European health limit value of 50µg/m^3 for several days (Figure 2).

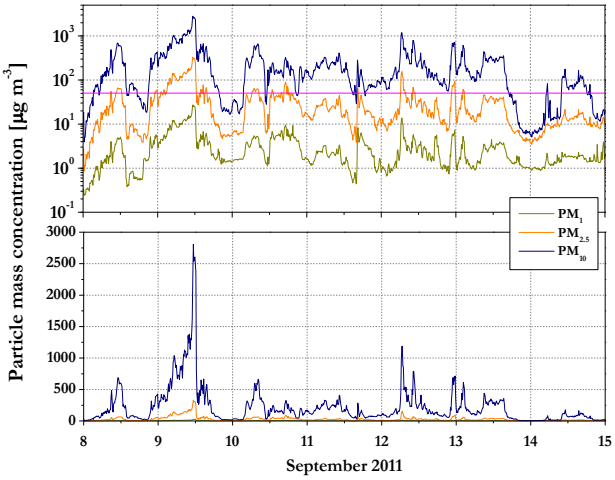

Figure 2. PM concentrations measured in Kirkjubæjarklaustur (SE-Iceland). The horizontal magenta line marked the European health limit value for PM_{10} of 50 µg/m^3 over 24 hours.

The PM_1 concentration was also significantly increased during this period. Strong northerly and north-easterly winds caused these events but when the wind direction turned to southeast, mineral dust and volcanic aerosols were also observed in the west part of Iceland including the capital region.

Presenting author email: mnishi@nies.go.jp

Asian mineral dust is transported from the desert and loess areas of China and Mongolia to Japan, and even to transport around the world by the prevailing westerly winds. The mineral dust (well-known as kosa aerosol) generated from the northern Asia areas is estimated about several hundred million tons every year. The most deposition mounts of mineral dust surrounding Japan was reported to take account for that transported from Gobi desert, where is situated in Mongolia and the inner-Mongolia in China. Asian mineral dust has been interested by a wide range of scientific disciplines, such as meteorology, environmental science, medical science and precision engineering. We would like present to develop the new certified reference material, name of Gobi Kosa, available to use for various scientific experiments and quality control of chemical analyses.

We collected 1200 kg of surface soil (0-5cm) at four sites in southern Gobi desert area, Mongolia, where is located around 109°(east longitude) and 44°(north latitude). Heavy sand storms generate frequently at the sites area, in the springtime. The primary material of surface soil was sampled in May, 2011. The fine particle dust was collected by the cyclone separator with the 10 micro-meter for cut-off efficiency from the raw material, in the meteorological observatory, Sainshand, near Gobi Desert. The second material was obtained about 4kg, and then the material was transported to Japan. The final sieving and homogeneity procedure was performed, and then about 1kg. Two (g) of the final material was sealed into each of 600 brown glass bottles. There were sterilized by exposure to cobalt 60 irradiation.

The particle size distribution of Gobi Kosa was obtained by analyzing a microscopic image using image analysis software (OLS3500/SFT-3500, Olympus and Shimadzu) (Fig. 1). The detection limit of this method was 1 μm. About 1500 particles of Gobi Kosa was measured, almost particles were verified less than 10 micro-meter in diameter. The average of particle diameter was 2 micro-meter. The gravimetric density of the particles are about 2.5, therefore the aerodynamic diameter is calculated about 3.2 micro-meter. As the aerodynamic mean diameter of kosa aerosols observed in Japan has been reported 3-5 micro-meter range, this size of Gobi Kosa is consequently reasonable. Major components of Gobi Kosa exhibit in Table 1. Al, Fe, Ca, Ti are the primary indicator elements for Asian mineral dust. The concentration ratios of Fe, Ca, Ti to Al in kosa aerosols, were in the narrow ranges of 0.52-0.59 (Fe), 0.51-0.73 (Ca) and 0.049-0.082 (Ti), as shown in Table1. The ratios in the Gobi Kosa were very similar to those of kosa aerosols collected in Japan.

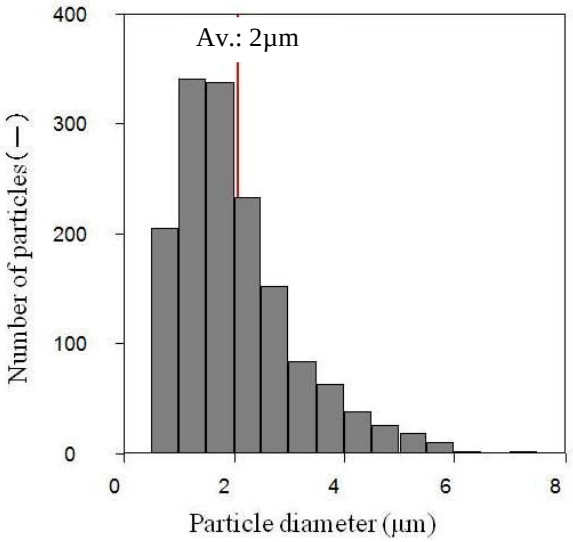

Figure 1 Size distribution of Gobi Kosa

Table 1 Elemental components of Gobi Kosa and comparison of the (X/Al) ratios with those in 4 examples of typical kosa aerosols collected in Japan

	Gobi Kosa		kosa aerosols (4examples)
	(mg/Kg)	(X/Al)	Range (X/Al)
Al	7.76	1	1
Ca	4.31	0.555	0.51 - 0.73
Fe	4.16	0.536	0.52 - 0.59
K	2.22	0.286	0.30 - 0.37
Mg	1.49	0.192	0.27 - 0.31
Na	0.936	0.121	0.17 - 0.50
Ti	0.454	0.0585	0.049 - 0.082
Mn	0.0801	0.0103	0.013 - 0.015

Presenting author email: chernandezp@aemet.es

Top heights of the Planetary Boundary Layer (PBL) and the Saharan Air Layer (SAL) during two Saharan dust events were compared by using both a Vaisala ceilometer CL51 (CL51; 910 nm) and a Micro Pulse Lidar (MPL; 523 nm) in Tenerife, Canary Islands.

Ceilometers were originally conceived for both cloud and PBL height detection, but not specifically to measure the dust layer. However, a previous study showed that the CL51 is capable of detecting mineral dust within the SAL (*Hernández et al., 2011*). That study was carried out in the Canary Islands in winter when Saharan dust intrusions occur within the Marine Boundary Layer, MBL, (*Viana et al., 2002; Alonso-Pérez, 2008*), with both the CL51 and the MPL located at the Santa Cruz Observatory (SCO; 28.5º N, 16.2º W, 52 m a.s.l.) a background urban station located in the metropolitan area of Santa Cruz de Tenerife that belongs to Izaña Atmospheric Research Centre.

Two case studies are presented in this work. From 14 October to 24 November 2011, the CL51 was installed at Izaña Observatory (IZO; 28.3º N, 16.5º W, 2373 m a.s.l.), which is representative of the free troposphere, and the MPL was located at SCO, within the MBL. In this period, an exceptional episode of Saharan dust intrusion at high altitude occurring from 15 to 17 October, 2011 was studied.

During the second period of the inter-comparison, both instruments have been located at SCO within the MBL. Our second case study is the Saharan dust episode occurred in December 5-11, 2011.

The PBL and SAL heights were determined using the gradient method. The PBL and SAL correspond respectively, to the first and subsequent measurable minima of the derivative of the CL51 and MPL backscatter signals. Also, we have developed a methodology for determining the SAL heights using relative humidity (RH) and temperature vertical profiles from radiosoundings.

Our results have been analysed using ancillary information: 1) analysis of airmass origin reaching the site, perfomed using both HYSPLIT 4 and ECMWF backtrajectories; 2) simulations of vertical profiles of dust concentrations using the BSC-DREAM8b dust model; 3) vertical profiles of temperature, RH and wind direction from radiosonde and ozonosonde stations, at Güímar and Jardín Botánico respectively, both in Tenerife 4) aerosol optical depth from Izaña and Santa Cruz de Tenerife AERONET stations; 5) Moderate Resolution Imaging Spectroradiometer (MODIS) and Meteosat Second Generation (MSG) satellite imaginery 6) ECMWF and the non-hydrostatic mesoscale meteorological MM5 models and 7) heights of PBL and aerosol layers and extinction coefficient measured at SCO provided by the Micro Pulse Lidar Network (MPLNET).

We have found a good agreement between the Vaisala CL51 ceilometer and the MPL in the determination of the PBL and SAL heights, noting that in winter season is more challenging for the MPL to detect dust layers because they travel at lower altitudes. The SAL heights determined by RH and temperature vertical profiles are also in good agreement with the results obtained by CL51 and MPL.

We would like to thank to Vaisala for providing the ceilometer CL51. Thanks to Reijo Roininen for the information about the ceilometer. Yballa Hernández enjoys a grant from the Meteorological State Agency of Spain, Ministry of Agriculture, Food and Environment of Spain to carry out studies in remote instrumental techniques.

Presenting author email: ccaminog@aemet.es

Northern Africa is the largest source of emission of mineral dust into the atmosphere. Mineral dust has a significant effect on human health and a strong interaction with the climate system. The main impact of mineral dust on the economy is related to visibility reduction, especially affecting air and ground transportation. It is necessary to characterize and quantify the mineral dust over the source regions to better understand the dust cycle and to assess its impacts.

Near dust source regions, there is a huge lack of PM10 (particulate matter with diameter less than 10 micrometers) measurements. Moreover, satellite remote sensing techniques have significant limitations over highly reflective surfaces, such as deserts, and therefore, provide limited performance over dust source regions. Due to all these limitations, given that meteorological stations provide a good spatial distribution and temporal resolution near dust source regions, we use visibility observations provided by meteorological stations as an alternative tool to characterize and quantify the concentration of mineral dust in Northern Africa.

The first goal is to derive an empirical relationship between PM10 concentration and horizontal visibility at Izaña Observatory (IZO, 28.30ºN, 16.49ºW, 2367 m a.s.l., under free troposphere conditions). The second goal is to assess whether this empirical relationship can be used to derive PM10 concentrations under desert conditions in North Africa.

In the first part of this work, summer data from the period 2005-2010 measured at IZO were used to determine the empirical relationship between PM10 concentration and visibility. The analysis was restricted to the summer months at IZO, because Saharan dust intrusions over IZO mainly occur during this season.

In an attempt to avoid fog or rain events, we excluded from calculations observations with relative humidity higher than 75% or any reported precipitation. Additionally, we used aerosol optical depth and Ångström exponent (α) from a collocated AERONET station to avoid events with dominant marine or anthropogenic aerosol, according to *Basart et al (2009)*.

A good empirical relationship to estimate PM10 at IZO from visibility data was found. Preliminary tests indicate that, in comparison with other equations found in the literature *D'Almeida (1986)* and *Shao et al (2003)* for visibility and PM10 and *Ben Mohamed et al (1992)* for total suspended particles and visibility, our empirical relation improves the quality of the fit.

In the second part of this work, in order to evaluate the performance of the derived empirical relationship in Northern Africa, the equation was tested for Sahelian stations reporting PM10 data: Baninzoumbou in Niger, Cinzana in Mali and M'Bour in Senegal, from the AMMA (African Monsoon Multidisciplinary Analysis) network, described by *Marticorena et al (2010)*.

Our resulting empirical relationship reproduces quite well the PM10 observations recorded at AMMA sites. It may be concluded that the empirical relationship found at IZO can be used as a new approach for estimating PM10 from horizontal visibility measurements from meteorological stations in Northern Africa.

The present work was carried out in the context of the MACC II project at the Spanish Meteorological Agency (AEMET). The authors would like to thank AERONET Network, AMMA Network and National Climatic Data Center (NCDC).

Particulate Matter Deposition Monitoring: Neglected Importance of Titanium?

G. Jereb[1], G. Dražič[2] and B. Poljšak[1]

[1] University of Ljubljana, College of Health Studies, Poljanska 26 a, 1000 Ljubljana, Slovenia
[2]Department for Nanostructured Materials, Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia
Keywords: particulate matter, deposition, monitoring, Titanium
Presenting author email: gregor.jereb@zf.uni-lj.si

Particulate matter deposition was measured at Slovenian coastal area in municipality of Koper. Three one year measurement campaign (2005-06, 2007-08 and 2009-10) were adopted in the vicinity of Port of Koper. Main reason for starting mentioned measurement was complaints from nearby inhabitants, who live near by the depot of coal and iron ore. For many years the inhabitants of Ankaran and its surroundings (the closest residential area is 1 km from the storage sites) have been complaining about the pollution of their residential area with emissions from the terminal EET in the Port of Koper. Port of Koper already introduced several dust control measures in order to reduce dusting to the environment from the EET terminal (coal and iron ore manipulation and storage place).

The amount of particulate matter deposition was determined gravimetrically using Bergerhoff deposition gauge for sampling and precise analytical weight for gravimetric analysis. Additionally samples were qualitative and quantitative analyzed using SEM EDXS. Chemical analysis on annual samples was also carried out in order to determine the amount of selected (Fe, Al, Cu, Zn, Cd, Pb, Cr, Ni, As) metals.

The study was designed to assess the dustiness in the region and determine the difference between vertical and horizontal (contribution of wind) deposition. Additionally the impact of background and correlation between dust deposition, the weather (especially extreme) and the activity at the Port of Koper was evaluated.

During the preliminary study (2005/06 - Figure 1) extreme values of particulate matter deposition in Port's surroundings were detected. During time period 2007/08 (Figure 2) and 2009/10 (Figure 3) elevated levels of suspended particles were not detected. Main reason for relatively lower values of dust deposition might be in rather good weather conditions and also in introduced precautionary "anti dust" measures taken by the Port of Koper.

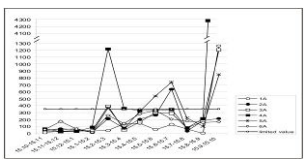

Figure 1: Particulate matter deposition - 2005/06

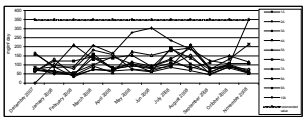

Figure 2: Particulate matter deposition - 2007/08

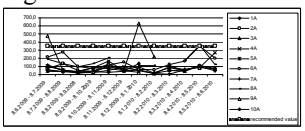

Figure 3: Particulate matter deposition - 2009/10

Main purpose of the study was to investigate the amount of particulate matter deposition and try to link it with the activities in the Port of Koper. Additionally also assessment of effectiveness of adopted "anti dust" measures was part of our interest. However, using SEM additionally interesting discovery was found. SEM/EDXS was employed to differentiate particles of coal and iron ore from other particles collected in the sampling device. An extremely large number of particles of titanium, all of which were present mainly in the smaller size fractions (less than 1 µm up to max 5 µm) were found during all three sampling intervals. Additional sampling sites were placed in Ljubljana (distance from Koper is 100 km) and also there particles of Titanium were found. According to SEM micrographs we can conclude that this particles are anthropogenic, however the main source of these particles remains unknown.

Presenting author email: mcabello@umh.es

The diurnal variation of the concentration of suspended particulate matter in the range of 0.25-32 µm, segregated by size, is studied in relation to meteorological (solar radiation, wind speed, relative humidity, temperature) and top soil (moist content and temperature) parameters.

Measurements were made at two rural environments in the western Mediterranean (located 18 and 8 km inland), in the framework of two projects: RESUSPENSE and EroHondo. Aerosol spectrometers with 31 particle size channels (Grimm mod. 190 and 365) and meteorological stations were used.

The relationship between dust concentrations and wind speed has been recently addressed in detail. Overall, submicron particles show lower concentrations the higher the wind speed, and dilution is the dominant mechanism. In contrast, particles larger than 15 µm present a net increase with increasing wind, just from the first 1 m s^{-1}. Human activity in the surroundings may maintain moderate levels of particle in the size range 2-12.5 µm. These particles show a strong reduction in concentrations even with light winds, although higher wind speeds lead to a net increase in concentrations due to resuspension (Orza et al., 2011).

To reduce the number of the 31 particle size channels to a smaller number of uncorrelated variables, a varimax rotated principal components analysis (PCA) was performed. Then, one representative particle size was selected for each identified factor.

Soil and air parameters show inertia to solar radiation (Fig.1). Temperatures (of top soil and air) peak around one hour later of the maximum of solar radiation, while relativity humidity shows a minimum. Sea breeze increases wind speed later in the central hours of the day.

The diurnal patterns of each representative particle size concentration are totally different. While the smallest particles show an increase during the late afternoon and night hours, the concentration of the largest ones raises during the central hours. Photo-chemical processes during the afternoon and the dispersion of the pollutants from the surrounding cities lead to the increase of the smaller particles concentration, which are accumulated within a shallow nocturnal boundary layer. In the morning, they are dispersed by the wind and a higher boundary layer. Convection (topsoil temperature greater than air temperature at 2m) is found to be the mechanism that facilitates the entrainment of the largest particles even at light winds. This fact has direct implications for modelling and understanding air quality in semi-arid environments.

Mineral dust produced from windblown soils and deserts is one of the largest contributors to the global aerosol loading and has strong impacts on regional and global climates, long-term climate trends as well as marine and terrestrial ecosystems.

Knowledge of the compositions of atmospheric dust is pertinent to understanding its impact on human health and climate. Epidemiological studies have consistently shown an association between Air Particulate Matter pollution and the number of deaths from cancer and cardiovascular and respiratory diseases.

African dust is a special case in that it is comprised almost entirely of inorganic materials and the concentration of pollutant species is relatively low.

Cape Verde is located in an area of massive dust transport from land to ocean, and is thus ideal to set up sampling devices that will able the characterization and the quantification of the dust transported from Africa.

The main objectives of CV-Dust project are: 1) to characterize the chemical and mineralogical composition of dust transported from Africa by setting up an orchestra of aerosol sampling devices in the strategic archipelago of Cape Verde; 2) to identify the sources of particles in Cape Verde by using receptor models; 3) to elucidate the role Saharan dust may play in the degradation of Cape Verde air quality; 4) to model processes governing dust production, transport, interaction with the radiation field and removal from the atmosphere.

The project is a joint initiative of Aveiro University and Technological and Nuclear Institute (Lisbon, Portugal), together with the Cape Verde University and the support of the Cape Verde Atmospheric Observatory.

Almost all Cape Verde islands soils and sediments are from volcanic origin, but some islands, like Boavista, are covered by aeolian sands, composed by calcium carbonated minerals. So, it is expected to find some heterogeneities on the mineralogical composition of the atmospheric dusts.

Aerosol sampling is being performed at Praia airport during one year and mineralogical composition is being studied by X-ray diffraction, TEM and scanning electron microscopy.

PM10 sampling is being carried out since January 2011, and samples from the first 3 months are under studies.

Two subsamples were collected from each filter. Two diffractograms from each subsample were carried out, with and without spin. The four diffractograms were analyzed jointly, giving the mineralogical qualitative composition as well as the relative proportions for each identified mineral.

Iron hydroxides, such as lepidocrocite and goethite, and carbonates, such as calcite and siderite, are the most discriminating phases, allowing to differentiate 3 subsets:

- Iron hydroxides rich
- Calcite rich
- Siderite rich

Samples showing higher PM10conc. belong to first group, whereas those with lower PM10 conc. belong to second one.

On the contrary, silicates, such as quartz, feldspars and phyllosilicates (mainly micas), do not show any particular tendency, being ubiquitous and generally on small amounts. They show a trend to be more discrete in the carbonate-rich samples (also, with lower PM10 conc.), as expected.

The identification of the main sources and origins of the particles sampled in the archipelago will be carried out by integrating complementary tools such as Principal Component Analysis, Positive Matrix Factorization, Chemical Mass Balance, Multilinear Regression Analysis, Air Mass Back trajectories analyses, meteorological data and particle size segregate analysis.

Introduction

The mineral dust from deserts (e.g. Sahara) contributes largely to the content of tropospheric aerosols. Their long-range transport has impacts on air quality in several regions. To characterize 3D spatial and temporal variations of particulate concentrations and to establish a relationship between the emission sources and observed pollution levels dispersion models are used as valuable tools.

The present work aims to contribute to a better understanding of the role played by Saharan dust in the degradation of air quality in Cape Verde. For this purpose a modelling approach have been implemented and validated against the aerosol measurements.

Methodology

In the scope of CV-Dust project, the islands of Cape Verde, located in an area of massive dust transport from land to ocean, were chosen for air quality assessment.

The Dust REgional Atmospheric Model (DREAM) (Nickovic *et al*, 2001) designed to accurately describe the eroded desert dust cycle in the atmosphere has been used, in its updated version BSC-DREAM8b (Pérez *et al*, 2006) (www.bsc.es), to characterise long-range transport of mineral dust to Cape Verde. The model predicts 3D fields of dust concentration in the troposphere, taking into account all major processes of dust life cycle, such as dust production, horizontal and vertical diffusion and advection and wet and dry deposition. It includes 8-bin size distribution within the 0.1-10 µm radius range and dust-radiation interactions.

The simulation domain of BSC-DREAM8b covers North Africa, Europe and Middle East with an horizontal resolution set to 1/3ºx1/3º (~50kmx50km) and 24 z-vertical layers (up to ~15 km). Meteorological fields are initialized every 24h and boundary conditions updated every 6h with the NCEP/NCAR I global analysis (0.5ºx0.5º). USGS 1-km vegetation dataset and FAO 4-km global soil texture data are considered. In this study, 3-hour averages outputs were taken for the region of interest: 13ºN to 19ºN and 26ºW to 14ºW.

Measurements used for model evaluation have been provided by a field campaign (part of CV-DUST Project) performed during one year, from January 2011 to January 2012, at the former airport of Praia, Cape Verde.

Preliminary results

Figure 1 depicts the map of predicted PM10 concentrations for a day characterised by synoptic dynamics associated with dust uplift and transport till Cape Verde area (February 28, 2012).

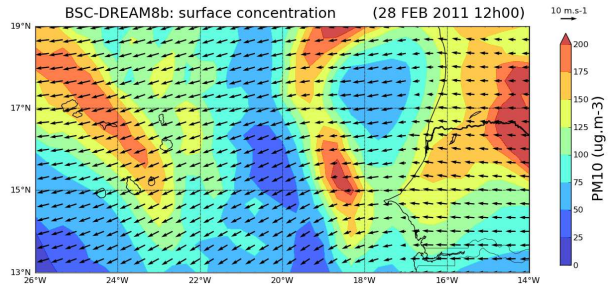

Figure 1. Map of predicted PM10 concentrations for 12 a.m. of February 28, 2012.

Figure 2 depicts the time series plot of predicted and observed PM10 concentrations in Praia, Cape Verde, during the field campaign period (when both predicted and observed data are available). It is possible to identify similarities between the annual behaviour of observed and predicted concentrations. However, it is clear the model shows a tendency to under predict the surface levels of PM10.

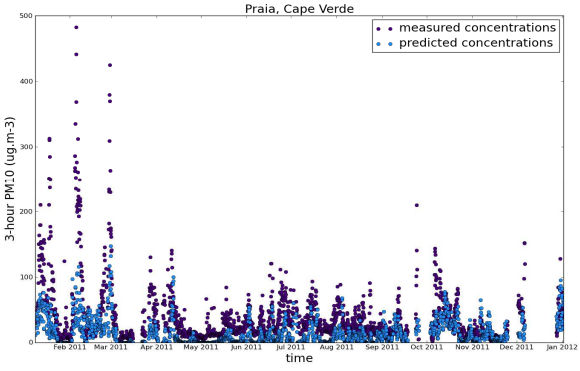

Figure 2. Time series plot of predicted and observed PM10 concentrations in Praia, (Jan 2011 - Jan 2012).

Saharan dust is the major source of aerosols emitted yearly to the atmosphere. The Iberian Peninsula, located at the North of the Sahara desert, is frequently affected by Saharan dust intrusions, especially during the summer period (Toledano et al., 2007; Bennouna et al., 2011; Guerrero-Rascado et al., 2009).

In June 2011, an airborne campaign was conducted by INTA in collaboration with Granada University intended to study Saharan dust aerosols properties. Flights were carried out over INTA "El Arenosillo" sounding station (ARN, 37.1N 6.7W) and Granada (GRA, 37.2N, 3.6W) under dust (D) and non-dust (ND) conditions. The data under ND condition were used as a "clean" reference for the D measurements. Four flights were carried out during the airborne campaign, two of them over each station.

The INTA atmospheric research aircraft was equipped with two optical particle counters designed by Droplet Measurement Technologies (DMT): PCASP-100X (15 bins, 0.1-3.0 μm) and CAPS (30 bins, 0.51-50 μm). The CAPS was equipped with optional depolarization module allowing determinations of refractive index and particle shape of the sampled aerosols. The algorithm to determine both refractive index and particle shape are based on the Mie theory.

Several particle counters and two CIMEL sun-photometers were deployed at both stations or in the vicinity of them. The size distributions retrieved by the airborne instrumentation are compared with in-situ measurements of particle counters and AERONET retrievals from the particle counters and CIMEL sun-photometers respectively. Data from CIMEL stations within the studied area have been used to provide a global image of the Saharan dust episode. Refractive index retrieved by the optional depolarization module is also presented and compared with CIMEL retrievals in this work.

The AOD at 440 nm during the flight for D conditions reached values of 0.48 and 0.30 over ARN and GRA, while under ND conditions the AOD reached 0.10 and 0.11 respectively. The ceiling of the Saharan dust intrusions detected by the aircraft was located at 6 and 5 km asl over ARN and GRA respectively. In both cases the concentration of particles in the coarse mode was higher at lower levels (2-3 km asl) than in the intrusion top height.

An oversampling issue in the coarse mode was noted for the PCASP measurements during ND days. This may be related with the low particle concentration found in this range.

The influence of the Atlas Mountains and the meteorological situation on the impact of African dust outbreaks on the Iberian Peninsula

J.A.G. Orza, M. Cabello

SCOLAb, Universidad Miguel Hernández, Elche, 03202, Spain
Keywords: mineral dust, meteorology.
Presenting author email: ja.garcia@umh.es

In this work it is shown that the Atlas Mountains, under the appropriate meteorological conditions, may lead to the injection of dust-laden air masses directly into the atmospheric boundary layer in the Iberian Peninsula.

Satellite imagery, CALIPSO and radiosounding vertical profiles, meteorological records, synoptic charts as well as back-trajectories (ERA-Interim, 1-deg lat-long resolution) have been used to study a number of cases.

A good example is the most intense African Dust (AD) outbreak, in terms of impact at ground level, registered in southern Spain. A daily PM10 concentration of 309 µg m^{-3} was recorded on 11 Oct. 2008 at the Viznar background EMEP station. Hourly PM10 levels of 500 µg m^{-3} were recorded in Malaga, and concentrations remained quite high till the end of 13 Oct., 2008.

The interaction of an upper level cut-off low which formed on 9 October over the Strait of Gibraltar with the Atlas Mountains led to cyclogenesis in the lee (to the south) of the Moroccan Atlas. As shown by satellite imagery, large quantities of particles were mobilized as a massive haboob to Mauretania and Western Sahara, while a broad area north and east of the low was strongly sheared and mobilized a huge amount of dust northwards on 10 October. On 11 October the depression shifted northwestward to the Gulf of Cadiz at the time that a wide high pressure system concentrated over Tunisia and Italy. Such combination enhanced the south to north advection to the Iberian Peninsula (Cabello et al., 2012). Trajectories passed over the ridge descending the lee slope northward to the Alboran Sea and Spain (Fig. 1). Strong downward movement of air is found at the lowest heights (e.g. 1000m). Meteorological data registered a pressure decrease in the preceding hours of the AD outbreak, followed by a sharp increase just at the time of the dust impact on PM10 levels.

In contrast, the most intense AD outbreak in terms of aerosol optical depth (AOD) was registered in Granada on 4-7 September 2007 (Guerrero-Rascado et al., 2009). This event is classified as the second in intensity in southwestern Spain concerning AOD (Antón et al., 2012). Daily PM10 at the background EMEP stations, however, were lower than 35 µg m^{-3}; and hourly PM10 levels of 150 µg m^{-3} were recorded in Malaga with duration of a few hours. Mediterranean advection at low levels was induced by a strong high pressure system located over the British Isles and a deep low over southeastern Europe that extended to the central Mediterranean. A thermal low was present in all northern Africa and dust advection to the Iberian Peninsula was driven by a depression SW of the Gulf of Cadiz that intensified on 5 September (Fig. 1).

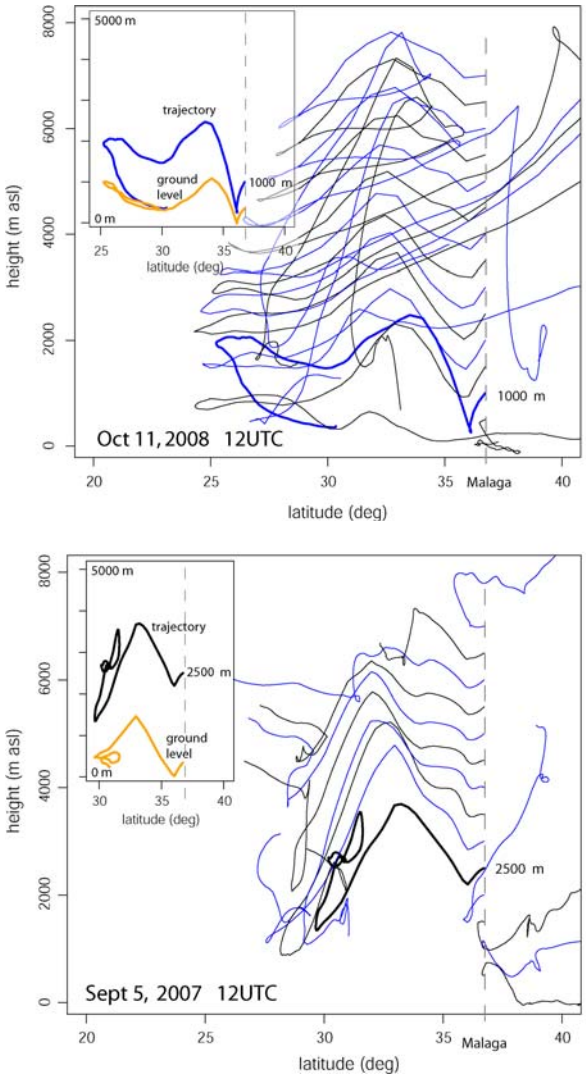

Figure 1. Plots of height vs. latitude of 96-hour trajectories arriving at Malaga (southern Spain) at 500 m steps. The insets depict the lowest trajectory with African origin and its corresponding ground level (peak is the Atlas; lowest point the Alboran Sea).

Computational investigation of vinylhydroperoxide dissociation: there is a barrier

Theo Kurtén[1], Neil M. Donahue[2]

[1] Laboratory of Physical Chemistry, University of Helsinki, P.O. BOX 55, FI-00014, Finland

Keywords: aerosol chemistry, SOA, ozone, vinylhydroperoxide
Presenting author email: theo.kurten@helsinki.fi

The oxidation of unsaturated hydrocarbons is one of the most important, yet least understood, aspects of the atmospheric component of the carbon cycle. Oxidation of terpenes (mainly by ozone) is one of the largest sources of secondary organic aerosols (SOA). The ozonolysis reaction is strongly exothermic, and proceeds via several intermediate steps, leading to a complex and variable product distribution even for relatively simple alkenes. The short lifetime and high energy of key intermediate species makes experimental characterization and separation of the individual reaction steps difficult. Many of the open issues in alkene ozonolysis concern the reactivity and fate of the Criegee Intermediates (CI), high-energy carbonyl oxides with partial biradical character. The reactivity of Stabilized Criegee Intermediates with key aerosol precursors such as SO_2 and NO_2 has recently (Welz *et al*, 2012) been experimentally shown to be significantly higher than previously measured – precisely as predicted by computational chemistry (Kurtén *et al*, 2011).

Besides leading to semivolatile or non-volatile products capable of forming SOA, ozonolysis also leads to the formation of OH radicals. This link between two of the three major atmospheric oxidants (the third being NO_3) is important, as it is one of the main routes by which OH can be formed at night, when direct photochemical sources are absent. In order to explain the pressure and time dependence of measured OH yields (OH radicals produced per consumed O_3 molecule), Drozd et al (2011) concluded that OH formation from ozonolysis proceeds via at least two intermediates, one of which is the vibrationally stabilized CI. The second intermediate was suggested to be the vinyl hydroperoxide (VHP), with a general structure $R_aR_bC=C(R_c)$-OOH where $R_{a,b,c}$ are hydrogens or alkyl groups. VHPs are formed from CIs via unimolecular isomerization. Unlike the highly reactive SCI, stabilized VHP is a relatively unreactive molecule (though one that decomposes rapidly to form OH). The atmospheric implications of stabilization data are thus dramatically different depending on which species – SCI or VHP – is produced. However, for VHP stabilization to be possible, that decomposition must involve a "tight" transition state with an energy barrier.

The dissociation of the simplest vinyl hydroperoxide CH_2=CH-OOH has been studied computationally, but with contradictory results. Richardson et al (1995) predicted that the dissociation reaction has a barrier, while some more recent studies (see e.g. Kuwata et al, 2003) have found - or assumed - the VHP decomposition to be barrierless. Common to all previous studies is their reliance on single-reference computational chemistry methods, which are unable to account for the static electron correlation associated with the resonance forms (CH_2=CH-O• and C•H_2-CH=O) of the vinyl oxide radical formed in the reaction.

We have reinvestigated the VHP dissociation using multireference methods more appropriate to the system (MRCISD(4,4)/cc-pVTZ, with energy corrections at higher levels), and found that the dissociation is indeed associated with a modest energy barrier. The corresponding transition state is shown in Figure 1. The transition state is connected by a reaction path to the reactant VHP on one side, and to a CH_2CHO•••HO radical – radical complex on the other side (see Figure 1). The transition state lies about 18 kcal/mol above the reactant and 3 kcal/mol above the product complex in enthalpy. Combining the MRCISD results with W1BD calculations for the overall reaction energetics indicates that the product complex is bound by about 7 kcal/mol with respect to free CH_2CHO + OH. Kinetic modeling will be performed in order to evaluate the impact of the computed reaction energetics on atmospheric ozonolysis chemistry.

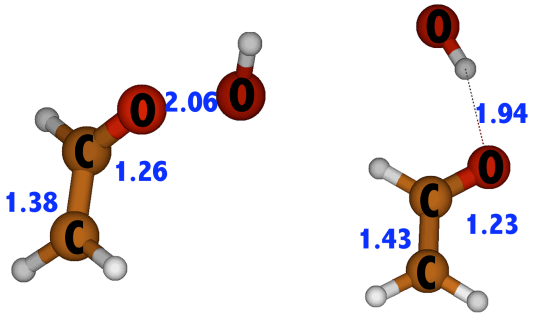

Figure 1. Transition state (left) and product complex (right) for the CH_2=CH-OOH → CH_2CHO + OH dissociation reaction, at the MRCISD(4,4)/cc-pVTZ level. Selected bond lengths are given in Ångström.

Calculations were performed using Gaussian 09 (Frisch et al, 2009) and Molpro 2010.1. (Werner et al, 2010). We thank the CSC IT Centre for Science in Espoo, Finland for computer time.

Reaction of airborne allergenic protein with different nitrating agents

K. Selzle, C. Ackaert, S. Kofler, G.J. Oostingh and U. Pöschl

Department of Biogeochemistry, Max-Planck Institute for Chemistry, Mainz, 55128, Germany
Molecular Biology Department, University of Salzburg, 5020 Salzburg Austria
Keywords: protein nitration, NO_2, O_3, reactive oxygen species, aerosol chemistry, bioaerosols
k.selzle@mpic.de

Proteins account for up to ~5% of urban particulate matter, influence the physiochemical properties of atmospheric particles, and play a major role as airborne allergens (Franze et al. 2003)

Several studies indicated that proteins could be nitrated by NO_2 and O_3 gas in atmosphere and the nitration took place at the tyrosine residue (Franze et al. 2005). Moreover, studies have suggested that nitration can change the allergenicity of proteins (Gruijthuijsen et al. 2006, Untersmayr et al., 2010).

To get a better understanding of the nitration procedure, the reaction products and pathways of protein nitration were studied with three different nitration reactants. The recombinant major birch pollen allergen Bet v 1.0101 was nitrated by liquid tetranitromethane (TNM), by liquid peroxynitrite, and by gaseous nitrogen dioxide and ozone (NO_2+O_3) as illustrated in Fig 1. Each method was applied in multiple steps of titration to obtain proteins with different nitration degrees and to get information about reaction efficiency and site selectivity. The nitration degrees of individual nitrotyrosine residues (NDY) were determined by site-specific quantification with HPLC-MS/MS and compared to the total protein nitration degrees (ND) determined by photometric detection with HPLC-DAD.

The observed nitration patterns showed the site selectivity of protein nitration which depended on the nitrating agent, reaction conditions and molecular structure of the protein (Fig. 2). These findings suggest different nitration mechanisms as well as interesting insights in nitration pathways occurring under summer smog conditions in the atmosphere (NO_2 and O_3) or during inflammatory processes in the human body (peroxynitrite).

The chemical mechanisms and molecular processes that lead to adverse health effects of NO_2 and O_3 are, however, still poorly understood. We suggest that protein nitration by air pollutants plays a major role in the increase of allergies in the western countries besides nutrition effects and excessive hygiene practices.

Temperature dependence of water activity in aqueous solutions of alcohols and organic acids

Gouri Ganbavale[1], Claudia Marcolli[1], U. K. Krieger[1], Greta Stratmann[1], Andreas Zuend[2], Thomas Peter[1]

[1]Institute for Atmospheric and Climate Science, ETH Zurich, Zurich, 8092, Switzerland
[2]Department of Chemical Engineering, California Institute of Technology, Pasadena, California, 91125, USA
Keywords: aerosols, vapour pressure, organics, temperature dependence.
Presenting author email: gouri.ganbavale@env.ethz.ch

The properties of tropospheric aerosols in terms of their hygroscopicity, phase transitions and light scattering are of great interest in view of their cloud forming and climatic characteristics. Aerosols are complex mixtures of organic and inorganic constituents. The organic aerosol fraction is expected to be present in liquid or amorphous state since a large number of organic compounds depress the temperature at which crystalline solids form (Marcolli et al 2004).

In the upper troposphere homogeneous ice nucleation and cirrus cloud formation occur on aqueous aerosol particles that grow into ice crystals by dissipating supersaturated water vapors. According to Koop et al. (2000) homogeneous ice nucleation in aqueous supercooled solutions does not depend on the nature of the solute but only on water activity, aw, the ratio between the water vapor pressure of the solution and of pure water under the same conditions. If aqueous aerosol particles are in equilibrium with the surrounding gas phase, aw and ambient relative humidity correspond. Thus aw of solutions at low temperatures is a crucial parameter for homogeneous ice nucleation.

Activity coefficients of organic solutions may exhibit a considerable temperature dependence that has to be explicitly parameterized in thermodynamic models in order to achieve accurate predictions at temperatures other than room temperature (Zobrist et al., 2008). However, most water activity data of aqueous organic solutions has been acquired at room or elevated temperatures. If temperature dependence of the activity coefficients is neglected, errors on the order of 10-15% in aw at the homogenous freezing temperature may result (Zobrist et al., 2008), which in turn would induce large uncertainties in estimating the direct and the indirect effects of aerosols.

To measure aw over a wide composition range while focusing on low temperatures, we use different measurement techniques. Direct aw measurements with an AquaLab dewpoint water activity meter (Model 3TE, Decagon devices, USA) cover the temperature range from 289-313K.Hygroscopicity measurements of single levitated aerosol particles with an electrodynamic balance cover dry conditions up to ice saturation from 200 to 300 K. The ice melting curves obtained from DSC measurements yield solid-liquid equilibria that can be directly related to the melting point depression as a function of aw.

To complement and validate these measurement techniques, we developed a setup to measure absolute vapor pressures of solutions at low temperatures and applied it to binary aqueous organic mixtures. Since we attribute measured absolute vapor pressures totally to water vapor pressures, we are restricted to binary mixtures with low organic vapor pressures that lie within the experimental uncertainty of the absolute vapor pressure. Moreover, we need an effective degassing procedure prior to the measurement to remove the air that is dissolved in the solutions.

Measurements were performed for alcohols/polyols and organic acids covering the –OH and –COOH functional groups which are commonly a part of tropospheric aerosols. Vapor pressure measurements are conducted for binary organic mixtures of water with namely 1,4-butandiol and the multi-component dicarboxylic acid mixture M5 composed of DL-malic, maleic, malonic, glutaric and methylsuccinic acid, counting among the most frequently detected in the atmosphere. Measurements were conducted over the concentration range of 10-90 wt % and temperature range of 223 to 290K. The measured vapor pressure values are used to calculate aw using the Murphy and Koop (2005) parameterization.

Results agree well within 2% of error with the aw measurements done at room temperatures and EDB measurements done at low temperatures. Strong temperature dependency was observed at low temperatures in case of 1,4-butanediol and M5 mixtures. Interestingly, binary M5 and water mixtures show a reversal of the trend of decreasing water activity with decreasing temperature at low temperature. This shows the need to measure water activities over a wide range of temperatures and compositions for various organic functional groups. We will conduct vapor pressure measurements for further interesting organic mixtures. This data will be implemented in the group contribution model AIOMFAC developed by Zuend et al. (2008) to improve the temperature dependency parameterization for low temperatures.

The two radicals OH and HO_2, which are collectively known as HO_x, play crucial roles in tropospheric chemistry. The OH radical is responsible for the majority of the oxidation in the troposphere, whilst HO_2 is cycled back to OH. The OH radical is also responsible for controlling the concentrations of many reactive species, for example volatile organic compounds (VOCs). It is therefore important to be able to accurately predict OH and HO_2 concentrations in the troposphere.

Some recent field studies have measured significantly lower HO_2 concentrations than are predicted by constrained box models. Some of the differences between the model calculations and field measurements have been attributed to uptake of HO_2 by aerosols (Jaegle *et al.*, 2000; Sommariva *et al.*, 2006; Mao *et al*., 2010). However, there have been very few laboratory studies on HO_2 uptake by aerosols and the rates and mechanism of the HO_2 loss by aerosols are still uncertain. It is therefore essential to gain a better knowledge of the uptake of HO_2 by different aerosols under different conditions. If this is achieved then the uptake coefficients can be included within models to provide a better description of tropospheric processes involving HO_2.

The HO_2 uptake coefficients for a range of inorganic and organic aerosols were measured at room temperature (≈293 K) and atmospheric pressure (≈760 Torr) using an aerosol flow tube combined with the Fluorescence Assay by Gas Expansion (FAGE) technique. FAGE is a highly sensitive laser induced fluorescence based detection method which allows the experiments to be done with low HO_2 concentrations (≈10^8-10^9 molecule cm^{-3}). The HO_2 radicals were injected into the aerosol flow tube using a moveable injector which allowed position dependent HO_2 profiles to be created as a function of different aerosol concentrations. The aerosols were produced by placing a solution in an atomiser or by using homogeneous nucleation and HO_2 was formed by the photolysis of water vapour in the presence of trace amounts of oxygen. Particle size distributions were measured with a Scanning Mobility Particle Sizer (TSI).

The HO_2 uptake coefficients were measured and found to follow first order kinetics for a variety of aerosols. The HO_2 uptake coefficient was measured for dry inorganic aerosols (γ= 0.000- 0.001), wet inorganic aerosols (γ= 0.002- 0.005), wet copper doped ammonium sulfate aerosols (γ= 0.28) and ammonium sulfate aerosols doped with different molar amounts of iron (γ=0.003- 0.06). The pH dependence of the HO_2 uptake coefficient was also investigated, however, no dependence was observed. The HO_2 uptake coefficients onto a range of both wet and dry organic aerosols were measured and found to be small (γ<0.008) with the exception of humic acid aerosols which had a larger uptake coefficient that was also dependent on relative humidity (γ=0.008-0.13). However, humic acid was found to contain metals, which may explain the higher uptake coefficient. Finally, the temperature dependence of the HO_2 uptake coefficient is being studied for a range of aerosols.

Keywords: organic aerosols, nitrogen oxides, neutron reflectometry
Presenting author email: sebastiani@ill.eu

Aerosols attract more and more the attention of the scientific community, because their impact on the Earth's radiative balance and on cloud formation is still largely unknown [*e.g.* Solomon *et al.*, 2007]. A key feature for aerosol behaviour is the presence of organic material both in the bulk and at the surface [Fuzzi *et al.*, 2006].

Our interest concerns the kinetics of oxidation reactions occurring on a surfactant monolayer at the air-water interface. Oleic acid is widely used as proxy for organic aerosols [Dennis-Smither *et al.*, 2012, Docherty & Ziemann, 2006, Hung & Tang, 2010], because of its presence in the atmosphere, for example due to meat cooking processes [Allan *et al.*, 2010]. Unlike the overwhelming majority of studies, we follow the fate of the oleic acid monolayer at the air-water interface. The reaction is driven by oxidising agents such as nitrogen oxides NO_y (NO_2, NO_3 and N_2O_5), present only during night-time, because they are rapidly photolysed by sunlight [Wayne *et al.*, 1991].

Thanks to the *in situ* production of NO_y from the reaction between NO_2 and O_3, a wide range of concentrations is accessible. Neutron reflectometry and deuterium labelling of molecules allow us to follow the reaction with high time resolution (less than 10 seconds per measurement).

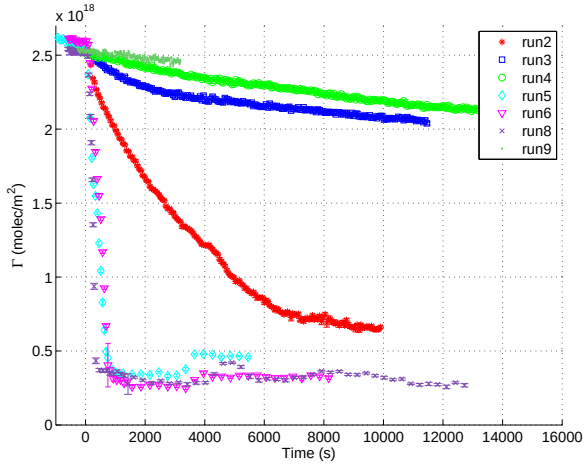

Figure 1: Decays of oleic acid surface excess as a function of time for different $[NO_3]$ and $[N_2O_5]$.

The monolayer is obtained by spreading a solution of chloroform and deuterated oleic acid on a subphase, made up by a mixture of H_2O and D_2O (8.1% by volume), in a Langmuir trough contained in a custom-built environmental chamber. The initial surface excess is controlled by changing the surface area by movable barriers; the surface pressure, which is directly related to the surface excess, is measured throughout the experiment.

In Fig.1 the decays of surface excess (Γ) are shown as a function of time for different ratios of $[NO_3]/[N_2O_5]$. At the end of the reaction the surface excess reaches a value substantially greater than the minimum Γ measurable, demonstrating that the reaction consistently leaves material at the interface. We found that once the layer is compressed again, the reaction restarts and the surface excess decays back to the previous minimum value.

The kinetic interpretation of these decays will give information on the rate coefficient specific to the reaction between the organic monolayer and the oxidant. Our aim is to understand this single component system in order to be able to move forward to multi-component systems, and investigate how the presence of different surfactants affects the rate coefficient. Complementary optical techniques, such as ellipsometry and Brewster angle microscopy, will be used to characterise the behaviour of multi-component monolayers, in order to optimise the use of neutron reflectometry and isotopic contrast variation to compare relative rate coefficients of the compounds in multi-component systems.

This work was supported by allocations of beam time at the Institut Laue-Langevin (Grenoble, France). The experiment was performed on FIGARO at the ILL. FS is grateful for support from ILL and the University of Reading in the framework of the NEATNOx studentship programme.

From free electrons to H_2SO_4 - assessing the efficiency of ion catalysed SO_2 oxidation

N. Bork[1,2] and H. Vehkamäki[1]

[1]Department of Physics, University of Helsinki, Helsini, 00014, Finland
[2]Department of Chemistry, University of Copenhagen, Copenhagen, 2100, Denmark
Keywords: Ion-induced nucleation, aerosol catalysis, air ions, sulfuric acid, chemistry
Presenting author email: nicolai.bork@helsinki.fi

Understanding the properties of clouds is one of the most challenging aspects within atmospheric chemistry. It is well known that a seed is needed to initiate nucleation and that the primary seeding is sulfuric acid (H_2SO_4). Understanding the properties of clouds is thus closely related to understanding the properties and in particular the atmospheric production of H_2SO_4 .

The most important source is UV induced oxidation of SO_2 , but recently, a number of studies have found evidence of a new synthesis mechanism, complimentary to this. This mechanism in known to invoke ions, but until now, no established mechanism can account for the observations (Kirkby *et al*, 2011).

We have initiated a line of studies dedicated to the discovery of this mechanism and the assessment of its importance. We have systematically investigated the very first interactions and reactions of a free atmospheric electron. Previously, we have established the size distributions of $O_2^-(H_2O)_n$ and $O_3^-(H_2O)_n$ clusters. Further, we have demonstrated that the rate of oxidation of SO_2 to $O_2SO_3^-$ by a $O_3^-(H_2O)_n$ cluster is collision limited (Bork et al, 2011). See also Fig. 1. This is particularly encouraging since the oxidation step of S(IV) to S(V) is known to be rate limiting of UV induced SO_2 oxidation (Loerting and Liedl, 2000).

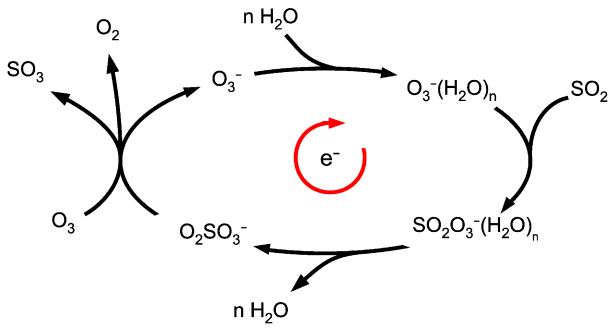

Fig. 1: The reactions involved in a simple catalytic cycle converting SO_2 to SO_3 . The catalyst is the electron.

We have continued these studies by considering the most likely chemical fate of $O_2SO_3^-$. Here, we report the reactions initiated by collision with O_3 . We have calculated the thermodynamic properties of all relevant species and complexes using density functional theory and statistical mechanics. Reaction rates were determined using transition state theory.

We find two major reaction channels,

$$O_2SO_3^- + O_3 \rightarrow \begin{cases} O_2 + O_3^- + SO_3 & (1) \\ O_2 + O_3SO_3^- & (2) \end{cases}$$

All ionic species in Reactions (1) and (2) have been observed in field studies and in experiments and are known products of ionizing radiation (Ehn *et al.*, 2010). However, until now the chemistry producing these otherwise rare species have been unknown.

We report and analyse the following results:

- The thermodynamics of Reactions (1) and (2) as well as several reactions of minor importance.
- The energy barriers and transition states, if any exist, of all reported reactions. See also Fig. 2.
- Reaction rates and rate constants at typical conditions.
- The relative rates of Reactions (1) and (2). This is of particular interest since Reaction (1) will close the catalytic cycle enabling the electron to catalyse the oxidation of another SO_2, whereas Reaction (2) stabilizes the electron and hence terminate its catalytic effect.
- The overall effects of this catalytic cycle at varying degrees of ionization, temperature, humidity and altitude and compare to experimental and field data.

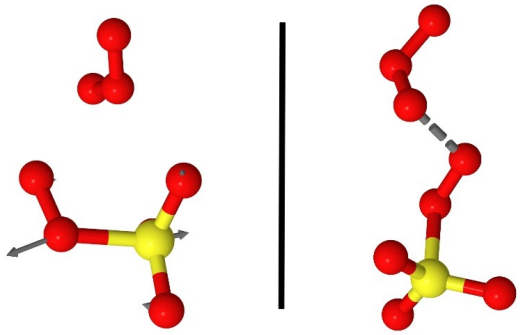

Fig. 2: Left: One of the vibrational modes leading to dissociation of the $O_2SO_3^-$ cluster and closing of the catalytic cycle, i.e. Reaction (1). Right: The transition state in the oxidation of $O_2SO_3^-$ to $O_3SO_3^-$, i.e. Reaction (2).

Simultaneous study of gas and particulate products formed from isoprene oxidation: laboratory and field measurements

C. Rio[1], S. Rossignol[1], S. Fable[1], L. Chiappini[1]

[1]Institut National de l'Environnement Industriel et des Risques (INERIS), 60 550 Verneuil-en-Halatte, France
Keywords: Isoprene, SOA, Gas-particle distribution, Smog chamber.
Presenting author email: caroline.rio@ineris.fr

Isoprene is one of the most abundant non-methane hydrocarbons emitted by vegetation into the troposphere. For a long time, it has been generally accepted that isoprene oxidation did not contribute to global SOA burden because of the volatility of its main oxidation products (methacrolein, methyl vinyl ketone…) (Pandis, 1991). It is only recently that isoprene oxidation contribution to SOA formation has been proven (Edney, 2005; Kroll, 2006).

There are still remaining uncertainties on the importance of isoprene contribution to atmospheric SOA and further studies combining ambient measurements of tracers, identified in laboratory experiments, coupled with atmospheric modeling are needed to better parameterize SOA yields and quantitatively model SOA production from isoprene oxidation (Carlton, 2009).

Therefore, the first part of this work focuses on laboratory experiments to study isoprene oxidation under realistic conditions in the EUropean PHOtoREactor (EUPHORE) in Valencia during the period 13–22 September 2010 (Figure 1(a)): seed aerosols (10 µg/m^3) were present in the chamber before isoprene and H_2O_2 introduction (70 ppb and 4 ppm respectively) under sunlight irradiation and a relative humidity close to 30 %. Moreover this study of the (isoprene + OH) reaction was performed under free-NOx condition.

A method recently developed in our laboratory (Rossignol, 2012) was used to investigate the chemical composition of both gas and particulate phases of SOAs formed.

This method consists in using stainless steel Tenax-TA adsorbent tubes previously coated with PFBHA (to specifically study carbonyl compounds) or MTBSTFA (to specifically study hydroxyl compounds) to collect the gas phase. Particulate sample are collected onto filters (quartz and Teflon-Quartz) subsequently exposed to PFBHA or MTBSTFA before analysis. These tubes and filters are subsequently analyzed by thermal-desorption coupled with gas chromatography and mass spectrometry (TD-GC-MS) analysis.

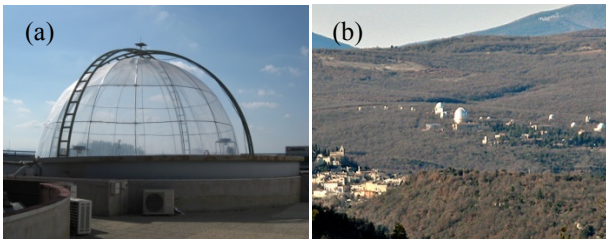

Figure1: (a) EUPHORE smog chamber, (b) St.Michel l'Observatoire with OHP in the background

About thirty compounds have been positively or tentatively identified in gas and/or particle phases. Some of these are monofunctionalized such as methacrylic acid or methacrolein, others are polyfunctionalized such as malic acid. These compounds have been quantified and for those identified in both gas and particulate phases, an experimental partitioning coefficient was calculated.

In a second time, these results will be compared to real atmosphere samples during a field campaign which will take place in June 2012 at the Observatoire de Haute provence (OHP; situated in southeast France) (Figure 1(b)) as a part of the CANOPEE field campaign. This work falls within the framework of a research program about the study of combined model-measurement of intra canopy chemistry. Not only gas and particles samplings will be realized but particles formation and isoprene emission will be observed at the same time.

Results obtained in both smog chamber and field campaign during isoprene oxidation will be presented and discussed.

Aerosol yields from ozonolysis of α- and β-pinene in simulation chamber experiments with low precursor concentrations

H. Saathoff, K.-H. Naumann, and O. Möhler

Institute for Meteorology and Climate Research, Karlsruhe Institute of Technology, Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany
Keywords: aerosol chemistry, secondary organic aerosol, aerosol formation, low concentrations
Presenting author email: harald.saathoff@kit.edu

Secondary organic aerosols (SOA) from the oxidation of biogenic volatile organic compounds (BVOC) are a large fraction of the tropospheric aerosol especially over tropical continental regions. The dominant SOA forming compounds are monoterpenes of which pinene is the most abundant. The reactions of monoterpenes with OH radicals, NO_3 radicals, and ozone yield secondary organic aerosol mass in highly variable yields. Despite the various studies on SOA formation the influence of temperature and precursor concentrations on SOA yields are still major uncertainties in tropospheric aerosol models. In previous studies we observed a negative temperature dependence of SOA yields for SOA from ozonolysis α-pinene and limonene (Saathoff et al., 2009). However, this study as well as most of the literature data for measured SOA yields is limited to terpene concentrations of several ppb and higher, hence about an order of magnitude higher than terpene concentrations even near their sources. Monoterpene concentrations in and above tropical or boral forests reach values up to a few tenth of a ppb during daytime decreasing rapidly with altitude in the boundary layer (Kesselmeier et al. 2000; Boy et al., 2004).

Therefore we investigated the yield of SOA material from the ozonolysis of α- and β-pinene under simulated tropospheric conditions in the large aerosol chamber AIDA on time scales of several hours and for terpene concentrations between 0.1 and 1 ppb. The temperatures investigated were 243, 274, and 296 K with relative humidities ranging from 25% to 41%. The organic aerosol was generated by controlled oxidation with an excess of ozone (220-930 ppb) and the aerosol yield is calculated from size distributions measured with differential mobility analysers (SMPS, TSI, 3071 & 3080N) in the size range between 2 and 820 nm. On the basis of the measured initial particle size distribution, particle number concentration (CPC, TSI, 3775, 3776, 3022), and trace gas evolution model calculations were done using the aerosol model COSIMA supplemented by a SOA module (Saathoff et al., 2009).

As previously reported for higher SOA concentrations the overall SOA yields from ozonolysis of α- and β-pinene increase significantly with decreasing temperature. However, compared to the yields extrapolated from experiments done with higher terpene concentrations the SOA yields at ambient like concentrations are surprisingly high. They reach values of up to 20% at 243 K for organic aerosol mass concentrations of about 0.5 µg m^{-3} even without additional seed aerosol.

Figure 1 shows the evolution of integrated SOA mass and particle number during ozonolysis of 109 ppt and subsequently 377 ppt α-pinene by an excess of initially 282 ppb of ozone. Please note that OH radicals were not scavenged in this experiment.

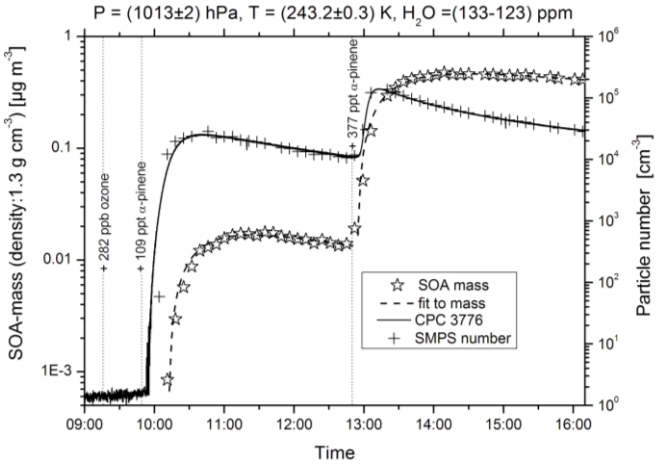

Figure 1 shows the evolution of the particle mass concentrations calculated by integration of the measured particle size distribution using a particle density of 1.3 g cm^{-3} as well as the particle number concentration for particles larger than 2.5 nm.

This paper discusses the temperature dependent SOA yields from the ozonolysis of α-pinene and β-pinene in comparison with data from literature.

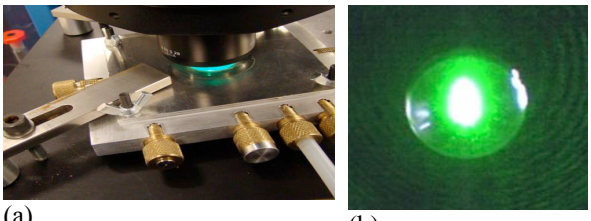
Keywords: aerosol chemistry, ozone, organic aerosols, phase changes, laser tweezers
Corresponding author's email: c.pfrang@reading.ac.uk
Session: Multi-phase chemical processes and interactions involving aerosol

Self-assembled phase behaviour of surfactant molecules during atmospheric ageing may have a major impact on the fate of organic aerosols and thus on climate change. For direct quantification of phase changes, compositional changes and kinetic parameters we will perform studies of the oleic acid/ water/ ozone system using laser Raman tweezers combined with small- and wide-angle X-ray scattering, SAXS/WAXS, at the Diamond Light Source in August 2012. This work is complemented by off-line laser Raman tweezers and X-ray scattering investigations at RAL and Reading.

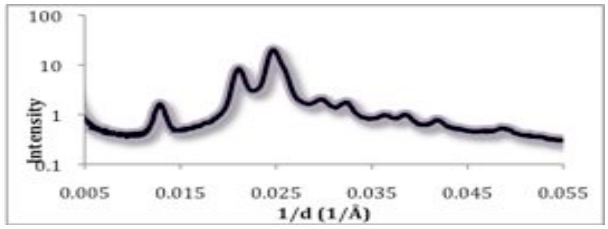
Atmospheric aerosols are key components of the climate system: they affect the climate directly, by scattering and absorbing solar radiation, and indirectly, by inducing cloud formation.[1] While atmospheric lifetimes of volatile compounds are largely determined by chemical kinetics,[2] phase-dependent mass transport parameters are important additional factors for organic aerosol components.[3] Nearly all atmospheric aerosols contain organic compounds that are often surface active, in particular fatty acids. These include stearic and palmitic acids found in marine aerosols and produced by biological degradation,[4] and oleic acid suggested as major component of cooking aerosols, mostly from seed oils.[5] Such surfactants would be expected to be present in their ionic form, where they would self-assemble into a range of aggregate structures including micelles, multi-lamellar vesicles, and other lyotropic phases. It has been



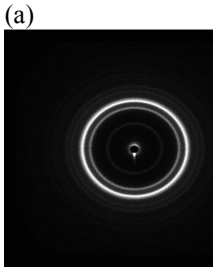
(a) (b)

Fig. 1 (a) Reading-built cell for laser Raman tweezers studies. (b) Image of levitated organic droplet.

proposed that this self-assembly would impact the properties of the aerosol,[4] potentially affecting its light scattering, and its atmospheric water uptake.[6] It has also been suggested as a mechanism for slowing down the rate of certain reactions involving the organic surfactant molecules themselves, potentially accounting for an unresolved discrepancy whereby their measured lifetimes in the atmosphere are much longer than those predicted from chemical kinetic parameters.[7,8] Feasibility of studies of atmospheric organic aerosol with laser Raman tweezers has been demonstrated at RAL.[9,10] Fig. 1(a) shows the laser-tweezing cell developed for experiments at RAL. Oxidation of organic droplets with O_3 and nitrogen oxides has been studied in this cell; a custom-made laser Raman tweezers aerosol reaction chamber has been designed at Reading, constructed at Diamond and tested successfully at RAL.



(a)



(b)

Fig. 2 Off-line XS results for ~ 50 wt % oleic acid / H_2O mixture at pH = 7. (a) Integrated intensities *vs.* 1/d obtained from diffraction pattern in (b). The sharp peaks indicate self-assembled structures on the nano-scale consistent with cylindrical micelles packed into a hexagonal array.

We levitated oleic acid/ water droplets at relative humidities controlled by balancing dry and wet O_2 flows. Once the droplet was stabilized, we initiated O_3 generation using a pen-ray ozoniser. We varied the conditions to achieve target mixtures and followed changes in composition by Raman spectroscopy. A 532 nm laser will be fibre-coupled for online Raman spectroscopy simultaneous with SAXS/WAXS studies at Diamond. A range of oleic acid/ water mixtures in bulk was studied in a Nanostar system at Reading to pin down key compositions leading to phase changes. Preliminary analysis of the Diamond experiment in August 2012 will be presented together with off-line work (see Fig. 2).

Characteristics of polymer blend particles produced by evaporation of binary solution droplets of incompatible polymers

V. Rajagopalan, E. A. Grulke and A. K. Ray

Department of Chemical Engineering, University of Kentucky, Lexington, KY 40506, USA
Keywords: droplet charge limit, evaporation, solute precipitation
Presenting author email: akray@engr.uky.edu

Polymer blend microparticles find wide range of applications in the field of opto-electronic devices, drug delivery systems, organic solar cells, and so on. These applications require generation of polymer blend microparticles with specifically tailored electrical, optical and mechanical properties. The final properties of these particles depend on the configuration (core-shell, hollow structures, etc.) and the degree of phase separation in the blend. The useful range of properties can be significantly expanded if uniformly blended polymer particles can be synthesized from arbitrary pairs of immiscible polymers. The precise control of the phase separation in polymer blends is difficult as there is inherent phase separation. The extent of phase separation in many polymer blends can by reduced by conventional methods that are limited to polymer pairs in certain property ranges. An approach based on evaporation of solution microdroplets, containing two immiscible polymers dissolved in a common solvent, has the potential for producing uniformly blended polymer microparticles. The production method based on solvent evaporation from solution droplets offers a number advantages such as high surface area, confinement effects (i.e., atto- to femto-liter volumes), and yields desirable nano- and micro-structures that are not achievable through conventional techniques. By limiting the timescale of solvent evaporation to less than that of polymer diffusion and self-organization, phase separation can be inhibited in a droplet, and thus homogeneous polymer-blend particles of immiscible polymers can be produced. The evaporation rate can be controlled by the judicious choice of solvent, temperature, and initial droplet size. In the present study we have examined characteristics of polymer blend particles produced from incompatible polymers pairs such as polyvinylcarbazol (PVK) and polystyrene (PS), polyvinyl chloride (PVC) and Poly(methyl methacrylate) (PMMA), PS and PMMA, under various conditions.

Experiments were conducted on highly mono-disperse microrddroplets that were generated using a modified vibrating orifice droplet generator. Microrddroplets were produced from a solution that was prepared by dissolving two incompatible polymers in a common volatile solvent. The effects of solvent, initial droplet size, temperature and airflow rate are studied by analyzing the final morphology of particles and the extent of phase separation. Final morphology of the particles was examined using a Scanning electron microscope (SEM) and the degree of phase separation was studied by using an Energy Dispersive X-Ray Analysis (EDS) on ultra-thin slices of produced particles and by Differential Scanning Calorimetry (DSC).

The results show that the droplet evaporation rate plays the most dominant role on the morphology of the final microparticles. The uniform polymer blend microparticles are produced by rapid evaporation of microdroplets, but the phase separation is observed when the droplet evaporation rate is reduced through solvent properties and environmental temperature.

An Inversion Method for Aerosol Particle Concentrations in the CERN CLOUD Experiment

C. Williamson[1], D Wimmer[1], K.Lehtipalo[2], J. Curtius[1] and the CLOUD collaboration

[1]Institute for Atmospheric and Environmental Sciences, Goethe University of Frankfurt, Frankfurt/M. Germany

Keywords: nucleation growth rates, ion-induced nucleation, size distribution, inverse problems, CLOUD experiment.
Presenting author email: williamson@iau.uni-frankfurt.de

A proposed link between galactic cosmic rays (GCRs) and cloud formation has been the subject of lively scientific debate (Marsh and Svensmark, 2000; Carslaw et al, 2002; Kirkby, 2007). One possible mechanism for this link is ion-induced nucleation, which is currently poorly understood. The role of ternary species, such as ammonia and organics, in aerosol nucleation has also not yet been fully characterized (Zhang, 2010).

A better understanding of the role of ions, amines and organics in aerosol nucleation can be achieved through analysis of aerosol particle growth rates under controlled conditions. The CLOUD-experiment (Cosmics Leaving OUtdoor Droplets) at CERN (European Organisation for Nuclear Research) has been set up to study the effect of GCRs on cloud formation (Kirkby et al 2011). It consists of an almost perfectly clean aerosol chamber containing synthetic air, controlled levels of sulphuric acid and negligible or controlled levels of amines and organics. Relative humidity and temperature are also controlled. The chamber can be run in a completely neutral mode (no ions present) by the application of a clearing field, with ambient surface levels of GCRs and with a high flux of simulated GCRs from the proton synchrotron beam. Conditions in the chamber are monitored by a number of instruments, including many measuring particle concentrations: two diethelene-glycol condensation particle counters (DEG-CPCs), two particle-size-magnifiers (PSMs), a CPC-battery, several Air Ion Spectrometers, a nano-differential mobility analyser, a laminar diffusion tube and a scanning mobility particle sizer.

This is the first time an integrated analysis of data from multiple instruments in the CLOUD experiment has been performed. Each instrument is sensitive to different sized particles with different efficiencies, with several of the instruments sensitive for particles in the 1-3 nanometre size range. These efficiencies were measured and the data was fitted using a four-parameter exponential function as described by Wehner et al. (2010). The results of this fitting are used to create a matrix describing the detection efficiency of each instrument for discretised diameter channels, which, along with the measured particle concentrations, forms the input for an inversion method based on that described by Fiebig et al. (2005). This produces smooth, non-negative size distributions without the use of any initial assumptions for the shape of the distribution, while taking into account the uncertainty of each of the instruments. Growth rates are calculated from the time development of these size distributions. The growth rates are important parameters for deriving the initial nucleation rates (at critical size) and for a detailed understanding of condensation, evaporation, coagulation, and wall loss processes in the 1-20 nm particle size range.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. Development of an aqueous-phase mechanism for secondary organic aerosol formation

F. Couvidat[1], K. Sartelet[1] and C. Seigneur[1]
[1]CEREA, Joint Laboratory École des Ponts ParisTech/EDF R&D, Université Paris-Est, 77455 Marne-la-Vallée, France
Keywords: Aerosol model, Modelling (regional), SOA (Second. Organic Aerosols)
Presenting author email: couvidaf@cerea.enpc.fr

H^2O (Hydrophilic/Hydrophobic Organics) is a Secondary Organic Aerosol (SOA) model based on the molecular representation of SOA and on the partition of two types of compounds: hydrophilic species (which condense preferrentially on an aqueous phase) and hydrophobic species (which condense only on an organic phase). This model integrates the state of art knowledge and takes into account the condensation of semi-volatile compounds, formation of SOA from various precursors and several related processes. However, this model does not take into account the aqueous-phase chemistry of clouds and the formation of low-volatility compounds which can lead to SOA formation after cloud evaporation. The aim of this study is to take into account cloud chemistry and to estimate its impact on SOA formation. Impact of cloud chemistry on aerosols concentrations in Europe is estimated with the model from August 1st to August 15th 2002.

SOA formation from glyoxal, methylglyoxal, methacrolein, methylvynylketone and tetrols formation in an aqueous phase are included in the model. This new mechanism relies on published mechanisms and on recent experimental data. Fig. 1 shows the impact of cloud chemistry on ground concentrations. Only small quantities of SOA (between 2 and 14 ng/m^3) are formed in the model via the oxidation of Volatile Organic Compounds (VOC) in clouds. This seems to indicate that in-cloud oxidation of VOC has only a minor impact on SOA concentrations over Europe. However, impact of cloud chemistry could be higher in more humid areas with high emissions of biogenic emissions like Amazonia where high concentrations of tetrols were found [Claeys et al. (2004)].

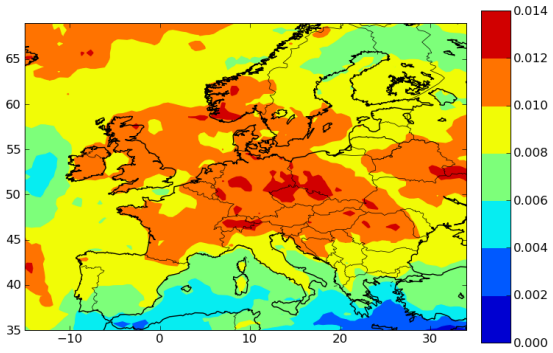

Figure 1: Ground concentrations (μg.m^{-3}) of SOA formed by aqueous-phase reactions over Europe from August 1st to August 15th 2002.

A simple aging mechanism of SOA in the aqueous phase of clouds was also developped and included in the model. This aging mechanism assumes that some Semi-Volatile Organic Compounds (SVOC) can be absorbed in clouds and be oxidised to form less volatile compounds. Clouds could then influence the oxidation and partitioning of existing aerosols. Impact of clouds on chemical aging will be studied to estimate whether or not clouds can contribute to organic aerosol formation over Europe.

This work was funded in part by ADEME, the French Agency for the Environment and Energy Management.

Capturing of low-level CO_2 using AC particles

Y. H. Lim, Y. M. Jo†

Department of Applied Environmental Science, Kyung Hee University, Yongin, Gyeonggi-do, 446-701, Korea
Keywords: CO_2 adsorption, Activated carbon, MEA, Impregnation, Volume reduction
Presenting author email: ymjo@khu.ac.kr

Well insulation of modern buildings including residentials, industrial, schools, subways, etc deteriorates the public indoor air quality(IAQ)(Lim et al., 2010). Carbon dioxide level is one of the key indicators of IAQ as well as the main greenhouse gas of concern (Lee & Jo, 2008). Development of CO_2 capture and storage techniques using adsorption processes is of great interest due to their low energy requirement and low capital cost (Ranjani et al., 2005).

Nitrogen surface groups on particulate AC adsorbent, of which basis was coconut(WSC-470) was introduced from amine. In order to enhance the adsorption capacity, a commercial particulate AC was modified with MEA(monoethanolamine) by methods of impregnation and volume reduction. Impregnation method was a direct process to incorporate MEA onto the AC surface, whilest volume reduction method the solvent reduction by means evaporation till achieving the concentrated solution. The AC particles were immersed in an aqueous solution of 1.0M MEA with different solvents (distilled water, methanol and ethanol) at 40 ^oC and dried. Methanol and ethanol were chosen for their low boiling points(64.7 ^oC, 78.3 ^oC) comparing to water(100 ^oC) (Chatti et al., 2009). The completed adsorbents were analyzed by XPS and BET, and the adsorption capacity was evaluated in a fixed bed. The XPS proved chemical functionalities over the AC surface. Table 1 summarizes the elemental composition(at. %) for the prepared AC surface. The amount of nitrogen funtionalites over raw AC was 0.7%, and the modified samples were more than the raw AC. Volume reduction method was found to be better than the impregnation method.

Table 1. Elemental compositions of AC adsorbents by XPS

AC(WSC-470)		Atomic ratio(%)		
Method	Solvent	C	N	O
Imp.	H_2O	90.01	1.81	8.18
	C_2H_5OH	88.88	1.81	9.31
	CH_3OH	89.38	2.03	8.59
Vol. reduction	H_2O	86.55	2.37	11.08
	C_2H_5OH	88.18	2.53	9.29
	CH_3OH	88.26	2.51	9.24
Raw AC		93.30	0.70	6.00

The specific surface area of the prepared AC samples measured by BET is given in Table 2. It showed that grafting of nitrogen groups would decrease the surface area blocking tiny pores.

Table 2. BET surface area of raw and modified ACs

AC(WSC-470)		Surface area(m^2/g)
Raw AC		1369.60
Imp.	H_2O	954.53
	C_2H_5OH	1149.30
	CH_3OH	1071.41
Vol. reduction	H_2O	754.77
	C_2H_5OH	490.63
	CH_3OH	860.33

Figure 1 is the adsorption amount of raw and modified AC adsorbents. The CO_2 adsorption capacity of the modified ACs increased steadily with the increase of N-groups. According to the XPS analysis, the most N-groups were found in a samples of MM-AC prepared with volume reduction. In more details, the more NH_2-like N-groups as well as amine were distributed on the MM-AC adsorbent. The present study revealed the selective capability of dry capture of CO_2 in the atmosphere.

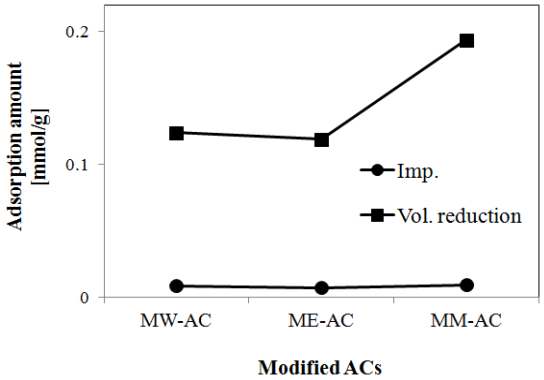

Figure 1. Adsorbed amount of CO_2 on the modified ACs (CO_2 conc. 3000ppm).

SOA Formation from Acid Catalysed Rearrangement Reactions

Y. Iinuma[1], A. Kahnt[1,2], O. Böge[1] and H. Herrmann[1]

[1]Leibniz-Institut für Troposphärenforschung, Leipzig, 04318, Germany
[2]Present address: Department of Pharmaceutical Sciences, University of Antwerp, Antwerp, B-2610, Belgium
Keywords: SOA, Smog chamber, Aerosol characterisation
Presenting author email: yoshi@tropos.de

The influence of acidic seed particle on SOA formation has been received a significant attention in the past decade since Jang *et al.* (2002) have presented evidence for multifold increases in SOA formation through acid catalysed particle phase reaction. The enhanced SOA formation is attributed to the formation of accretion compounds from acid catalysed reaction of carbonyl compounds, peroxy compounds, or the formation of organosulfates from alcohols and epoxides.

Reactive uptake of gas-phase semi-volatile organic compounds has been reported to be an important pathway leading to the formation of organosulfates, and enhanced SOA formation (e.g. Iinuma *et al.*, 2009; Surratt *et al.*, 2010), though it does not explain increases in SOA production for some of VOC oxidation experiments in which no organosulfate formation is observed (e.g. α-pinene ozonolysis). In this study, we present a formation of highly reactive VOCs from acid catalysed multiphase reactions of monoterpene oxides. Subsequent oxidation of the highly reactive VOCs forms significantly more SOA than the precursor VOCs. The process involves both gas- and particle phase reactions and likely plays a role in SOA formation in the ambient atmosphere. Table 1 summarises experimental conditions used in the present study.

Table 1. Chamber experiment conditions used in this study

	α-Pinene oxide	*β-Pinene oxide*
Initial HC Conc. [ppbv]	100	100
Initial Ozone [ppbv]	0, 60	0, 60
RH%	0, 50	50
Temp [ºC]	20	20
Reaction Time [h]	~ 3	~ 3
Sampling [h]	1 (1.8 m^3)	1 (1.8 m^3)
Seed Particle	pH 0, 7	pH 0, 7

Figures 1 and 2 show the SOA mass increases as a function of experimental time for α-pinene oxide and α-pinene oxide, respectively. For both VOCs, almost no SOA mass increase was observed in the case of neutral seed aerosol experiments regardless of the ozone concentrations. On the other hand, significant increases in the SOA mass were observed for both VOCs in the presence of acidic seed aerosol and ozone. In the case of β-pinene oxide, acidic seed aerosol is sufficient to promote significant SOA formation from a reactive uptake process that forms organosulfates (Iinuma *et al.*, 2009).

In the presence of acidic seed aerosol, both α-pinene oxide and β-pinene oxide isomerise forming monoterpene aldehydes and alcohols that react rapidly with ozone, leading low volatile SOA compounds. This mechanisms partly explains the increased SOA formation in the presence of acidic seed particle.

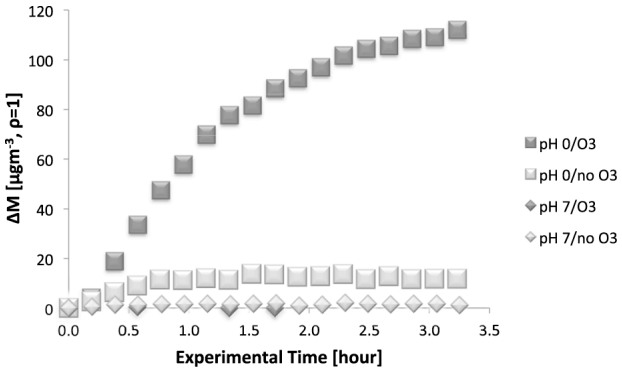

Figure 1. SOA mass increase as a function of experimental time for α-pinene oxide.

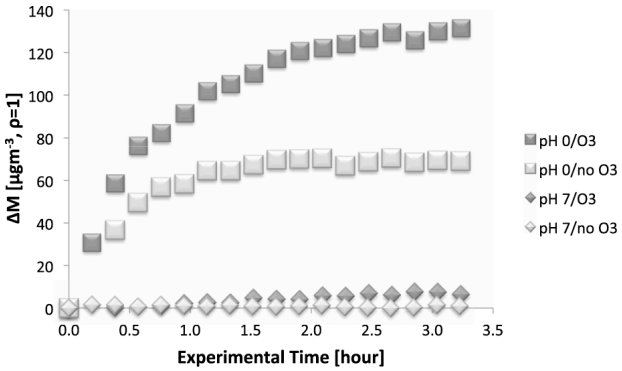

Figure 2. SOA mass increase as a function of experimental time for β-pinene oxide.

Surface tension and aggregate formation in nanoaerosols containing model HULIS compounds

T. Hede[1]

[1] Department of Meteorology, Stockholm University, S-106 91 Stockholm, Sweden

The frequently used theory for water vapour condensation, water droplet growth and stability is Köhler theory (Köhler, 1936). This theory, however, is based on the assumption that the cloud condensation nuclei consist of inorganic salt and mineral dust. It has been shown that a large fraction of the CCN consist of organic compounds (Novakov and Penner, 1993). We have studied secondary organic aerosol compounds that are Humic-like substances (HULIS) (Hede *et al*, 2011). We focus on three compounds that make up model HULIS compounds. Cis-pinonic acid (CPA), pinic acid (PAD) and pinonaldehyde (PAL). These model HULIS compounds are amphiphilic and have surface active properties that can decrease the surface tension and thereby lower the supersaturation needed for water vapour condensation, according to Köhler theory.

In order to study nanoaerosols and to determine the molecular properties of these systems, we conducted molecular dynamics (MD) simulations. MD simulations use Newtonian laws of motions and apply this to a computer model of a system. From the trajectories, orientations of the individual molecules as well as surface tension was determined. In Fig. 1 the surface tension reduction dependent on the concentration of each model HULIS compound is shown. The data is fitted to the Szyszkowski equation (Szyszkowski, 1908).

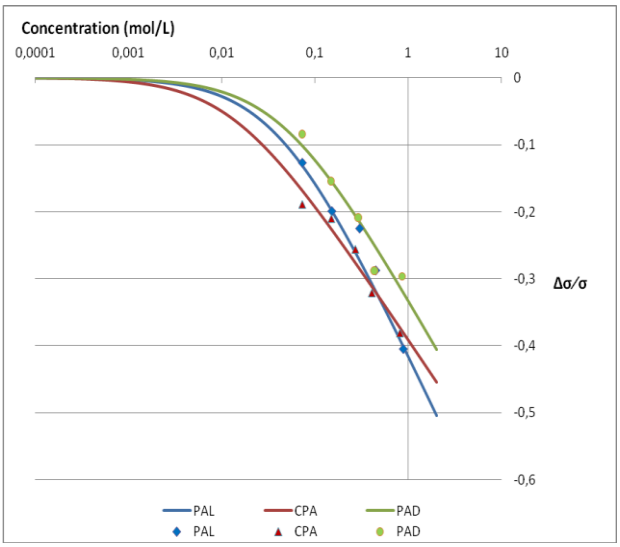

Figure 1. Szyszkowski curves for the model HULIS compounds CPA, PAD and PAL.

We could show that the surface tension reduction was high for these compounds, and that or simulated data was comparable to experimental data (Shulman *et al*, 1996)

We could also show that the model HULIS compounds not only accumulated at the surface, but also formed an aggregate inside the nanoaerosol. This is also reported in an experimental study by Virtanen *et al* (2011).

These results are of importance for the understanding of the structure and properties of organic compounds in nanoaerosols, and the use of MD simulations opens up for a new area of research in the field of aerosol science.

Formation and aging of secondary organic aerosol through evaporation of aqueous phase processed isoprene reaction products

F. Siekmann, P. Renard, B. Temime-Roussel and A. Monod

Laboratoire Chimie Environnement, Aix-Marseille Université, Marseilles, 13003, France
Keywords: isoprene, SOA, clouds, evaporation, AMS, LC/MS
Presenting author email: frank.siekmann@uni-bayreuth.de

Reactive volatile organic compounds (VOC) emitted from biogenic sources, can be oxidized in the gas phase to transform into more water-soluble compounds that readily partition into atmospheric water droplets. Due to further oxidation in the liquid phase, higher molecular and less volatile compounds can be formed. Upon water evaporation, these less volatile products can remain at least in part in the particle phase, leading to secondary organic aerosol (SOA) formation (Carlton et al., 2009; Ervens et al. 2011).

In laboratory experiments, we investigated the ability of methyl vinyl ketone (MVK) and methacrolein (MACR), the two main gas phase atmospheric oxidation products of isoprene, to form secondary organic aerosol (SOA) through aqueous phase OH-oxidation and subsequent water evaporation.

In the first step, the oxidation products of MVK and MACR in the aqueous phase were studied by ESI-MS and LC-ESI-MS analysis. The aqueous phase chemical composition brought clear evidence for the formation of oligomer systems having a mass range up to 1400 Da (Liu et al., 2012). The intensity and masses of oligomers became increasingly important as precursor initial concentrations increased from 2 to 20 mM.

Subsequently, these aqueous phase oxidation products were studied in nebulization-evaporation experiments for their ability to generate organic aerosol. For these studies, AMS and SMPS analysis were used to determine the composition and mass of the dried aerosol. Furthermore, filter samples were taken to check for any chemical artifact due to the nebulization and drying steps.

The mass concentration of these SOA increased significantly with the reaction time. The evaluated SOA mass yield ranged from 2 to 12%, depending on the reaction advancement, for both precursors.

For both precursors, the oligomers were responsible for the SOA formation during nebulization experiments. The AMS results indicate differences, regarding the relative importance of oligomerisation and aging processes during aqueous phase photooxidation. The composition of the generated aerosol and the influence of initial precursor concentrations and reaction time will be presented and discussed.

Influence of reaction conditions on the formation of dimers and peroxides originating from the ozonolysis of a-pinene and the OH reaction of nopinone

A.Mutzel, Y. Iinuma, O. Böge, A. Kahnt and H. Herrmann

Leibniz-Institut für Troposphärenforschung, Permoserstr. 15, Leipzig D-04318, Germany
Keywords: VOCs, SOA, Aerosol characterization
mutzel@tropos.de

The oxidation of biogenic volatile organic compounds (BVOC) leads to the formation of a wide range of products with multiple functional groups. The formed semivolatile products can partition into the particle phase and therefore they contribute significantly to the formation of secondary organic aerosol (SOA). Especially peroxides and dimeric compounds are suggested to make up a significant fraction of SOA (Docherty et al., 2005 and Kalberer et al., 2004). Although several studies exist about the formation of SOA originating from the monoterpene oxidation (see review by Hallquist et al., 2009) there is a gap in the knowledge about the involved species and the influence of the reaction conditions on the SOA formation.

The focus of the present study is to compare the formation of dimers and peroxides from the ozonolysis as well as from the OH radical reaction of monoterpenes and their related compounds. Two sets of chamber experiments were conducted for this purpose. The first set of experiments comprised the oxidation of α-pinene with ozone in the presence of carbon monoxide as OH scavenger. In the second set of the experiments the OH radical reaction of nopinone was examined. The OH radicals were generated using the ozonolysis of tetramethylethylene (TME). For both set-ups the influence of relative humidity (rh) and initial particle concentration (P_{ini}) were examined (Table 1).

Table 1. Reaction conditions for both experimental sets (temperature 20±1°C)

Relative humidity [%]	Initial Particle concentration P_{ini} [m^{-3}]
0	≈ 20 000
50	≈ 10 000, 20 000, 40 000
75	≈ 20 000

The formed particulate products were collected using a denuder/filter sampling device. One half of the filter was used for the analysis using HPLC/(-)ESI-TOFMS and the second half for the peroxide test. The peroxides were determined using an iodometric-spectrophotometric method developed based on the method described in Docherty et al., 2005.

The detected peroxides show a strong dependency on the reaction conditions. The peroxide content decreased with increasing particle concentration for both the OH radical reaction and the ozonolysis. In contrast to the ozonolysis samples, the peroxide content decreases with increasing relative humidity for the OH radical reaction. These strong dependencies can be caused by the influence of relative humidity on the partitioning behavior of the peroxides and their corresponding precursor (Seinfeld et al., 2001). Additionally, a direct influence of experimental conditions on the formation reactions cannot be excluded.

The further analysis of the particle-phase compounds revealed a number of monomeric and oligomeric compounds. The major monomeric products were detected at the mass to charge ratios (*m*/z) 157, 171, 185, 203 and 231 corresponding to terebic acid, terpenylic acid (Claeys *et al*., 2009), pinic acid, 3-methyl-1,2,3-butanetricarboxylic acid (Szmigielski *et al*., 2007) and diaterpenylic acid acetate (Iinuma *et al*., 2009). In addition pinonic acid with *m/z* 183 was detected from α-pinene. The detected monomeric compounds are also strongly influenced by relative humidity and seed particle concentration, which is explained by a change in partitioning behaviour.

Furthermore, among the detected dimers, one major dimer was identified from both α-pinene and nopinone. This compound with *m/z* 357 corresponds to $C_{17}H_{25}O_8$. The formation of this compound showed different response to the reaction conditions. In the ozonolysis experiments, the amount increased with increasing relative humidity and with particle concentration. Contrary, an influence of particle concentration was not seen during the OH radical reaction. This observation and the missing correlation between the formation behaviour of *m/z* 357 and the peroxide content give a hint that the observed dimer at *m/z* 357 likely contains no peroxide structure.

Comparison of sesquiterpene oxidation products in secondary organic aerosol from different vegetation zones

A. van Eijck[1], C. Kampf[1], T. Hoffmann[1]

[1]Institute for Inorganic and Analytical Chemistry, Johannes Gutenberg-University, Duesbergweg 10-14, 55128 Mainz, Germany

Keywords: Aerosol characterization, Atmospheric aerosols, Field measurements, Organic acids

Presenting author email: van.Eijck@uni-mainz.de

Secondary organic aerosol (SOA) has a huge impact on air quality and potentially climate change. It influences the Earth radiative budget through absorbing, scattering and reflecting radiation as well as the formation of clouds because the particulates can act as cloud condensation nuclei (CCN). Furthermore, SOA plays an important role for human health. SOA is formed from gaseous precursors which get oxidized by ozone, OH- and NO_3-radicals in the atmosphere. Due to their low vapor pressure these degradation products can nucleate to form new particles or they can condense on existing aerosol particles. Despite the major progress in research during the last few years the actual chemical composition as well as the contribution of various volatile organic compounds (VOCs) to the formation of secondary organic aerosol is still partially unknown.

Recent studies indicate that sesquiterpenes play an important role in the formation of SOA because of the low volatility of their oxygenated products (Lee *et al*., 2006). Their emission is estimated to be about 14,8 Tg per year (Henze *et al*., 2008), and some studies indicate that it can be as high as 30 or 40 % of the total monoterpene emission (Tarvainen et al., 2005; Helmig et al., 2007). However, these emission rates remain highly uncertain due to the lack of quantitative emission rate measurements. In addition, the knowledge about the actual atmospheric degradation mechanism and the main oxidation products of sesquiterpenes is quite limited. β-Caryophyllene, α-humulene, α-farnesene and β-farnesene are the most abundant sequiterpenes in many sesquiterpene emission profiles. But also aromadendrene, α-bergamotene and δ-cadinene and germacrene-D can contribute significantly to some emission profiles (Duhl *et al.*, 2008).

Furthermore the difference between the measured OH reactivity and the calculated OH reactivity indicates, that some undetected reactive biogenic volatile organic compounds emitted by vegetation are responsible for the excess of OH reactivity. Several studies suggest the assumption, that this excess of reactivity arises from sesquiterpene emissions (Kim et al., 2011).

To determine the major oxygenated products of sesquiterpenes in SOA, reaction chamber experiments with six different sesquiterpenes and ozone were performed in a 100 L reaction chamber. Their major oxidation products were determined. To measure the time dependent formation of initial oxidation products, an APCI-IT-MS was directly connected to the reaction chamber. After 2 hours the APCI-IT-MS was replaced by a filter holder and the generated aerosol was collected for 17 hours. In case of β-caryophyllene five different acidic oxidation products were synthesized and these acids were used for quantification. Atmospheric air samples taken during the HUMPPA campaign summer 2010 in Finland and during the BEACHON-RoMBAS campaign summer 2011 in Colorado, USA were analyzed for sesquiterpene oxygenated products. The major sesquiterpene oxidation products in the ambient air samples were quantified and compared to the amount of monoterpene oxidation products found in the filter extract. The mainly emitted sesquiterpenes in the two different vegetation zones were compared and the correlation with different meteorological data was analyzed.

Produced from biologic ocean activity, fatty acids are ejected into the atmosphere along with sea salt on their surface (Mochida, Kitamori et al. 2002). They are also emitted by cooking activity or biomass combustion. Once in the atmosphere, these compounds will be oxidized leading to the modification of their chemical and physical properties. Ozonolysis of oleic acid ($C_{18}H_{34}O_2$) is one of the most studied heterogeneous reactions as a model for aging of organic particle matter (Zahardis and Petrucci, 2007). Depending on experimental conditions and techniques used, the reactive uptake coefficient ranges between ~7×10^{-4} and ~10^{-2} . γ determination is also depending on the way where the kinetics is monitored (loss of ozone or oleic acid or appearance of reaction products). In this work, we fully characterize the reaction by measuring *in line* concentrations evolution of the products and of the reactants in the gas phase and in the condensed phase.

The heterogeneous ozonolysis of oleic acid particles have been studied in an aerosol flow tube (AFT). Ozone is generated by UV photolysis of O_2 and measured with a UV photometric analyzer (Thermo Scientific). Particles are generated by homogeneous nucleation of oleic acid vapors. Size distributions recorded by a scanning mobility particle sizer exhibit a monodisperse distribution centered at 130 nm. Particles are exposed to a large range of ozone concentrations from 30 to 650 ppb during 200 to 500 seconds. The originality of this study is to perform uptake experiments by measuring the loss of ozone as a function of the aerosol surface density. The later is modified by varying continuously the liquid oleic acid temperature leading to increase the aerosol concentration and, therefore, the aerosol surface density. Those measurements have been conducted by exposing particles concentrations (from 0 to 10^6 cm^{-3}) to stable ozone concentrations and monitoring the remaining ozone downstream the AFT.

The reactants and the products of the reaction have been measured in both gas and particle phase. The particle phase has been characterized online by an aerosol mass spectrometer (AMS) and collected on filters for Gas Chromatography – Mass Spectrometry (GC-MS) analysis. Gas-phase products have been measured by a Proton Reaction Transfer – Time of Flight – Mass Spectrometer (PTR-ToF-MS).

From the measurements, we derived the value of the uptake coefficient (γ_{obs}) as a function of the ozone exposure (10^{-5} to 3.5×10^{-4} Atm.s). It appears that γ_{obs} depends on the ozone exposure and decreases from 1.2×10^{-3} to 2.5×10^{-5} suggesting that the uptake kinetic could be limited by diffusion processes at the surface or inside the particle. The GC-MS analyses have allowed us to quantify the loss of oleic acid and the appearance of products as a function of the exposure of the particle phase to ozone. HR-Tof-AMS analysis are confirmed the GC-MS data (see Fig 1).

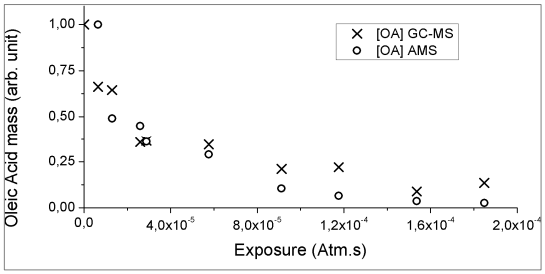

Fig 1: Normalized loss mass of oleic acid measured by AMS (m/z=264 amu) and by GC-MS as a function of ozone exposure.

Nonanoic acid, azelaic acid, 9-oxononanoic acid and nonanal reaction products have been quantified by GC-MS analysis. Moreover, under these specific conditions, it appears that there is up to 3 ozone molecules lost for only 1 oleic acid molecule consumed, which suggest that secondary ozonolysis takes place for high concentration of ozone.

Effect of ions on the measurement of sulphuric acid at CLOUD

Rondo, Linda[1], Kürten, Andreas[1], Ehrhart, Sebastian[1], Curtius, Joachim[1] and the CLOUD collaboration
[1]Institute for Atmospheric and Environmental Sciences, University of Frankfurt am Main, Altenhöferallee 1, 60438, Frankfurt am Main, Germany
Keywords: CIMS, sulphuric acid, ternary nucleation, ions, CLOUD experiment

Atmospheric aerosols exert an important influence on clouds and climate. It has been well established that nucleation from gaseous precursors comprises an important source of particles in the atmosphere, and that sulfuric acid (H_2SO_4) plays a crucial role in atmospheric nucleation. In addition, recent studies indicate that ammonia (Kirkby *et al.,* (2011)) and oxidised organic compounds (Metzger *et al*., (2010)) can enhance the nucleation rate by order of magnitude for a given sulphuric acid concentration. However, it is not yet clear what ternary substances contribute in atmospheric nucleation and whether ions play an important role in this respect.

One goal of the CLOUD (Cosmics Leaving OUtdoor Droplets) experiment at CERN is to investigate to what extent the presence of atmospheric ions affects new particle formation (Kirkby *et al*., (2011)). Neutral and ion-induced nucleation experiments are carried out in an aerosol chamber under precisely controlled conditions. Trace gases are added into the CLOUD chamber in order to observe their influence on the ternary nucleation. The source of ions in the chamber is either Galactic Cosmic Rays (GCR) or CERN's proton synchrotron (PS) beam, respectively (Duplissy *et al.*, (2010)).

Highly accurate and precise measurements of gaseous [H_2SO_4] are required in order to interpret the data and for deriving parameterizations of the nucleation rate for certain conditions.
Therefore, for reliable sulphuric acid concentration measurement a Chemical Ionization Mass Spectrometer (CIMS) with a corona discharge ion source (Kürten, *et al*., (2011)) is used. The principle of this measurement is based on the reaction between H_2SO_4 and NO_3^- primary ions followed by the detection of HSO_4^- ions with a mass spectrometer (Tanner and Eisele *et al*, (1993)).

During ternary nucleation experiments, the addition of organic trace gases resulted in a cross-sensitivity of the CIMS H_2SO_4 measurements due to ions (ion enhancement effect). The ternary trace gases that were used were NH_3, DMA (dimethylamine) and oxidised products of pinanediol. The observed increase in bisulphate ion concentration due to ions occurred mainly during the introduction of pinanediol at a concentration of several ppbv into the CLOUD chamber. The enhancement of this effect was only observed during ion induced nucleation measurements by using either GCR or the PS beam, respectively. By applying a high voltage (HV) clearing field inside the CLOUD chamber the ion effect on the CIMS measurement is completely eliminated since, under these conditions, all small ions are swept from the chamber in about one second.

Using a corona ion source for the CIMS proved to be an advantage when measuring sulphuric acid in the presence of organic substances inside the CLOUD chamber. When switching off the corona ion source, the observed HSO_4^- can only be produced by the ionisation radiation inside the CLOUD chamber and is therefore a background signal which needs to be subtracted when present during normal operation (see Fig. 1). In the presentation the charge effect will be explained in detail as well as the method used to derive the representative numbers for [H_2SO_4] during the ternary nucleation experiments conducted at CLOUD. In addition, it will be discussed whether this effect could potentially affect atmospheric sulphuric acid measurements

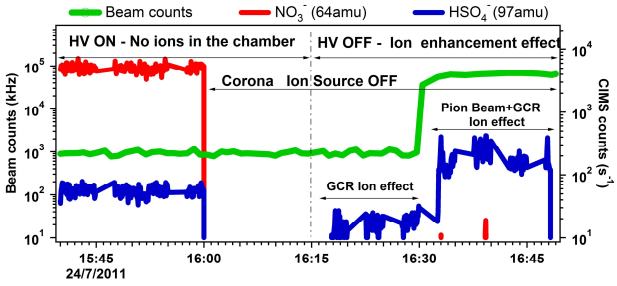

Figure 1. Example of the effect of charged pion beam to the monomer HSO_4^- concentration measured by CIMS during a nucleation run at the CLOUD chamber, when the corona ion source is being disabled.

For the first time, we have shown that thin films on an optically trapped aerosol can be probed and sized in real time. Optical trapping combined with white light broadband Mie Spectroscopy (Ward 2008, Schmitz 2011) has been used to determine the presence of a thin film on an aerosol droplet. This technique provides an ideal way to study the oxidation reaction of thin films on aerosol as it is non contact and therefore well represents atmospheric conditions. Initial results have been obtained that indicate the presence of a thin film of oleic acid on a sodium chloride aerosol.

The influence of aerosol on cloud formation and cloud radiative properties remains one of the largest uncertainties in aerosol radiative forcing as stated in the latest IPCC report, AR4 (IPCC 2007).

A major constituent of tropospheric aerosol is marine aerosol, which is often formed with a thin film of organic material present at the air/water interface (Tervahattu 2002). The interfacial films are made up of fatty acid molecules such as stearic and oleic acid, that originate from the breakdown of lipid membranes from ocean dwelling organisms such as phytoplankton. The fatty acids accumulate in the surface microlayer of the ocean, and can be incorporated as an organic coating at the air/water interface when marine aerosols are formed by wind action (Tervahattu 2002). As the thin film forms an encapsulating hydrophobic layer around the aerosol, it plays a central role in the chemistry and hygroscopic properties of the aerosol (Ellison 1999). Furthermore, this film also impacts on the ability of aerosol to form cloud condensation nuclei (CCN) and contribute to the aerosol radiative forcing of the climate (Ellison 1999).

Tropospheric chemical reactions of fatty acid thin films on aerosol, with ozone and atmospheric radicals have the ability to change aerosol properties. Such reactions can break down the hydrophobic thin film. It has been shown by King 2004, using an optical trapping technique, that the ozone oxidation of a thin film of oleic acid on sodium chloride aerosol alters the hygroscopic properties of the aerosol.

The subtle changes in Mie resonances between an uncoated sodium chloride aerosol and a sodium chloride aerosol coated with a thin film of oleic acid-highlighted by theoretical predictions in Figure 2, allow for size and refractive index characterisation of the aerosol.

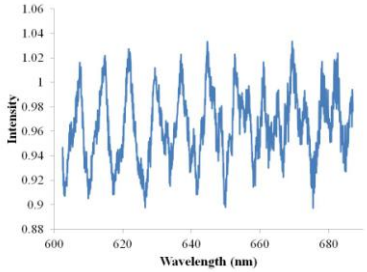

Figure 1. Experimental Mie resonances generated by an optically trapped sodium chloride aerosol with a thin film of oleic acid.

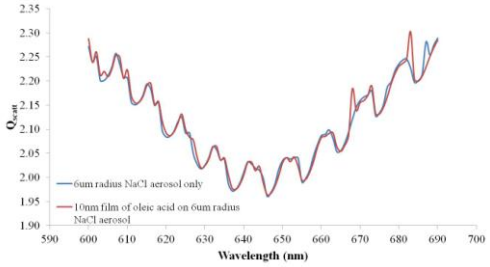

Figure 2. Theoretical Mie resonances for an uncoated 6µm radius sodium chloride aerosol and a coated 6µm radius sodium chloride aerosol with a 10nm thin film of oleic acid.

Future work will involve further fitting, modelling and refinement of the experimental technique.

Study on the effect of CO_2 partial pressure on mechanism of sulfation of calcium carbonate sorbent particle

Seongha Jeong[1], Kang Soo Lee[1], Sang In Keel[2], Jin Han Yun[2], and Sang Soo Kim[1]

[1]Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Republic of Korea

Presenting author email: jeongsh@kaist.ac.kr

Due to increasingly strict greenhouse gas emission regulations, Oxy combustion systems were introduced as a promising CO_2 recovery technique for use in power plants. In oxy-combustion, flue-gas recirculation creates an atmosphere that is primarily CO_2 with a small amount of O_2. Therefore, the phenomena of sorbent particles in an oxy atmosphere are different compared with those in an air atmosphere.

Direct sulfation of calcium carbonate sorbent particle which takes place under high CO_2 partial pressure atmosphere can be applied to Oxy combustion system. However, there's no apparent reaction mechanism about it in comparison with in-direct sulfation (Liu et al., 2000).

In this study, sulfation was performed by using a thermogravimetric analysis (TGA). Experiments were conducted at isothermal condition (1000ºC) with the gas stream of 20% O_2, 80% CO_2 for direct sulfation and 100% air for in-direct sulfation. In each case, SO_2 with concentration of 3000 ppm was injected. After reaction, the morphology of the surface and cross-section of the samples was observed using FIB-SEM. In addition, chemical compositions at the several positions were measured using EDS.

To determine the adsorption sites for SO_2 molecules, the spatial distribution of S-containing compounds was analyzed using EDS. Figure 1 shows that S-containing compounds (blue dots) were distributed over the entire particle in in-direct sulfation, whereas S-containing compounds were gathered around the surfaces of particles in direct sulfation.

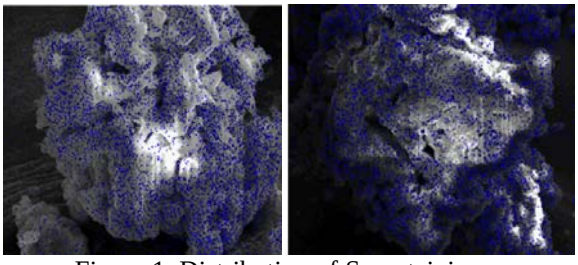

Figure 1. Distribution of S-containing compounds in cross-sectional images of $CaCO_3$ sorbent particles near the completion of in-direct sulfation (left) and direct sulfation(right).

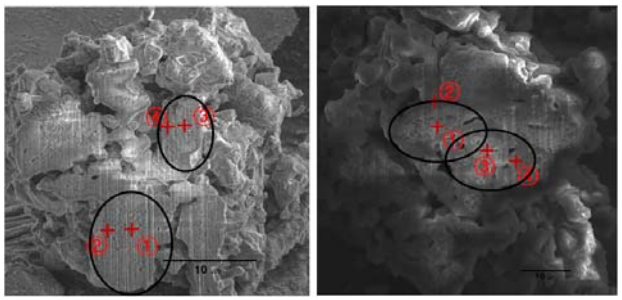

Figure 2. Cross-sectional SEM images of $CaCO_3$ sorbent particles near the completion of in-direct sulfation (left) and direct sulfation(right). Initial particle units are denoted by circles

Table 1. S/Ca ratio of the cross section of $CaCO_3$ sorbent particles

	S/Ca ration	
position	In-direct sulfation	Direct sulfation
①	0.72	0.058
②	0.34	0.047
③	0.64	0.12
④	0.40	0.88

Figure 2 and Table 1 show the quantitative distribution of S-containing compounds. Domains (circles) are the initial particle units. In in-direct sulfation, the S/Ca mole ratio at the surfaces of particles (denoted as ② and ④) was similar to that in the interior (denoted as ① and ③). In an direct sulfation, the S/Ca mole ratio at the surfaces of particles (denoted as ② and ④) was much greater than that in the interior (denoted as ① and ③). These results indicate that sulfation occurred over the entire interior of the particles in in-direct sulfation. In contrast, in direct sulfation, SO_2 molecules were absorbed into the interior through the surface of the particles.

This work was supported by Energy Resources Technology Development Project of the Korea Energy Management Corporation and by BK21 Program.

Pressure dependence of sulfuric acid induced SOA formation

P. T. M Carlsson, J. E. Dege, C. Keunecke, B. C. Krüger, J. L. Wolf and T. Zeuch

Institut für Physikalische Chemie, Universität Göttingen, 37077 Göttingen, Germany
Keywords: sulfuric acid, new particle formation, SOA, pressure dependence.
Presenting author email: tzeuch1@gwdg.de

Both mass balances of atmospheric aerosol and aerosol particle numbers are key issues in atmospheric science, since they are closely related to crucial processes like cloud formation and potential health effects of particles. Sulfuric acid (H_2SO_4) initiated new particle formation has been demonstrated in laboratory experiments to be able to account for nucleation events under ambient atmospheric concentrations (Sipilä et al. (2010)). Recently, it was shown that at least half of the observed particle growth rate in the 2-20 nm size range can be explained by condensation of products being produced from gas-phase chemistry (Donohue et al. (2011)).

In this work a new approach is presented for studying how sulfur and organic chemistry interact in the context of new particle formation. To the best of our knowledge the effect of pressure on this process has not been analysed until now. The ozonolysis of cyclohexene (CHEX) is used to generate condensable vapours. In the absence of SO_2 no H_2SO_4 is formed and very low particle number densities are observed. In the presence of SO_2 H_2SO_4 is produced by the reaction sequence

$$SO_2 + OH \rightarrow OHSO_2,\ OHSO_2 + O_2 \rightarrow HO_2 + SO_3,$$
$$SO_3 + H_2O \rightarrow H_2SO_4$$

The low particle number densities being generated during CHEX ozonolysis allow for an analysis of the sensitivity of the presence of H_2SO_4 in the gas mixture on new particle formation. Near the critical H_2SO_4 number density, where additional particle formation can be first observed, a similar sensitivity to recent near-atmospheric flow reactor experiments and atmospheric conditions is found. At higher H_2SO_4 concentrations the sensitivity is lower due to an increased loss of initial clusters by coagulation and condensation. The results are illustrated in figure 1. The similar sensitivity is striking considering our comparatively simple static reactor experiment (see Wolf et al. (2011)) and the difficulties in accurately determining the relation between sulfuric acid concentration and new particle formation in previous work. The dense vapour of condensable species being produced from CHEX ozonolysis seemingly takes over the role of the particle size magnifier in the Leipzig and Helsinki flow reactor experiments. H_2SO_4 number densities are derived by kinetic modelling using the well established rate coefficients for the reactions involved and the known OH yield for CHEX ozonolysis.

At low pressures (around 40 mbar) no significant new particle formation is observed even at high H_2SO_4 concentrations, which is shown in figure 2. These findings indicate that the collisional stabilisation of initial clusters is an important aspect for SOA formation processes involving sulfuric acid and organic compounds. The results may have implications for geo-engineering strategies based on stratospheric sulfur injection. However, at the moment caution is mandatory when room temperature laboratory results are extrapolated to stratospheric conditions.

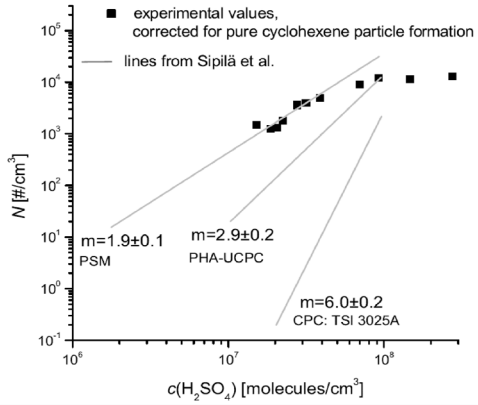

Figure 1. Additional particle formation during CHEX ozonolysis in the presence of SO_2 / H_2SO_4. T = 295±1 K, p_{tot}(synthetic air) = (450±10) mbar. The results are compared to slopes observed in flow reactor experiments using different CPCs, see Sipilä et al. (2010).

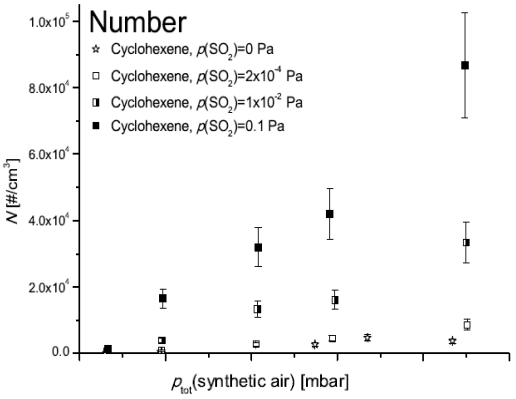

Figure 2. Pressure dependence of enhanced particle formation from CHEX ozonolysis in the presence of SO_2 / H_2SO_4.

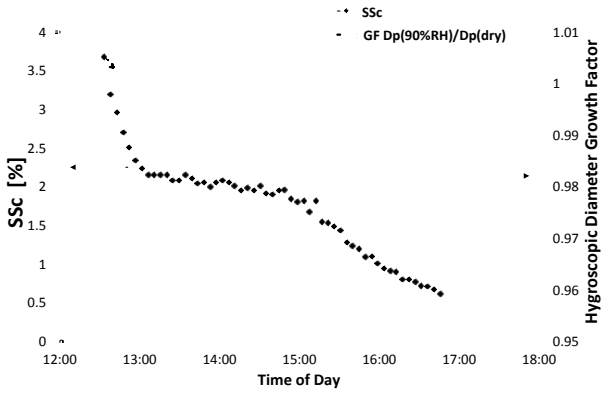
Aerosol particles play an important role in cloud formation processes. There is a direct effect from primary particles as well as an indirect effect from secondary aerosol particles formed in the atmosphere via complex gas-particle conversion processes. Secondary organic aerosols (SOA) can be formed when volatile organic compounds (VOCs) are present. Then part of the oxidation products from the VOCs condenses on pre-existing particles and produce SOA. This alters the particle properties, via condensation of the oxidised VOCs, which may lead to a lowered critical supersaturation (SS_c). Though, organic compounds will typically not suppress the water activity as much as inorganic salts. In general, the understanding of the properties of the SOA is scanty relative to the understanding of the major inorganics and is thereby of great interest for investigation.

This study is a continuation of a previous campaign, where exhaust from light duty vehicles were transferred to a smog chamber and photochemically aged (Nordin *et al*., 2012). The aerosol properties were monitored using an extensive instrumental set-up, obtaining information on morphology, density, volatility, particulate and gas composition as well as hygroscopic growth and cloud droplet nucleation. The present study focus on experiments using soot (from a flame soot generator and diesel car exhaust) and different SOA precursors (Toluene and m-Xylene). During the ageing procedure, the transformation of the hygroscopic behaviour and its link to the effect on cloud droplet activation were related to the organic fraction in the particle as well as particle size and morphology.

Hygroscopic properties were analysed using a Hygroscopic Tandem Differential Mobility Analyser (H-TDMA; Nilsson et al., 2009), the cloud-activation properties were measured using a Cloud Condensation Nucleus Counter (CCNC; DMT 100), and a soot particle aerosol mass spectrometer (SP-AMS, Aerodyne research) to determine the composition of the cores and the coatings of the particles. The particle mass-mobility relationship was characterized using a Differential Mobility Analyser-Aerosol Particle Mass Analyzer (DMA-APM; McMurry et al., 2002; Kanomax Japan 3600). A thermodenuder was introduced in series between the DMA and the APM, used for quantification of the size dependent mass fraction condensed onto the non-volatile soot cores. The particles were first size selected by the DMAs, according to their mobility diameter. This was followed by measurements in the APM, the H-TDMA and CCNC. Furthermore, it was investigated whether the diameter growth factor (GF; Fig.1), derived from H-TDMA data, could be used to predict SS_c for particles of a certain mobility diameter. During the latter campaign, the CCNC was operating using a modified measurement procedure, i.e. Scanning Flow CCN Analysis (SFCA) (Moore & Nenes, 2009), enabling rapid measurements with high time resolution of the supersaturation spectra, revealing more detailed, accurate and continuous results.

Fresh diesel soot particles show no hygroscopic growth and require a higher SS_c than predicted when using a simple model, based on the Köhler theory. The model only take the Kelvin effect into account, using the mobility diameter and assuming wettable particles (Rissler *et al.,* 2010). This is probably due to the agglomerated structure of the soot particles (e.g. Khalizov et al. 2009). At 90% relative humidity (RH), the soot particles collapse when coating exceeds 15-40% condensed organic material. Moreover, the cloud droplet activation is improved long before the particles show any hygroscopic growth at all, at 90% RH (Fig.1).



Figur 1. Preliminary SS_c decline for diesel soot particles (d_{dry}=150 nm) (data points), as well as the corresponding GF at 90% RH (solid black line) over time.

Hygroscopicity and optical properties of secondary organic aerosol formed in CESAM simulation chamber

C. Denjean[1], P. Formenti[1], B. Picquet-Varrault[1], Y. Katrib[1], E. Pangui[1], P. Zapf[1] and J.F. Doussin[1]

[1]Laboratoire Inter-Universitaire des Systèmes Atmosphériques (LISA UMR 7583), Université Paris Est Créteil – Val de Marne, Université Paris Diderot, 61 Avenue du Général de Gaulle, 94010 Créteil, France
Key-words: Hygroscopicity, optical properties, SOA (Secondary Organic Aerosols), Smog chamber
Presenting author email: denjean@lisa.u-pec.fr

Aerosol particles influence Earth's climate by scattering and absorbing light and by acting as cloud condensation nuclei. The impacts of organic aerosols on climate are poorly understood and require further understanding. To fill these gaps, the present work investigates the optical and hygroscopic properties of secondary organic aerosols (SOAs) generated from the ozonolysis of α-pinene at first and after having undergone atmospheric ageing reactions via an excess of ozone exposure or irradiation. Experiments have been performed in the atmospheric smog chamber CESAM, specifically designed to investigate multiphase processes and simulate atmospheric aerosol ageing (Wang *et al*, 2011). The chamber provides very realistic artificial solar irradiation and particle lifetime higher than two days.

The uptake of water of monodispersed SOA was measured using a Hygroscopicity Tandem Differential Mobility Analyser (H-TDMA) which was run at 90% RH and provided the hygroscopic growth factor (HGF). Parallel studies of hygroscopicity were done by varying linearly the relative humidity in the chamber from 0 to 100%. A Scanning Mobility Particle Sizer (SMPS, diameter range 20-800nm) and a Light Aerosol Spectrometer (WELAS, diameter range 0.2-10 µm) were used to directly follow the variation in size distribution as a function of relative humidity. The temporal evolution of the growth factor at 90% RH obtained with the H-TDMA for different ageing processes is shown in Figure 1. The hygroscopicity of α-pinene SOAs remained constant, with a growth factor around 1.05, during both ageing in dark conditions and ageing through ozone exposure. On the other hand, after ageing through irradiation exposure during 6h, SOAs exhibited a higher growth factor (HGF=1.15).

The investigation of optical properties of SOAs combined scattering and absorption measurements by a nephelometer and a spectral aethalometer directly connected to the chamber. The refractive indexes for the SOAs were derived from these measurements as well as from optical calculations using Mie scattering theory. As optical properties of atmospheric particles might depend on their affinity for water, the RH dependence of scattering coefficient and refractive indexes were also investigated. Results from absorption measurement of all experiments showed that α-pinene SOAs did not absorb in the visible region (imaginary part equal to zero). Figure 2 reports the temporal evolution of the real part of the refractive index at 525nm. We observed that the real part of the refractive index decreased during the α-pinene SOA formation. No trend was observed neither during ageing in dark conditions nor during ageing through excess ozone exposure. In contrast, significant increase of the real part of the refractive index was observed for SOAs exposed to irradiation. These observations are to be interpreted by observed concurrent changes in the particle bulk and surface chemical composition.

Isoprene (2-methyl-1,3-butadiene, C_5H_8) is one of the most abundant non-methane hydrocarbons emitted into the troposphere. Its annual global emission has recently been estimated in the range of 440 to 660 TgC (Guenther *et al.*, 2006). Because of its large concentrations and high reactivity with the hydroxyl radical (OH), isoprene can have a strong influence on tropospheric photochemistry. It has been determined recently that isoprene also plays a role in secondary organic aerosol (SOA) formation in the ambient atmosphere even if isoprene leads to low SOA yields. The aim of the present work was to study isoprene photo-oxidation with OH radical in order to investigate its oxidation products and resulting aerosol production. A special care was taken to the realism of the experiment: light source, NOx level, OH source and aging time (around 10 hours).

To do so, experiments were performed in CESAM chamber at LISA, specifically designed to investigate multiphase processes with a highly realistic irradiation compared to solar radiation (Wang *et al.*, 2011). Connected to the chamber, a large panel of instruments was used to monitor the gas-phase and the particulate phase during experiments. Gas-phase composition was analysed in-situ via a Fourier Transform Infrared Spectrometer (FTIR) and a Proton Transfer Reaction Mass Spectrometer (PTR-TOF-MS) as well as NO_x and O_3 analyzers. A Scanning Mobility Particle Sizer (SMPS, diameter range 20-800 nm) measured SOA size distributions and total concentrations inside the chamber. An Aerodyne aerosol mass spectrometer (TOF-AMS) was also used to investigate aerosol composition. In each experiment, around 500 ppb of isoprene was injected in the chamber before irradiation. During all the experiment, a very low continuous flow of NO was injected in order to mimic atmospheric emission and maintain oxidation rate, thanks to its propagating role. It therefore allowed us to investigate not only isoprene chemistry but also the fate of its products. Some experiments were carried out with initial ammonium sulfate seed aerosols. The typical temporal evolution of gas-phase and SOA concentrations observed in experiments without seeds is shown in Figure 1.

The major gas-phase oxidation products of isoprene we measured, in low NO conditions, are formaldehyde, methacrolein and methyl vinyl ketone identified as first-generation products, and also methylglyoxal and peroxyacetyl nitrate (PAN), identified as second-generation products. NO_2 to NO ratios, yields of all measured oxidation products and carbon budget were calculated. In all experiments, we noted a SOA production at the end of isoprene oxidation i.e. exhibiting a clear secondary products type growth. Several results (including SOA densities and yields, and O/C ratios) were obtained using SMPS and AMS data allowing us to characterise SOA formation and composition during the experiments. The gas-phase composition as well as the aerosol yields obtained during these experiments have been compared to results simulated by a 0D photochemical box model. The goal of this work was to assess whether or not the processes contained in current chemical mechanisms enable to reproduce observations in the gas-phase. It is aiming also at assessing if the vapour pressure based parameterization of the aerosol production in the model is able to reproduce experimental data for the particle phase.

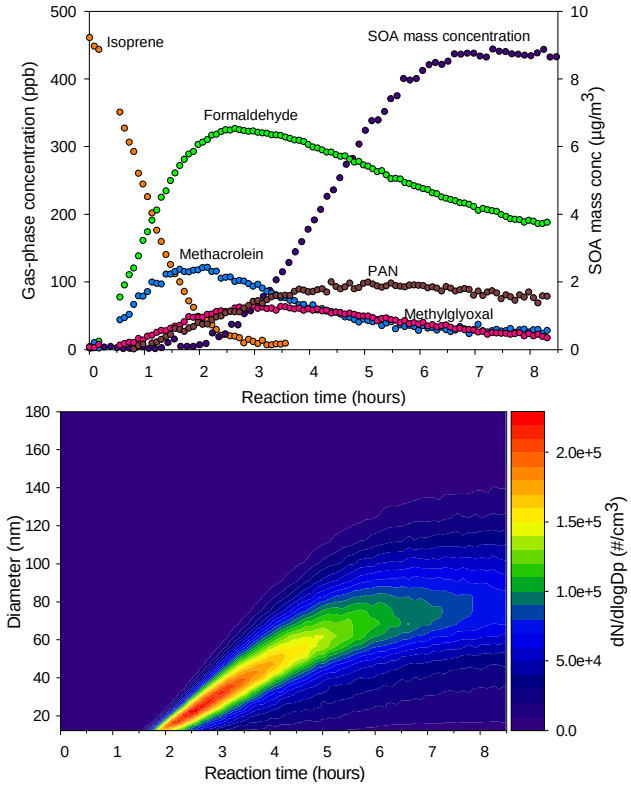

Figure 1. A typical temporal evolution of species in an experiment without seeds.

AMISOC (Atmospheric MInor Species relevant to the Ozone Chemistry at both sides of the jet) is a research project, funded by the Spanish R&D programme, devoted to improving the knowledge of minor constituents playing a role in ozone chemistry. The core of the project is two coordinated campaigns to be performed at: 1) the Atmospheric Sounding Station (ESAt) "El Arenosillo", Huelva, in the southwestern Iberian Peninsula, during May-June 2012, and 2) Tenerife (Canary Islands) in July 2013, located at mid- and subtropical latitudes respectively.

AMISOC-El Arenosillo (AMISOC-ARN) is conceived as a multi-instrument campaign in order to study the behavior of minor trace gases under heavy aerosol loading. This situation is frequent in spring- and summer-time when Saharan dust intrusions arrive at the SW-IP (Toledano *et al.*, 2007; Córdoba-Jabonero *et al.*, 2011). Simultaneous measurements of gases and aerosols are proposed, making use of different platforms and techniques. Ground level (including a 100m tower) and airborne (aboard INTA aircraft C-212) in-situ (gases, aerosols and meteorology) measurements as well as aerosol lidar and columnar sun-photometry observations in addition to local radiosoundings will be performed. Table1 summarizes the main instrumentation and techniques to be used in AMISOC-ARN.

The study of halogens in the atmosphere is a hot research field due to its implications on ozone chemistry and because their concentration at different levels in the atmosphere and seasonal dependences are not yet well known (Saiz-Lopez *et al.*, 2011, and references therein). In this context, the principal objectives for this campaign are:

- Evaluation of the impact of Atmospheric Boundary Layer (ABL) air masses on the vertical distribution of halogen radicals.
- Analysis of the daily evolution of tropospheric NO_2 and IO.
- Study of the correlation between nanoparticles and halogens.
- Quantification of the O_3 vertical depletion observed during Saharan dust events and the changes experienced in other minor species (NO_2 and IO).
- Interpretation of the results in the frame of the current accepted chemistry.

Table 1. Instrumentation/techniques to be used in AMISOC-ARN (*).

Instrument / technique	Platform	Measurements	Species / particle parameters
GASES			
MAX-DOAS	Ground-level	Remote sensing, vertical profiles (inversion alg.)	NO_2, O_3, IO and O_4 concentration
O_3 monitor	Ground-level	Surface in-situ	O_3 concentration
NO_x analyzer	Ground-level	Surface in-situ	NO and NO_2 concentration
SO_2 analyzer	Ground-level	Surface in-situ	SO_2 concentration
O_3 monitor	Airborne	In-situ, vertical profiles	O_3 concentration
NO_x analyzer	Airborne	In-situ, vertical profiles	NO and NO_2 concentration
AMAX-DOAS	Airborne	In-situ, vertical profiles	NO_2, O_3 and IO concentration
AEROSOLS			
APS	Ground-level	Surface in-situ	SD (micrometer range)
SMPS	Ground-level	Surface in-situ	SD (sub-micron range)
Nephelometer	Ground-level	Surface in-situ	SC, AE, BSF
LIDAR (MPL)	Ground-level	Remote sensing, vertical profiles	EX, BS
Sun-photometer (CIMEL)	Ground-level	Remote sensing, columnar-integrated	AOD, AE, SD
PCASP (OPC)	Airborne	In-situ, vertical profiles	SD (accumulation mode: < 3 μm)

Direct Surface Analysis of Size- and Time- Resolved Organic Aerosol

S.J Fuller[1], M. Kalberer[1], Y. Zhao[2], A.S Wexler[2]

[1]Department of Chemistry, University of Cambridge, Cambridge, CB2 1EW, UK

Presenting author email: sjf53@cam.ac.uk

Ambient aerosol particles have been shown to have significant health and climate implications. Studies of the chemical composition of aerosol particles are important to establish the mechanisms of their reactivity. However the aerosol composition, especially the organic fraction is highly variable with both time and the size fraction concerned. Many previous organic aerosol studies involved filter or impaction collection with a limited time resolution of typically a day. Combining a rotating-drum impactor (RDI) with Liquid Extraction Surface Analysis (LESA) allowed the study of separate size fractions collected over a 2-week period to be analysed with a 3-hour resolution using a high-resolution mass spectrometer for organic species identification. Similar RDI studies have used X-ray fluorescence for elemental analysis (Richard *et al*, 2010).

An RDI was used to collect size segregated aerosol samples for approximately 2 weeks from 11 am 25/5/2011 to 11 am 7/6/2011 from a dairy farm in California. The RDI allows time resolved continuous collection of ambient particle impaction samples (Raabe *et al*, 1988). Ambient air is sampled (16.7 lpm) and aerosol particles are collected via impaction on greased mylar substrates. The RDI sampler consists of 8 stages collecting samples in 8 size ranges, however only the samples from 2 stages, stage 3 and stage 8, were investigated in this study; these corresponded to the size ranges 2.5-1.15 and 0.26-0.09 μm respectively.

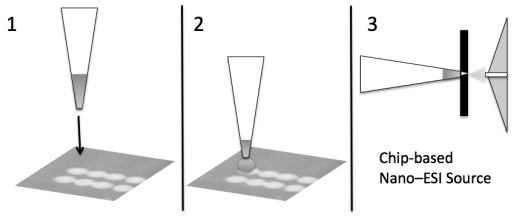

Figure 1. The LESA extraction process; a liquid junction is formed (2) before analysis by mass spectrometry (3).

The organic composition of stripes 3 and 8 were analyzed using a novel direct extraction technique - Liquid Extraction Surface Analysis (LESA). LESA is a mode of operation of the TriVersa NanoMate (Advion) chip-based Nano-ESI source (Kertesz *et al,* 2010). A small amount of solvent is dispensed with a pipette tip on the surface of the sample; the micro liquid junction is maintained to allow analytes present on the surface of the sample to dissolve. The droplet is aspirated and sprayed via an infusion method utilising the chip based electrospray ionsation (ESI). The size of the liquid junction translates to a time resolution of approximately 3 hours.

An ultra-high-resolution mass spectrometer (LTQ Velos – Orbitrap, Thermo-Scientific) was used to analyse the organic fraction following extraction by LESA. This data was used to determine the molecular formulae of the compounds found during the sampling period. For stage 3 a correlation was found between the N/C elemental ratio of species less that 150 Da in mass and the sample loading. This is shown in figure 2, the light areas of the black and white image correspond to high sample loadings that, following comparison with meteorological data, are due to wind blown dust from the local area. The higher N/C ratio found in these areas may be due to influence of fertilisers. In addition a number of amines, possibly from biomass burning, were found predominantly on stage 8.

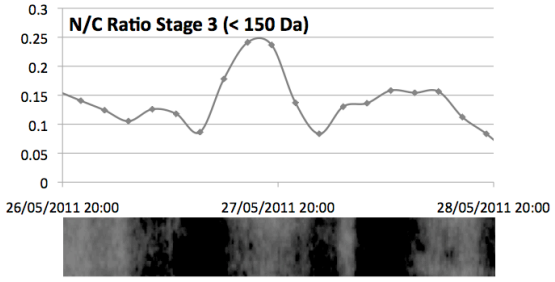

Figure 2. N/C elemental ratio, with stage 3 shown below. Variation with sample time and corresponds to sample loading.

This demonstrates that the combination of the RDI and LESA can be used for semi-quantitative analysis of organic trace components in ambient samples, with a high time resolution that can be easily compared to meteorological data.

Studies using photochemical aerosol chambers "also known as smog chambers" can provide valuable insights into the complex multiphase processes leading to the formation and transformation of atmospheric particulates. The Manchester aerosol chamber is an 18 m^3 photochemical batch reactor designed to study atmospheric processes of multicomponent aerosols under controlled and realistic conditions. Our research ranges from formation and transformation of secondary organic aerosols (SOA) under seeded and un-seeded conditions to investigations of the direct and indirect effects of multicomponent aerosols on climate. The facility enables us to evaluate and respond to hypotheses derived from field observations and provides a "test-bed" for evaluating (i) oxidation mechanisms of VOCs (e.g. Jenkin et al. (2012)) and (ii) processes in atmospheric models.

In order to enable this research, the facility is equipped with an array of state-of-the-art instruments measuring aerosol composition and properties as well as VOC precursors and their oxidation products. The chemical composition of the formed SOA is measured on-line using an Aerodyne Time-of-Flight Aerosol Mass Spectrometer (ToF-AMS). A hygroscopicity tandem differential mobility analyser (HTDMA) and a cloud condensation nuclei (CCN) counter are used to probe the hygroscopic properties and of the aerosols in the sub- and super-saturated regimes, respectively. A proton transfer mass spectrometer was used to study the evolution of the gas phase oxidation products.

In this poster, we will provide a technical description of the facility and discuss a number of scientific highlights obtained as part of the recently completed Aerosol Coupling in the Earth System (ACES) project, which focused on the formation and transformation of biogenic secondary organic aerosol (Hamilton et al., 2011; Alfarra et al., 2012). We will also present preliminary findings from a recently commissioned programme of research aiming to quantify remaining uncertainties related to the properties of aerosol particles determining their ability to form liquid droplets under ambient atmospheric conditions. Specifically, the programme aims to quantify (i) the impacts of semi-volatile components on aerosol water uptake; (ii) the impacts of aerosol phase on water uptake; and (iii) the impacts of aerosol phase on their IN behaviour.

This work was supported by the UK Natural Environment Research Council (NERC) through the APPRAISE and ACIDPRUF programmes.

COMPOUND SPECIFIC CONDENSATION TO SECONDARY ORGANIC AEROSOLS PROVIDING SIZE DEPENDENT INFORMATION

Presenting author email: ditte.mogensen@helsinki.fi

We are presenting the next version of the zero-dimensional model MALTE–BOX with implemented temperature depended saturation vapour pressures for atmospherically relevant organic compounds. We calculate size dependent secondary organic aerosol growth (from nucleation to accumulation mode), using a kinetic condensation approach, based on an open number of condensible organic vapours. We characterise the chemical composition of the formed aerosols and compare our results with atmospheric mass spectrometer (AMS) data.

As until now, modellers have mostly simulated the aerosol mass balance by using one or a few compounds (most often water, sulphuric acid and one or two organic compounds) as a representation for all condensing vapours or the Volatility Basic Set (VBS) (Donahue *et al.* (2006)). Those few studies that do take compound specific condensation into account, use a equilibrium partitioning approach for condensation, and generate a bulk aerosol, whereby all size information is lost. If we want to understand aerosol growth on a more process based level, we need to know what molecules contribute significantly to the aerosol mass in each size bin, and therefore compute the individual contributions from all possible candidates.

We are using the model MALTE-BOX for the implementation of saturation vapour pressures. MALTE–BOX is a zero–dimensional improved version of MALTE (Model to predict new Aerosol formation in the Lower TropospherE) (Boy *et al.* (2006)). It includes three parts; 1) emission, 2) chemistry, and 3) aerosol dynamics. The emissions of organic vapours from the canopy are calculated using MEGAN (Model of Emissions of Gases and Aerosols from Nature) (Guenther *et al.* (2006)). The chemistry is calculated using the Kinetic PreProcessor (KPP) (Damian *et al.* (2002)), with chemical reaction equations selected from the Master Chemical Mechanism v3.2 (Jenkin *et al.* (1997), Saunders *et al.* (2003)) via website: http://mcm.leeds.ac.uk/MCM/. The aerosol dynamic processes are simulated with UHMA (University of Helsinki Multicomponent Aerosol model) (Korhonen *et al.* (2004)).

For the calculation of the saturation vapour pressures, we use a script written by professor Gordon McFiggans' group at the University of Manchester. The script, which is written in the Python programming language, calculates the boiling temperature and following the saturation vapour pressures of any compound based on its molecular structure using Nannoolal's vapour pressure method (Nannoolal *et al.* (2008)). The saturation vapour pressures will be calculated for all the organic compounds listed on MCM's website. This includes 5707 chemicals. Following, the calculated saturation vapour pressures will be implemented in MALTE–BOX as look–up tables and tested together with and against the VBS code in comparison with certain selected chamber experiments including ozone – alpha-pinene.

Presenting author email: nonne.prisle@helsinki.fi

Surface active (surfactant) organic compounds are frequently observed in atmospheric aerosols. Long-chain fatty acids and their carboxylate anions constitute one important class of atmospheric surfactants. In aqueous solutions, such as aqueous aerosols and cloud droplets, surfactants preferentially adsorb at the air-water interface and can reduce the surface tension, compared to that of pure water. The aqueous surface activity is a central, but still not well constrained, property of organic aerosol components (Prisle *et al.*, 2010, and references therein).

We have investigated dilute aqueous solutions of the atmospheric surfactant sodium decanoate, using X-ray photoelectron spectroscopy (XPS) in combination with synchrotron radiation. We studied the chemical speciation in the aqueous surface, in terms of the relative abundances of the decanoate anion and the corresponding protonated form, decanoic acid, and the influence on these abundances of mixing in solution with some of the most common inorganic ions found in the atmosphere, the sodium and ammonium cations, and the chloride and sulfate anions (Seinfeld and Pandis, 2006). XPS is a highly surface and chemically sensitive spectroscopic technique (Hüfner, 1995) and in particular capable of resolving signals originating from the carboxylate and carboxylic acid groups of the decanoate/decanoic acid pair, respectively (Ottosson *et al.*, 2011). XPS has been adapted to the study of liquid surfaces by combination with the liquid-jet technique (Winter and Faubel, 2006).

We conducted liquid-jet photoelectron experiments at the Swedish national synchrotron facility MAX-lab in Lund, at the soft X-ray undulator beamline I411. The experimental setup and procedures have been described in detail by Bergersen *et al.* (2007). We investigated aqueous solutions of sodium decanoate (DecNa), as pure solute (binary) and in equimolar mixtures with one of the inorganic salts sodium chloride, sodium sulfate, ammonium sulfate, and ammonium chloride (ternary). Each solute composition was studied at concentrations corresponding to 10 and 25 mM DecNa. Results of these experiments are presented as core photo-electron spectra recorded in the carboxylate and carboxylic C1s energy region. At the X-ray photon energy used here (360 eV), the total experimental resolution in this energy region was better than 250 meV.

Adsorption of carboxylic compounds and their acid/base speciation from protonation/protolysis at the air-water interface may have significant implications for a number of atmospheric processes involving aqueous organic aerosols. Some of the process-level mechanisms that may be influenced are related to (i) heterogeneous reactivity of the aerosol surface, towards both gas and bulk aqueous phases, and thus to the formation of organic aerosol mass and the general chemical processing of atmospheric components, as well as to (ii) the thermodynamics of phase transformations in the atmosphere, such as organic aerosol hygroscopic growth, and cloud droplet and ice nucleation. These processes may in turn influence the overall atmospheric aerosol burden, composition, and properties, and thus affect various of the identified direct and indirect climate impacts of atmospheric aerosols (IPCC, 2007).

Directly probing the surfaces of the investigated aqueous solutions is greatly advantageous to conventional methods that rely on inferring surface composition and properties from those of the solution bulk phase, since no assumptions pertaining to the nature of molecular-scale interactions, phase equilibrium, or the applicability of specific adsorption isotherms are imposed on the system. Our presented results thus demonstrate the viability of the synchrotron XPS technique for studying properties of aqueous solution surfaces of immediate atmospheric relevance.

13-Carbon Isotopic Fractionation in Secondary Organic Aerosol Formation

C. Meusinger[1], U. Dusek[2], S.M. King[1], R. Holzinger[2], M. Bilde[1], T. Röckmann[2] and M.S. Johnson[1]

[1] Copenhagen Center for Atmospheric Research (CCAR), Department of Chemistry, University of Copenhagen, 2100 Copenhagen, Denmark

Keywords: SOA, isotopes, carbon, smog chamber.
Presenting author email: came@kiku.dk

Secondary organic aerosol (SOA) formed by oxidation of volatile organic compounds (VOC) is a main field of study in atmospheric research since its impact on climate, health and visibility is still not well understood. Given the vast amount of possible reactions involved in the oxidation of VOCs, reaction patterns are unclear and uncertainties of SOA yields are still large. Here, isotope measurements enable us to distinguish reaction pathways since they alter the isotopic composition of products and reactants (kinetic isotope effect, KIE). This in turn helps to establish chemical reaction schemes and to constrain budgets. Studied systems employing isotopes so far cover a wide range including atmospheric samples (Rudolph *et al*, 2002), gas-phase reactions (Iannone *et al*, 2010) and SOA generation (Irei *et al*, 2011; Fisseha *et al*, 2009).

The fundamental idea behind this research is to investigate the possible link between ^{13}C fractionation and oxidation state in organic aerosols. This poster presents an overview of (planned) experiments and initial results.

Our study is a first step in establishing a firm understanding of this complex link and aims to provide insight into SOA formation using stable carbon isotopes. Starting from precursors with natural isotopic abundance, aerosols will be created in chamber experiments by nucleation, i.e. without seeds present, from oxidation of volatile precursors using ozone. The resulting SOA will be collected on pre-treated quartz filters and subsequently analyzed for their carbon isotopic composition (^{13}C & ^{12}C.) KIEs will be presented for the following systems:

1) Single component organic aerosol generated using an atomizer and deposited on filters immediately after drying. Subsequently, the loaded filter is exposed to a flow of high ozone concentration.
2) Single component organic aerosol formed using an atomizer and introduced into a smog chamber together with ozone.
3) SOA from α-pinene ozonolysis created in a smog chamber.

Experiments 1 and 2 are designed to quantify the fractionation in filter handling and the potential ozonolysis of SOA only, while experiment 3 aims for the KIE of SOA formation from VOC.

The (dark) chamber experiments will be run at the Copenhagen Center for Atmospheric Research to generate the overall large amounts needed for the isotope analysis. Particle-size distributions are monitored continuously and GC samples are taken in intervals to keep track of precursor concentrations.

The isotopic measurements of the filters are done at the Institute for Marine and Atmospheric Research Utrecht using Isotope Ratio Mass Spectrometry. Here, the filters are heated stepwise (50-450 °C) in He to evaporate organic compounds that are subsequently converted to CO_2 for the isotope analysis. In parallel, the chemical composition is determined by Proton Transfer Ratio Mass Spectrometry at each heating step.

The setup will be presented in detail, along with first results and possible implications of the findings.

We thank IntraMIF and the Universities of Copenhagen and Utrecht for supporting this research. The research has received funding from the European Community's Seventh Framework Program (FP7/2007-2013) under grant agreement number 237890.

Sizing, Infrared Spectra and Phase Transitions of Neutral Water Clusters

C.C. Pradzynski[1], R.M. Forck[1], U. Buck[2] and T. Zeuch[1]

[1]Institut für Physikalische Chemie, Universität Göttingen, 37077 Göttingen, Germany

Keywords: water, neutral clusters, IR spectroscopy, size selection, sodium doping.
Presenting author email: tzeuch1@gwdg.de

The characterisation of clusters in the nanometer size range is a key issue in aerosol science. Especially nanometer sized water particles play an important role in Earth's atmosphere and interstellar space (Kulmala (2003), Klemperer and Vaida (2006)). Huge progress has been made in recent years in the development of instruments for measuring ionic clusters (Kirkby *et al*. (2011)). However, particle sizing and size selective spectroscopic experiments with neutral clusters are much more difficult to conduct. In two very recent studies (Yoder *et al*. (2011), Forck *et al*. (2012)) it was shown that the difficulty of size selection can be mastered for neutral clusters by using the sodium doping technique. The experimental steps are:

1) the generation of a molecular beam by a supersonic expansion
2) sodium doping of clusters in a pick-up cell
3) soft single photon ionization of the clusters

Sodium doping allows for a soft ionization because the weakly bound 3s electron be easily removed in a single photon process. In the absence of fragmentation the particle mass distribution can be determined directly by analyzing the time of flight mass spectra, see Yoder et al. (2011).

The interaction of the clusters with infrared (IR) light prior to photoionization allows the generation of size selective IR spectra. This method is called IR excitation modulated photoionisation mass spectroscopy and demonstrated for methanol clusters by Forck *et al*. (2012).

In the present work we show that the method has been successfully employed for characterizing the evolution of the structure of water clusters containing a few up to a few hundred water molecules. Therefore it is now for the first time possible to examine the process of water micro-crystallization with a reliable control of cluster sizes. In figure 1 theoretically predicted infrared spectra in the OH stretching region are compared with our size selective measurements. In general, the simulations of Buch et al. (2004) are in good agreement with the measured spectra. The main difference is the spectrum for around 48 water molecules, which in the experiment resembles more the spectrum of the larger clusters. On the basis of the now available IR spectra the actual cluster structures can be unraveled using state of the arte quantum chemistry methods.

By changing the expansion conditions (He vs. Ar expansions) the cluster temperature can be changed. This allowed for the first time the distinction of water clusters in the solid state and an amorphous more glassy state on the basis of size selected IR spectra. This phase transition was previously characterized by calorimetric means for anionic water clusters by Hock *et al*. (2009). The two spectra are shown in figure 2. The region below 3400 cm^{-1} shows only in the Ar expansion the characteristic solid state pattern depicted in figure 1.

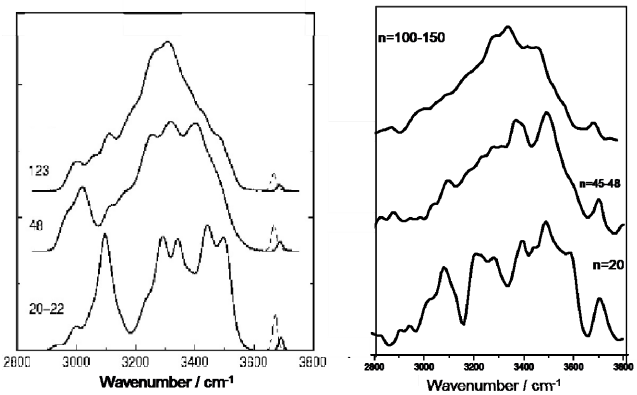

Figure 1. Predicted IR spectra for $(H_2O)_n$ (n=20-22,48, 123) (left panel, Buch et al. (2004)) compared with measured IR spectra of $Na(H_2O)_n$ (n=20,45-48, 100-150) (right panel).

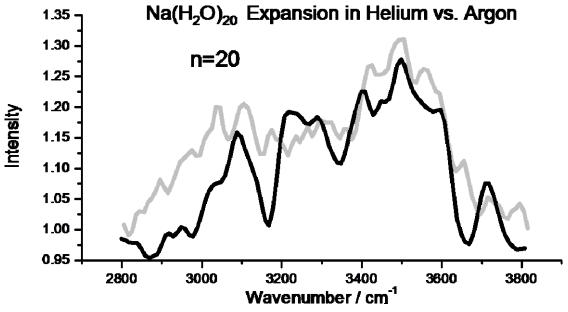

Figure 2. IR spectra for $Na(H_2O)_{20}$ in a cold Argon expansion (T <100 K, black line) compared with the warmer Helium expansion (T ~ 120-150 K, grey line).

The CLOUD (Cosmics Leaving OUtdoor Droplets) experiment at CERN investigates a possible influence of cosmic rays on aerosol particles and clouds by providing exceptionally clean and well-defined experimental conditions in a stainless-steel chamber of 26.1 m^3. Cosmic rays can be simulated by exposing the chamber to a pion beam. So far, the research at CLOUD has focused on nucleation experiments, as nucleation from gaseous precursors is an important source of particles in the atmosphere. Sulfuric acid (H_2SO_4) was found to play a crucial role in this process. Other compounds hypothesized as important are water, ammonia (NH_3), and yet unidentified organic compounds (e.g. Metzger *et al.*, 2010). Therefore, the CLOUD experiment investigated nucleation for different conditions, including varying concentrations of H_2SO_4 and NH_3. In later experiments, dimethyl amine was added as well as pinanediol ($C_{10}H_{18}O_2$). The latter was expected to yield oxidation products similar to those of certain naturally abundant volatile organic compounds, such as α-pinene.

The APi-TOF (Atmospheric Pressure interface Time-Of-Flight) mass spectrometer is developed by Tofwerk AG, and Aerodyne Research, Inc. (Junninen *et al.*, 2010), typically obtaining resolutions between 4000 and 6000 Th/Th. Sampling occurs directly from atmospheric pressure. No ionization of the sampled aerosol is performed, and only naturally charged ions are detected by the setup in use.

During experiments at CLOUD, nucleation events were triggered in the chamber by switching on UV light. Depending on conditions, nucleation occurred mainly or partly by ions. Using the APi-TOF, the composition of ions could be determined based on their exact masses and isotopic patterns (Ehn *et al.*, 2012). Before adding any organics into the chamber, cluster ions were found to always contain H_2SO_4 (Kirkby *et al.*, 2011). They also contained NH_3 molecules, with the NH_3:H_2SO_4 ratio depending on cluster size and experimental conditions, and, to a lesser extent, organic contaminant compounds, mainly amines. The addition of organics altered nucleation, growth, and ion spectra. Clusters involving a wide range of pinanediol oxidation products were observed up to 1500 Th, and the elemental composition of the most important clusters could be identified (e.g. Fig. 1). Also, the growth of clusters was commonly observable at a time resolution of 30 s and up to 3300 Th, with the highest observable masses corresponding to mobility equivalent diameters between 1.8 and 2.1 nm. Correlations between the abundances of individual ion clusters and various experimental variables will give detailed insights into the early steps of new (charged) particle formation in the CLOUD chamber.

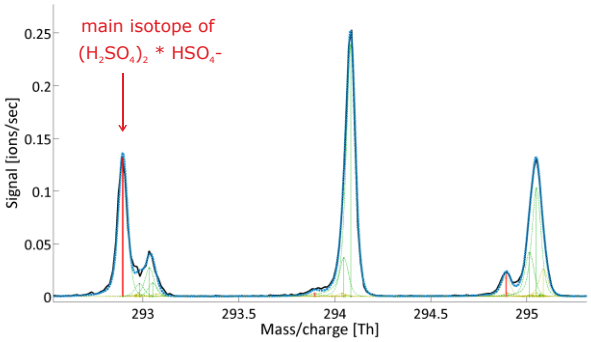

Figure 1. Section of a typical negative ion spectrum during nucleation. The isotopes of $(H_2SO_4)\bullet HSO_4^-$ are marked by red sticks. The sum of all identified compounds (blue dotted line), mostly including oxidized organics, explains well the signal (black line).

Presenting author email: frank.siekmann@uni-bayreuth.de

This work investigates the composition of secondary organic aerosol (SOA) from the photooxidation of isoprene and methacrolein by HR-TOF-AMS measurements. The experiments were performed during the CUMULUS campaign at the CESAM reaction chamber (4.2m^3, stainless steel).

Both compounds were chosen because of their relevance in the atmospheric SOA formation. Isoprene is the most abundant volatile organic compound with a global emission of 500–750 Tg/yr. Methacrolein is one of its main first-generation gas phase oxidation carbonyl products, with a molar yield of 20–28% (Zimmermann and Poppe, 1995; Lee et al., 2005). Recent field and laboratory studies indicate that the oxidation of isoprene forms secondary organic aerosol (Carlton et al., 2009). Furthermore, Surratt et al. (2006) demonstrated a major contribution of methacrolein in the SOA formation through isoprene reactivity.

For both precursors, isoprene and methacrolein, reaction chamber runs were performed with initial concentrations of 500 ppb; the initial [NO] was approx. 100 ppb.

The study of these two compounds allowed us to report differences and similarities regarding the composition of SOA formed from the different precursors during the experiments.

Another task in this study is the influence of the humidity on the composition of the aerosol. The experiments started at dry conditions; after SOA formation, the relative humidity in the reaction chamber was increased up to 100%. This enabled us to simulate real atmospheric conditions, e.g. in terms of gas-droplet-aerosol interactions.

SOA derived from photooxodation under relative high NO_x conditions also has non-negligible content of organonitrates, which fragments in the AMS forming NO^+ and $NO2^+$ (Chhabra et al., 2010).

Time evolution of mass spectra and O/C-, H/C-, N/C and OM/OC ratios as well as the role of organonitrates, especially during high humidity periods, will be presented and discussed.

This work was supported by the French embassy in Germany and the ANR CUMULUS.

Pathways from aromatic aldehydes to aerosol in urban atmosphere: a competition between oxidation and photopolymerization

T.A. Maksimova[1], G.G. Dultseva[1,2] and S.N. Dubtsov[1]

[1]Institute of Chemical Kinetics and Combustion, SB RAS, Novosibirsk, 630090, Russia

Presenting author email: dubtsov@kinetics.nsc.ru

Aromatic aldehydes are considered as the markers of anthropogenic emission due to their presence in urban air as primary pollutants emitted from engines. However, aromatic aldehydes are also emitted by vegetation, which is a tremendous source of photonucleating compounds on the global scale. The atmospheric fate of aromatic aldehydes generally depends on the chemical nature of substituents and includes several pathways. The most important routes of gas-to-particle conversion of aromatic aldehydes are photooxidation and photopolymerization. To evaluate the details of these mechanisms, we studied photonucleation of benzaldehyde, as a representative of technogenic pollutants, and salicylic aldehyde, as a representative of the emissions of biological origin. The presence of the aldehyde group in both molecules makes them photochemically active, but the presence of OH group in salicylic aldehyde renders specific features to the mechanism of its photooxidation.

Aldehyde vapour was photolyzed in a flow reactor in the absence and in the presence of environmentally significant additives, such as ozone, water vapour, and nitrogen dioxide. Free radicals generated photolytically were studied using spin trapping technique with sampling directly from the reactor. Chemical analysis of the gas and aerosol products was carried out by means of high-performance liquid chromatography, UV, IR, NMR spectroscopy, and gas chromatography – mass spectrometry. The amount of photopolymer was determined with respect to the reference, benzaldehyde vapour in nitrogen. Water vapour was demonstrated to act as a clustering agent for aldehydes, simplifying intermolecular interactions participated by photoexcited species. The role of ozone is much more complicated. Reacting with aldehydes it adds its oxygen atoms into the organic molecule thus taking part in the formation of condensable products. Ozone hinders photo-polymerization almost completely, and the product is highly oxygenated, containing only a small amount of aromatic fragments.

Special attention was paid to the mechanism of the interaction of aromatic aldehydes with NO_x, in particular nitrogen dioxide. A combination of NO_x with aldehydes is an immediate route to peroxy nitrates, clear indicators of photochemical smog even nowadays, in spite of all the precautions against air pollution (Zhang, 2011). In addition to aerosol-forming capacity, nitrogen dioxide is a photoactive species giving rise to atomic oxygen. This is why NO_2 is a very efficient suppressor of photopolymerization of aromatic aldehydes. For example, the amount of photopolymer in benzaldehyde photolysis decreases with an increase in the concentration of NO_2, while the concentration of diphenyl peroxide increases. Here diphenyl peroxide is the product of chain termination in the interaction of O with phenyl radicals formed in photodissociation of benzaldehyde: $Ph + O \rightarrow PhO \rightarrow (PhO)_2$.

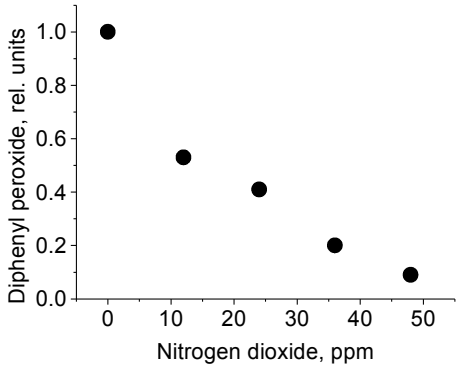

Fig. 1. Concentration of diphenyl peroxide *versus* NO_2.

No diaryl peroxides were detected in the products of photolysis of salicylic aldehyde. In addition, spin trapping studies failed to detect the formation of short-lived free radicals in the system, unlike for the case with benzaldehyde, when phenyl and phenoxy spin adducts were detected. The aerosol product exhibited the loss of the hydroxyl group at the aromatic ring. This allows us to suppose that the prevailing reaction route for the reaction of salicylic aldehyde with free radicals of any origin is detachment of the hydrogen atom of OH group. This example shows how substituents change reaction pathways even for the compounds of the same class.

Comparing the toxicity of products formed in photopolymerization and in oxidation, one can see that the latter route gives much more toxic intermediates and final products. Negative health effects of photochemical smog are in part due to the biological action of N- and O-containing aromatics formed under sunlight in urban atmosphere. So, chemical analysis of photonucleation products allows us not only to evaluate reaction pathways but also to predict environmental effects.

Gas−solid interfacial phenomena play a key role in multiphase processes in atmospheric chemistry, affecting cloud and aerosol properties and influencing the radiation balance of the earth. In particular, mineral aerosols may be potential reactive surfaces for heterogeneous chemistry and a significant sink for many volatile organic compounds, as well as a vehicle for transportation of trace gases through the atmosphere. However, quantitative information on the gas/aerosol equilibrium of organic species is generally not available. In general, the fraction of organic compounds on aerosol surfaces is highly complex and variable, as it consists of a multitude of individual compounds from a variety of sources. Additional knowledge of heterogeneous processes, such as adsorption and reactions on the surface of mineral dust aerosols, could identify effective sinks and improve our understanding of global atmospheric chemistry.

In general, oxygenated organics with functional groups have a large tendency to be adsorbed on surfaces. Indeed, field measurements have shown that mineral atmospheric particles, such as aluminosilicate clays, often contain oxygenated organic components. Thus, it is interesting to study, at the molecular level, the adsorption of atmospheric volatile organic compounds (VOC) on model clay surfaces.

In this work, adsorption of formaldehyde, glyoxal, formic acid and oxalic acid on different silicate surface models is studied using quantum-mechanical methods. Both molecular clusters and a periodic crystal model of the (001) pyrophyllite surface have been employed, and all possible adsorption geometries have been considered. We find that silanol groups are always the most reactive adsorption sites, and adsorption at the cluster edges is favored. In the case of a periodic system hydroxyl groups on the octahedral phyllosilicate sheet are also reactive sites through the tetrahedral cavities (Figure 1). The effect of the studied VOC adsorption on the spectroscopic properties of the whole system is also analyzed in detail (Iuga et al. 2012). In all cases, significant frequency-shifts are detected in the vibration modes of both adsorbate and surface. The reactivity of these aerosol component with hydroxyl free-radical was investigated finding that these silicates are a good trap for free radicals.

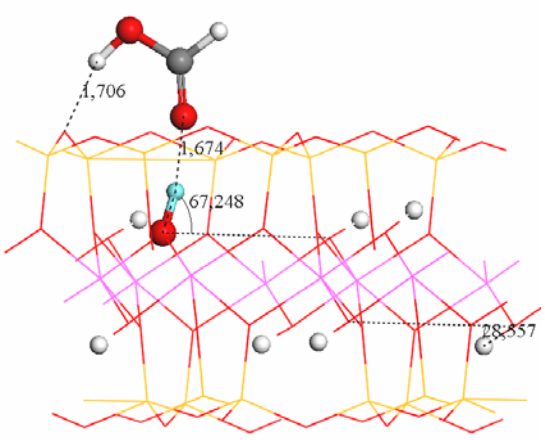

Figure 1. Adsorption complex ADS-1 of formic acid on the (001) surface of pyrophyllite.

Vehicles are a major source of particulate matter (PM) in urban areas. A large fraction of ambient PM consists of organic aerosol (OA), either primary (POA), from direct emissions, or secondary (SOA), formed via gas-phase reactions. Therefore any attempt to mitigate the effect of on-road vehicle emissions on public health and the environment should consider not only primary aerosol emissions but also secondary aerosol production potential (SAPP). However, only the primary aerosol from on-road vehicles is currently subject to direct legislation.

SOA formation from diesel exhaust has been reported, (e.g. Robinson *et al.*, 2007), but SOA formation from other common vehicles including gasoline vehicles has not. The effect of different conditions, such as fuel type, engine technology and ambient temperature on SOA formation remains unknown.

Here we determine emission factors (EFs) (g kg^{-1} fuel) for primary PM and for SOA, from two- and four-stroke scooters, a gasoline car and a truck, all complying with the latest European emissions standards. We also quantified the effect of using alkylated gasoline in scooters, liquid petroleum gas (dual fuel) in trucks and the effect of ambient temperature on SOA formation from gasoline cars and from trucks.

Vehicle exhaust was introduced into the new PSI mobile smog chamber during regulatory driving cycles on chassis dynamometers at the European Joint Research Centre Ispra, Italy. A high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) equipped with a $PM_{2.5}$ lens was used to quantify OA. Black carbon (BC) was measured using a multi angle absorption photometer (MAAP) and an Aethalometer (AE 33 prototype). A high resolution proton transfer time-of-flight mass spectrometer (PTR-ToF) was used to investigate volatile organic compounds and a suite of instruments was used to quantify CO, CO_2, CH_4, total hydrocarbon and other gases. EFs were calculated with a carbon mass balance applied to smog chamber data.

All gasoline vehicles showed significant SAPP. SOA/POA ratios were up to 27.1 for the gasoline car (Figure 1) vs. 1.4 from the truck. Average PM EFs, with the inclusion of SOA and BC, were higher from the gasoline car than from the diesel truck: 0.21 vs. 0.10 g kg^{-1} fuel, respectively. This large SOA formation is likely a consequence of higher gaseous hydrocarbon emissions from the gasoline car: 1.01 vs. 0.16 g kg^{-1} fuel for the truck.

OH exposure in smog chambers can be calculated from the decay rate of nine times deuterated butanol spiked into the chamber (Barmet *et al.*, 2011). Using this technique we show that SOA formation from gasoline exhaust would occur within 12-14 hours in the real atmosphere (colourscale, Figure 1).

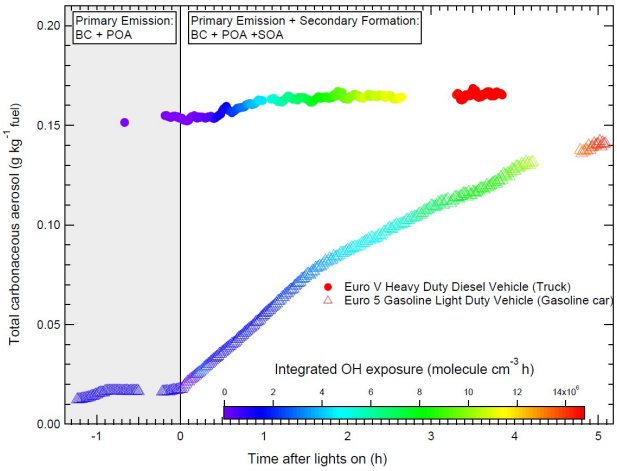

Figure 1: Carbonaceous aerosol and secondary aerosol formation emission factors from a gasoline car and a diesel truck vs. time in the PSI mobile smog chamber.

We demonstrate that aerosol emissions from gasoline vehicles can be significantly enhanced due to SOA formation and may match or even exceed those of diesel vehicles. This large SOA formation has substantial implications for emission controls which currently do not consider SAPP.

Optimization of a GC/MS method to analyse products from photo-oxidation of biogenic and anthropogenic mixtures of VOCs

O. Pindado Jiménez[1], R.Mª. Pérez Pastor[1], M. García Vivanco[2], M. Santiago Aladro[2]

[1]Chemistry Division, CIEMAT, Madrid, 28040, Spain
[2]Department of Environment, CIEMAT, Madrid, 28040, Spain
Keywords: Chemical analysis, GC-MS, SOA (Second. Organic Aerosols), Water soluble organic compounds.
Presenting author email: oscar.pindado@ciemat.es

Secondary organic aerosols (SOA) constitute a significant fraction of atmospheric particles. Much progress has been made in recent years concerning SOA formation, particularly due to experiments performed in smog chambers. Nevertheless there is still an important lack of knowledge about SOA composition.

The objective of this work is the development of an analytical methodology to quantify the composition of SOA and water soluble secondary organic aerosol produced as a result of the photo-oxidation of two different experiments performed in a smog chamber (EUPHORE, Ceam, Spain) by gas chromatography/mass spectrometry. Each experiment comprised the oxidation of a different mixture of volatiles organic compounds: an anthropogenic mixture in experiment 100609 (toluene, 1,3,5-trimethylbenzene, o-xylene and octane) and a biogenic one in experiment 240609 (α-pinene, limonene and isoprene).

The method consists in a double extraction with water & methanol jointly to a double derivatization with O-(2,3,4,5,6) pentafluorobenzyl hydroxylamine hydrochloride (PFBHA) and N,O-bis (trimethylsilil) trifluoroacetamide (BSTFA). Emphasis has been placed in developing a soft extraction to minimize losses of volatiles and a multistep derivatization technique to quantify the maximum number of compounds. Figure 1 shows the scheme of the whole methodology.

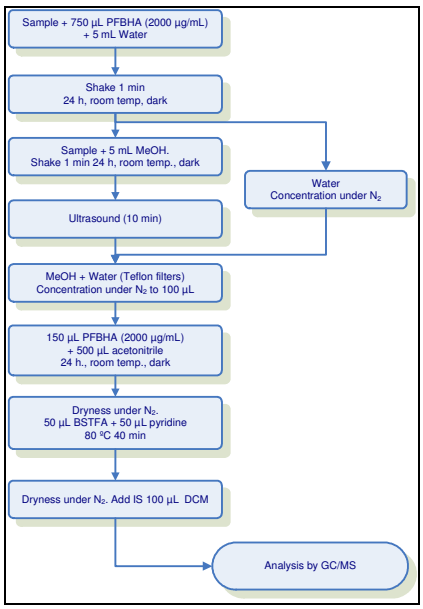

Figure 1: Scheme of analytical procedure to quantify components of SOA and WSOA.

Up to 20 compounds have been identified such as phenol, oxalic acid, malonic acid, benzoic acid, maleic acid, succinic acid, 2,3-butadione, citraconic acid, 4-etoxyphenol, glycolaldehyde, hydroxyacetone, glyoxilic acid, adipic acid, piruvic acid, norpinonic acid, pinic acid, 1,4-methylbenzoquinone, glyoxal, methylglyoxal and pinonic acid. Compounds were well separated in less than 25 minutes and identified through their mass spectra.

Figure 2 shows the collected mass of the compounds identified in each experiment.

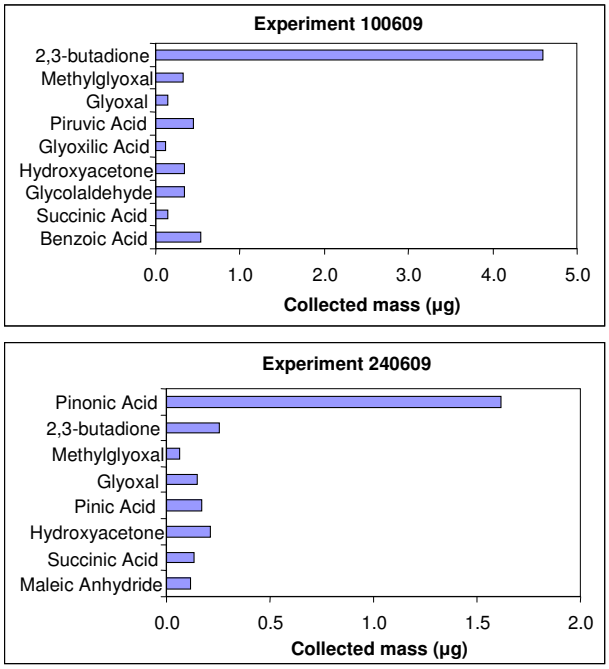

Figure 2: Collected mass of identified compounds in each experiment.

Adequate validation parameters such as applicability, selectivity, linearity, precision, recovery, detection limit, quantification limit and sensitivity have been found. However, this methodology was not suitable to analyze anhydrides, as they got hydrated during extraction, driving to the formation of dicarboxylic acids. In the light of these results, further research must be done.

This work has been financed by the Spanish Economy Ministry (project CGL2008-02260/CLI)

Development of a new tool to study atmospheric aerosol particles origin

L. Bourcier[1] and B. Geypens[1]

[1]Institute for Reference materials and Measurements - Joint Research Centre - European Commission, 2440 Geel, Belgium

Keywords: carbonaceous particles, source identification, isotopic ratio.

Presenting author email: laureline.bourcier@ec.europa.eu

Information on the atmospheric composition, from the local to the global scale, is of strategic value in particular for climate and air quality related studies. Stable isotope research for both compounds specific and bulk analysis finds its applications in various fields (Hoefs, 1987; Flanagan et al 2005). One of its applications is the source identification since the $^{13}C/^{12}C$ is highly dependent on its origin. This has been done by the study of the stable carbon isotopic composition ($^{13}C/^{12}C$) (Cachier et al 1989; Widory et al., 2004; Ceburnis et al., 2011).

In the literature, the simultaneous characterization of OC/EC and $\delta^{13}C$ is made with two different analyses (Huang et al., 2006). Our objective is to develop a method to obtain in one single analysis the OC and EC concentrations (instead of the total carbon, usually studied) and their isotopic ratios. For that purpose, we connected an Isotopic Ratio Mass Spectrometer (IRMS, Delta Plus, Thermo Scientific) behind a modified Sunset lab. instrument by using an open split coupling (Conflo II, Thermo Scientific). These data may allow a better linking of the particles to their origins.

The calibration of OC and EC is performed with known amount of sucrose, as usually used. For the isotopic ratio, since the standard VPDB is in very limited quantity, we used methionine to calibrate the analysis.

To test our instrumental set-up, sampling has been performed on the roof of the institute's building, located in forested area.

Results

We observed a pretty good repeatability for the analysis of specific compounds like beet sugar (± 0.90 ‰) or real samples (± 2.23 - 4.13 ‰ for OC and ± 1.11 – 1.23 ‰ for EC). Nevertheless, there is still a need of investigating closely the fractionation artefact since we observed a difference of 3.3 ‰ between the EA-IRMS (reference method) and the sunset-IRMS.

We cannot discuss yet about trends and origin but we can already notice a high $\Delta^{13}C_{OC\text{-}EC}$ ($\delta^{13}C_{OC}$-$\delta^{13}C_{EC}$), consistent with forested area and indicating the mixing of carbonaceous aerosol particles from different sources.

Aerosol time of flight mass spectrometry (ATOFMS) is one of the most powerful state of the art techniques which allows both size and chemical characterization of single airborne particles (Gard *et al* 1997). Data analysis is still a challenge and in the present study three different data treatment techniques have been applied (PMF, K-means ART-2a) to a rural background dataset collected in Harwell, UK.

For the first time, PMF analysis was directly applied to single particle mass spectra as opposed to data previously clustered with another technique. The analysis was performed on a total of 56898 single particle mass spectra allowing the extraction of 10 factors. The results show that PMF analysis applied to single particles makes a deconvolution of their mass spectra and it extracts factors with very well defined and characterized chemical profiles, representing inorganic species, i.e. NIT (nitrate), SUL (sulphate), NaCl, and different elemental and organic carbon families including fresh EC, aged EC, oxidized organic aerosol, aromatic, and two organic nitrogen factors. In addition, for each extracted component (PMF factor), its temporal trend, both in terms of scores, equivalent number of particles and volume, is obtainable concurrently with its size distribution.

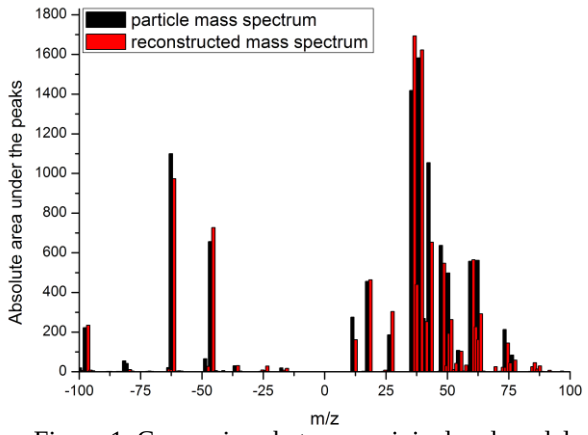

Figure 1. Comparison between original and model reconstructed mass spectrum of a particle made of 3% SUL, 10% NH4-OOA, 17% EC+, 8% OC-Arom, 2% EC-, 6% K, 7% NIT, 18% OC-CHNO, and 30% unexplained.

Moreover, a study of correlations among PMF factors could turn to be useful for study of the mixing state of particle components. In fact, it has been possible to identify two different elemental carbon contributions: fresh (EC-) and aged (EC+) elemental carbon internally mixed with secondary species.

The results of PMF analysis were compared to those obtained from K-means cluster analysis and ART-2a artificial neural network analysis. While K-means and ART-2a give broadly overlapping results by dividing the dataset into the different particle types, PMF makes a deconvolution of particle mass spectra and extracts their major contributing chemical species or important classes of components. In fact, from Figure 1 it may be seen that more than one factor is necessary to reconstruct a particle mass spectrum (Giorio *et al* 2012).

The joint deployment of factor and cluster analysis techniques, considering the different characteristic features, could be very promising to better understand particle properties and composition.

Moreover, temporal trends of factors and clusters were compared with independent ion and non refractory organic carbon measurements performed with a GRAEGOR (Thomas *et al* 2009) and an AMS (Drewnick 2005) in order to evaluate the performance of the data analysis. The results showed that the temporal trends of PMF factors are correlated to the corresponding species concentrations and thus PMF analysis could prove to be useful for quantification purposes.

Analysis of surgical aerosols by on-line single particle and high resolution mass spectrometry

K.-P. Hinz[1], A. Fendt[1], K.-C. Schäfer[1], Z. Takats[1] and B. Spengler[1]

[1]Institute of Inorganic and Analytical Chemistry, Justus Liebig University Giessen, Giessen, D-35392, Germany
Keywords: Aerosol mass spectrometry, Chemical composition, Single particle analysis
Presenting author email: klaus-peter.hinz@uni-giessen.de

Analysis of single particles by online mass spectrometric instrumentation has been widely used for the investigation of aerosols. The method provides chemical and physical characterization of individual particles with high temporal resolution combined with a high level of specificity. Transportable instruments of this type can be operated directly at sites of interest during ambient measurements enabling in situ characterization of aerosols in various fields such as atmospheric science, homeland security, workplace control or medicine. During surgical interventions biological tissue is commonly treated by surgical lasers or electrosurgical instrumentation. These procedures generate large numbers of neutral or charged gas-phase biomolecules and aerosol particles. Surgical smoke can be harmful or infectious, but on the other hand it carries valuable chemical information about the tissue being dissected. For the latter reason, mass spectrometric methods were applied to tissue identification and differentiation and a mass spectrometry assisted surgery method was developed (Schäfer, 2009).

Application of mass spectrometric instrumentation in private homes or hospitals requires devices with reduced instrumental size and improved performance for a user friendly long-term operation. For this purpose, the compact mobile laser mass spectrometer LAMPAS 3 (19" rack, 150 cm in height) was developed (Hinz, 2011). All necessary components are arranged as compact as possible to reduce the overall size of the instrument. The highly robust instrument is designed for operation under field conditions and can be easily transported by only one operator. Particles are directly introduced into the instrument using an impact-free inlet system. After particle detection and sizing an actively triggered UV laser evaporates and ionizes the detected particles. Generated ions are analyzed by a bipolar time-of-flight mass spectrometer. During optimization several instrumental features (voltage settings, delayed ion extraction, use of a reflectron time-of-flight analyser) were integrated to significantly improve mass accuracy.

Several measurement series in the laboratory were performed to investigate surgical smoke generated during disintegration of biological tissues samples using standard electrosurgical equipment. The aim of these measurements was a comprehensive analysis of surgical aerosols with complementary methods for a better understanding of mechanistic aspects, advanced description of tissue dissection processes and improved tissue identification. For this purpose, the gaseous part of the smoke was analysed by a high resolution Orbitrap mass spectrometer (ThermoScientific GmbH, Germany) employing the REIMS method (rapid evaporative ionization mass spectrometry) for direct identification of biomolecules under atmospheric pressure conditions (Schäfer, 2009). Simultaneously, the LAMPAS 3 instrument and an optical particle counter (OPC) were operated to investigate the particle phase of the smoke. Statistical methods were used for tissue discrimination and allocation.

Spectra of both mass spectrometers showed characteristic patterns particularly in negative ion spectra. Orbitrap spectra were characterized by very high mass resolving power and high mass accuracies enabling direct identification of tissue components. Spectra were dominated by phospholipid signals and thermal decomposition products of phospholipids. LAMPAS spectra showed ion signals in a broad mass range for both ion polarities. Results of measurements during dissection of various tissue types will be presented. More detailed investigatons will be performed in the future to improve the analysis of surgical aerosols and to establish a reliable mass spectrometry-assisted surgery for improved medical treatments.

Artefacts Associated with ChemVol® Impactor Sampling of Semivolatile Organic Compounds (SVOCs)

E. Galarneau[1], M. Patel[1,2], G. Poole[3], J.-P. Charland[3], and J. Brook[1]

[3]Air Quality Research Division, Environment Canada, Ottawa, Ontario, K1A 0H3, Canada
Keywords: semivolatile organic compound, SVOC, impactor, ChemVol®, sorption, polyurethane foam, PUF
Presenting author email: elisabeth.galarneau@ec.gc.ca

The ChemVol® is a high-volume cascade impactor air sampler aimed at separating airborne particles of different sizes. Polyurethane foam (PUF) rings are used conventionally as impaction substrates. The sampler was designed to capture involatile aerosols though it has subsequently been used to sample semivolatile organic compounds (SVOCs) (e.g., Sun et al., 2009).

Polyurethane foam is commonly used to capture the gaseous fraction of SVOCs in non-impactor high-volume filter-sorbent sampling. It is prone to breakthrough for more volatile compounds and/or at warm temperatures, but has nonetheless been used extensively for many years.

We hypothesize that PUFôs inherent sorption capacity makes it unsuitable as a ChemVol® substrate when SVOCs are among the target compounds. By extension, erroneous attributions of toxicity to particulate rather than combined (gaseous plus particulate) concentrations can occur if chemical methods capable of extracting SVOCs are used on ChemVol® PUF media. Tests of this hypothesis are described below as is a method that separates the sorbed gaseous compounds from those that are truly particulate.

Unsubstituted polycyclic aromatic hydrocarbons (PAHs) of molecular weight 178 to 228 g mol^{-1} were used as test compounds. First, the sorption of gaseous compounds was documented. The creation of a particle-free air stream was attempted by placing the after-filter upstream of the impactor stages rather than downstream as is typically the case.

This configuration was only partly successful in creating a particle-free stream of air. Deposits were observed on the three final stages of the sampler indicating that fine particles < 2.5 µm were flowing through the upstream after-filter and on to the impaction substrates. However, stages collecting coarser particles > 2.5 µm were largely deposit-free. As a result, the two coarsest ChemVol® stages (*viz*., 2.5-10 µm and > 10 µm) were chemically extracted and it was assumed that recovered PAHs had been collected on the PUFs exclusively from the atmospheric gas phase.

Results from the ChemVol® were compared to results from collocated and contemporaneous samples collected with a conventional high-volume filter-sorbent sampler. The ñparticle-freeò ChemVol® PUFs collected substantial quantities of PAHs that were found to be mostly gaseous in the high-volume samples (e.g., phenanthrene MW 178 g mol^{-1}, see Figure 1, and fluoranthene MW 202 g mol^{-1}). However, measured concentrations were less on the ChemVol® PUFs than on the filter-sorbent PUFs, indicating that the sorption on the ChemVol® media captured only a portion of the available gas-phase concentration. Very little chrysene (MW 228 g mol^{-1}) was found on the ñparticle-freeò ChemVol® PUFs and this is consistent with its phase distribution being overwhelmingly particulate as determined by filter-sorbent sampling.

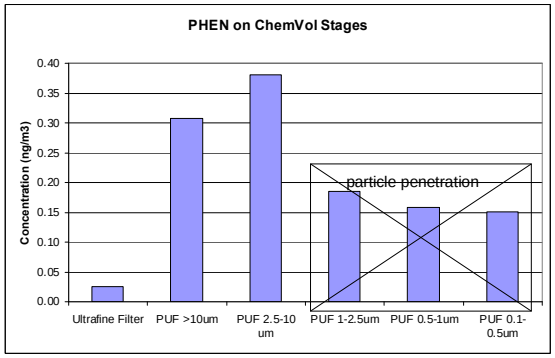

Figure 1: Phenanthrene Sampled by ChemVol® After Particle Removal

Previous reports in the literature (e.g., Becker et al., 2005) have suggested that collected particles can be separated from ChemVol® PUFs by sonication in water and/or alcohol. Microscopic examination of PUFs showed them to be largely particle-free after sonication preceded by wetting of the deposit area with alcohol. Subsequent extraction of the sonicated particles allowed for quantitation of collected particulate PAH without interference from sorbed gaseous compounds.

This work was conducted under the ALMITEE Project of Natural Resources Canadaôs Program for Energy Research and Development (PERD).

In-situ methylation thermal extraction GC-MS method for the determination of anhydro-sugars in atmospheric aerosol samples

G. Matuschek, A. Wüst

Helmholtz Zentrum München, German Research Center for Environmental Health (GmbH), Ingolstaedter Landstr. 1, 85764 Neuherberg, Germany
Keywords: In-situ methylation, anhydro-sugars, WSOC, particulate matter, aerosols.

The monosaccharide anhydrides levoglucosan (1,6-anhydro-b-D-glucopyranose), mannosan (1,6-anhydro-b-D-mannopyranose) and galactosan (1,6-anhydro-b-D-galactopyranose) are formed exclusively during combustion of cellulose and hemicelluloses, respectively. Therefore, they are source specific molecular markers for biomass burning and should be found in residues of incomplete combustion of fuels containing cellulose or hemicelluloses. Simoneit et al. (1999) were one the first who showed that levoglucosan and related degradation products from cellulose could be used as molecular markers for the presence of emissions from biomass burning in atmospheric fine particles (PM). Thus, during the last decade, the monosaccaride anhydrides, especially levogucosan, mannosan and galactosan have received increasing relevance as an important class of the water soluble organic compounds (WSOC) sub fraction of organic aerosols.

Although many studies reported on the monosaccharide's content of organic aerosols, a limited diversity of analytical methods is seen. The most frequently used methods are GC/MS methods, based on solvent extraction of the filter samples, followed by derivatisation using various silylating agents. Several studies, using this analytical technique have revealed that the WSOC fraction is dominated by oxygenated multifunctional polar compounds containing hydroxyl, carbonyl and carboxyl as well as amide and amino groups (Nolte et. al. 2002). Due to the time consuming derivatisation step, one of the key questions regarding reliable chemical analysis is the necessity of derivatisation. Some few studies, performing GC/MS analysis of non-derivative samples, either reported poor chromatographic behaviour or did not include detailed methodology description (Fraser 2000, Fine 2001).

Although a recently published study, using two dimensional GC-MS showed good results (Ma 2010), derivatisation seems to be necessary and a fast, simple and reliable derivatisation method is required.

In this work, a novel method for the determination of levoglucosan (1,6-Anhydro-β-D-glucopyranose) and its isomers galactosan and mannosan is described. The method is based on thermal extraction (thermal desorption) of filter samples of particulate matter under addition of tetramethylammonium hydroxide (TMAH). This in-situ methylation omits the use of hazardous silylation reagents as well as time and labour consuming reaction steps. Chemical analysis is performed by gas chromatography (GC) combined with quadrupole mass spectrometry. Evaluation of the in-situ tmethylation thermal extraction GC-MS method revealed low relative standard deviations (< 10 %), no carryover for the three analytes and detection limits of 0.6, 6 and 8 ng for levoglucosan, galactosan and mannosan respectively. The method was successfully applied to polar extracts of particulate matter samples as well as to original PM filter samples.

Studying Atmospheric Aerosols by Acoustic Levitation: Linking Head Space Solid-Phase Micro-Extraction (HS-SPME) with Gas Chromatography-Mass Spectrometry (GC-MS).

S. Almabrok, G. Marston and C. Pfrang

Department of Chemistry, University of Reading, P.O. Box 224, RG6 6AD Reading, Berkshire, UK
Keywords: Solid-Phase Micro-extraction, Acoustic Levitation, α-Pinene, Ozone.
Presenting author email: s.h.almabrok@reading.ac.uk

Climate change is one of the most important global environmental problems affecting natural ecosystems, food production, availability of fresh water as well as human health.(1) In acoustic levitation, a sound wave is generated between a piezoelectric transducer and a flat or concave reflector; therefore, by altering the distance between transducer and reflector a standing wave can be created and small samples of solids or liquids can be levitated.(2) This study has been conducted to improve our understanding of the reactions of O_3 and NO_3 with a range of terpenes found in the Earth's atmosphere and of the formation and properties of associated organic aerosols. For these investigations, a combination of acoustic levitation with gas chromatography-mass spectrometry (GC-MS) has been achieved by head space solid-phase micro-extraction (HS-SPME). The experimental set-up is illustrated in Fig. 1 (a-b).

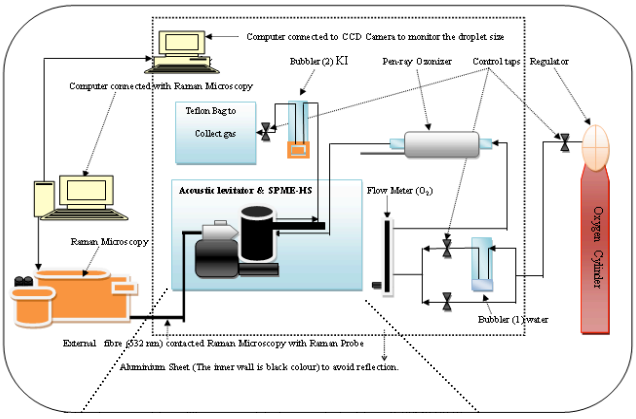

Figure 1 (a): Experimental set-up for the acoustic levitator with HS-SPME-GC-MS analysis.

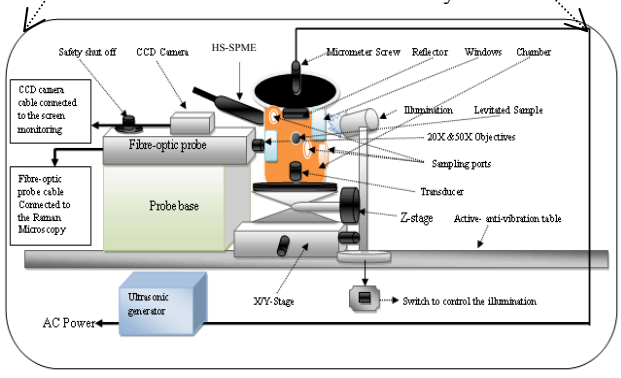

Figure 1 (b): Set-up for the combination of the acoustic levitator with HS-SPME (zoom into Fig. 1 (a)).

Fig. 2 shows the mass spectrum for a levitated droplet of pure α- pinene obtained by using HS-SPME-GC-MS under the following conditions: 174 ml/min flow of N_2, 5 min extraction time, and using a 100 µm polydimethylsiloxane (PDMS) coated fibre. Oxidation of acoustically levitated droplets of α-pinene and d-limonene has been studied in an environmental chamber that allowed control of the gas-phase surroundings and relative humidity. Several products could be identified mostly by comparison with reference samples in the same conditions including verbenone, verbenol, pinocarveol, carvone, carveol, norpinoaldehyde and pinonaldehyde (see example in Fig. 3).

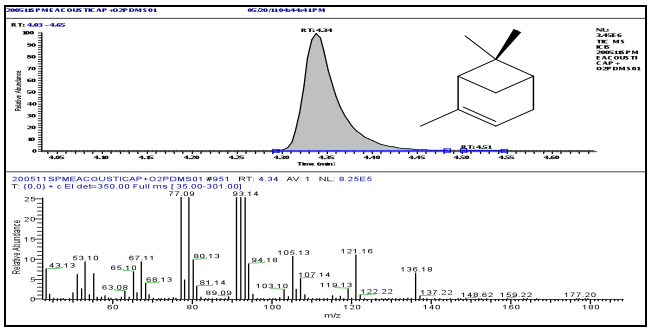

Figure 2: HS-SPME-GC-MS result for a levitated droplet of pure α-pinene (GC on top; MS below).

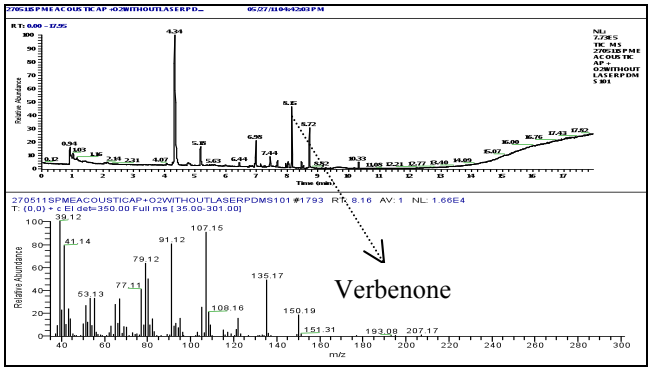

Figure 3: HS-SPME-GC-MS result for a levitated droplet of α-pinene after oxidative ageing (MS for the product verbenone).

Keywords: nucleation, nano particles, cut-off calibration, DEG-CPC, CLOUD experiment

One goal of the CLOUD (Cosmics Leaving OUtdoor Droplets) experiment at CERN is to investigate to what extent the presence of atmospheric ions affects new particle formation (Kirkby *et al*., (2011)). Neutral and ion-induced nucleation experiments are carried out in an aerosol chamber under precisely controlled conditions. For nucleation studies it is crucial to achieve very low and stable cut-off diameters in order to derive accurate nucleation rates. At the same time, however, significant auto-nucleation inside the particle counter as well as activation of pre-critical clusters should be avoided (Sipilä *et al.*, 2010). The so-called cut-off curve describes the detection efficiency of the particle counter as a function of particle size.

For the experiments at CLOUD two Diethylene Glycol-based CPCs (DEG-CPCs) have been set up and calibrated according to the design described by Iida *et al*. (2009). Operating temperatures and flows were chosen to realize cut-off diameters of 1.7 and 2.0 nm, respectively. To get a better understanding of the processes that lead to new particle formation in the middle and upper troposphere, the CLOUD campaign at CERN in autumn 2011 was dedicated to measure nucleation rates at temperatures well below 0°C. Therefore measurements at 3 different temperatures namely -25°C, -50°C and -65°C were carried out, respectively. The cut-off curves have to be determined for these low temperature sampling conditions. It is possible that a fraction of the freshly nucleated particles evaporates and shrinks to sizes with substantially lower detection efficiency while being transferred from the cold CLOUD chamber to the capillary and condenser of the DEG-CPC detection unit. Therefore, careful calibrations of the sampling and detection process have to be performed for the low temperature operating conditions. First exploratory studies were realized at CLOUD to determine the response and cut-off curves when low temperature aerosol samples enter the DEG-CPCs.

For these studies the CLOUD chamber is used as the particle generator. The advantage of the CLOUD chamber is that sufficient concentrations of nanometer-sized singly charged particles can be produced by ion-induced aerosol nucleation with the help of the ionizing beam from the Proton Synchrotron under very stable conditions. These particles can be directly classified using a nano-DMA (Differential Mobility Analyzer, model 5.710, Grimm Aerosol Technik).

To achieve a good resolution of the DMA a ratio between aerosol and sheath air flow of 1:10 was chosen As a reference instrument, a Faraday-Cup Electrometer could not be used because the particle concentrations at the nano-DMA outlet were too low. A Particle Size Magnifier (PSM, Vanhanen *et al.* (2011) was used instead because it realizes a very small cut-off diameter. By adjusting the instrument properly it is capable of counting 1nm particles with a high efficiency.

There is evidence that the detection efficiency curves are shifted to larger diameters for the low temperature condition. Reasons for the shift in detection efficiency will be discussed.

We would like to thank CERN for supporting CLOUD with important technical and financial resources, and for providing a particle beam from the CERN Proton Synchrotron. Presenting author email: mikko.aijala@helsinki.fi

The chemical composition of aerosols determines their physiochemical properties, which in turn affect *e.g.* their effects on climate and human health.

The Aerodyne Aerosol Mass Spectrometer (AMS, Canagaratna *et al.*, 2007) is a useful instrument for analysis of chemical composition and quantification of basic aerosol chemical species. However, this important ability of the AMS to quantitatively measure mass comes at a price: the 70 eV electron impact ionization fragments the sampled molecules, often leaving little trace of original molecular composition of the sample compound. The quality of AMS chemical analysis therefore depends significantly on data analysis methods, particularly on the reconstruction of a picture of the original molecular composition.

Typical AMS results provide concentrations of the main aerosol chemical species: nitrates, sulphates, ammonia, organics and chlorides. This classification is useful for many general purposes, but for studying aerosol physiochemical properties like particle hygroscopicity or volatility, additional molecular composition information is often required. In this study we present a simple method for assigning AMS main inorganic compounds – sulphates, nitrates and ammonia – into chemically more specific subgroups of sulphuric acid (SA), ammonium sulphate (AS), ammonium nitrate (AN) and organic nitrate. This can provide a way to better connect AMS measured aerosol chemical composition with observations of physiochemical properties from other aerosol instrumentation.

An estimate of ammonium sulphate and ammonium nitrate mass loadings can be derived using some basic chemical assumptions on acid-base reactions in forming salts, and assuming the aerosol is well mixed externally and internally. The latter assumption is often not fulfilled in ambient aerosol, but is a necessary first step in this type of analysis. Methods to account for incomplete mixing are an issue for further development. The calculation itself is inspired by, and closely related to, AMS collection efficiency (CE) estimations (Quinn *et al.*, 2006) and may prove to be of use in trying to better understand AMS CE dependencies on particle properties. Based on the relative molar amounts of ammonium and sulphate ions (NH_4^+ and SO_4^+) measured by the AMS, all observations can be divided into three distinct cases:

Case 1: the concentration of ammonium ions is lower than the concentration of sulphate ions ($[NH_4] < [SO_4]$). All available ammonia is taken up by sulphate to form ammonium bisulphate NH_4HSO_4. The rest of the sulphate ions are assigned to liquid phase sulphuric acid in particles. All nitrate signal is assumed to be from organic sources.

Case 2: $[SO_4] < [NH_4] < 2*[SO_4]$. All sulphate and ammonia is assigned to ammonium bisulphate or ammonium sulphate. All nitrate signal is attributed to organic nitrate.

Case 3: ($[NH_4] > 2*[SO_4]$). The leftover ammonium reacts with nitrogen condensed from gas phase to form ammonium nitrate NH_4NO_3. The rest of nitrate is assumed to be organic.

The estimate was tested on a month-long unit m/z resolution AMS dataset from the SMEAR II station in Hyytiälä, Southern Finland. The obtained inorganic-to-organic nitrate ratio was observed to correlate with the measured NO_2^+/NO^+ fragmentation ratio (Fig. 1), commonly used as a marker for the presence of inorganic nitrates. Further comparisons with instruments such as hygroscopicity and volatility tandem DMAs are ongoing to corroborate the results obtained using this method.

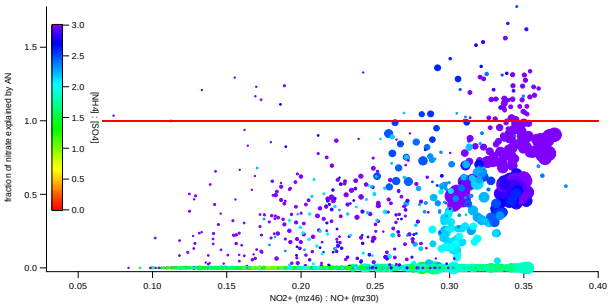

Figure 1. Fraction of nitrate signal explained by calculated ammonium nitrate loading, as a function of NO_2^+/NO^+ ion ratio. A high NO_2^+/NO^+ ratio is used as an indication of inorganic nitrate. Marker size describes AMS total nitrate concentration and colour the ratio of $[NH_4]$ to $[SO_4]$.

Simplifying the complex nature of water-soluble organic matter from atmospheric aerosols: new insights from comprehensive two-dimensional liquid chromatography

R.M.B.O Duarte, A.C. Barros and A.C. Duarte

CESAM & Department of Chemistry, University of Aveiro, 3810-193 Aveiro, Portugal
Keywords: Carbonaceous aerosol, Water soluble organic compounds, Chemical properties, Molecular weight.
Presenting author email: regina.duarte@ua.pt

Water soluble organic matter (WSOM) from fine atmospheric aerosols is inherently complex (Duarte *et al.*, 2005,2007,2008), and detailed information regarding its major structural components, or even its individual structures, still remains indiscernible. It is clear that the substantial heterogeneity of aerosol WSOM limits the quality of structural data obtained by high-resolution instrumental techniques (e.g. nuclear magnetic resonance or mass spectrometry), thus making their interpretation extremely difficult. In this sense, the synergistic application of any chromatographic separation protocol prior to a structural inquiry can be of particular value for unfolding the molecular complexity of WSOM from fine aerosols and, therefore, further advance the current understanding on this organic component. Comprehensive two-dimensional liquid chromatography (LC x LC) presents itself as an excellent choice to dramatically improve the separation efficiency of WSOM. This technique provides enhanced separation by combining two liquid chromatographic modes with different separation mechanisms.

Therefore, and for the purpose of resolving the chemical heterogeneity of WSOM from fine particles, comprehensive LC x LC was employed for the first time to map the polarity *versus* molecular weight (MW) distribution of a WSOM sample collected during a winter season. The specific objectives of this research include: 1) evaluating the potential of comprehensive LC x LC as a novel methodology for WSOM separation; 2) determining how size-distinguished fractions differ in polarity; and 3) reassessing the MW properties of the studied WSOM sample. For accomplishing these objectives, a method has been developed using a mixed-mode hydrophilic interaction column in the first dimension and a size-exclusion column in the second dimension. The LC x LC fractions were screened on-line by UV at 254 nm.

Findings suggest that the combination of two independent separation mechanisms is promising in extend the range of WSOM separation. The comprehensive LC x LC system allowed the fractionation of the aerosol WSOM sample into two clusters of fractions with apparently different polarity and MW distribution (Figure 1). It seems that smaller Mw group fractions are related to a more hydrophobic nature. The complete range of MW distribution provided by the comprehensive LC x LC method was found to be within the range of those reported in the literature (Kiss *et al.*, 2003, Samburova *et al.*, 2005).

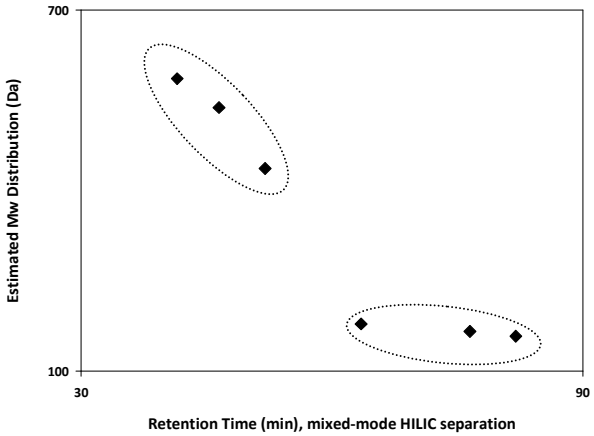

Figure 1. Mapping the polarity *versus* estimated MW distribution of the WSOM from fine particles.

Characterization of a thermal desorption mass spectrometer for freshly nucleated secondary aerosol particles

S. G. Gonser[1] and A. Held[1]

[1] Junior Professorship in Atmospheric Chemistry, University of Bayreuth, 95440 Bayreuth, Germany
Keywords: Aerosol mass spectrometry, Nucleation mode, SOA (Second. Organic Aerosols), Chemical composition.
Presenting author email: stefan.gonser@uni-bayreuth.de

Secondary aerosol formation introduces new particles to the atmosphere and is thereby relevant for human health and the global climate. Chemical reactions leading to atmospheric secondary aerosol formation are not yet fully understood. At the same time, analysing the chemical composition of freshly nucleated particles is still a challenging task.

We are currently finishing the development of a field portable aerosol mass spectrometer for nucleation particles with diameters smaller than 30 nm. The instrument consists of a custom-built aerosol sizing and collection unit coupled to a time-of-flight mass spectrometer (TOF-MS). The aerosol sizing and collection unit is composed of three major parts: (1) a unipolar aerosol charger, based on corona discharge from carbon fibres (e.g. Han *et al*, 2008), with an extrinsic charging efficiency of 32 % for 20 nm particles; (2) a compact radial differential mobility analyser (Zhang *et al,* 1995) for particle size separation in the range from 1 nm to 100 nm (geometric standard deviation of 1.09); and (3) an electrostatic precipitator where the aerosol is collected on a high-voltage biased metal filament, while a He counterflow protects the sample from contamination (see Fig. 1).

After collection, the aerosol sample is thermally desorbed, and the resulting gas sample is transferred to a Tofwerk CTOF mass spectrometer for chemical analysis.

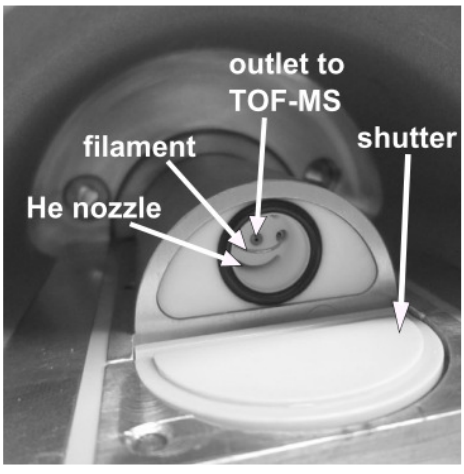

Figure 1. Photograph of the electrostatic precipitator. After collection, the filament is heated with the shutter closed, avoiding contamination of the gas sample.

Resistive heating of the filament allows temperature-controlled desorption of compounds of different volatility, thus facilitating the interpretation of the measured mass spectra.

We will present results of preliminary laboratory measurements performed in our aerosol smog chambers for calibration of the instrument. Secondary organic aerosol (SOA) is produced from photooxidation as well as dark ozonolysis of alpha-pinene. Particles with diameters below 30 nm are separated from the generated polydisperse particle population, collected in the electrostatic precipitator and subsequently analysed by the TOF-MS. The resulting mass spectra are compared to the chemical composition of laboratory generated SOA from published literature (e.g. Shilling *et al*, 2009), with alpha-pinene as precursor.

To date, the major part of published SOA mass spectra are measured with the Aerodyne aerosol mass spectrometer (AMS), determining the chemical composition of particles larger than 40 nm in diameter. The spectra measured with our instrument provide chemical information of freshly nucleated particles, extending the size range to the nucleation mode.

To evaluate the performance of our instrument in the field, we plan to conduct first measurements at the Waldstein research site of the University of Bayreuth before the end of this year.

Presenting author email: s.zorn@aeromegt.com

Mass spectrometry has become a very powerful tool for the analysis of the atmospheric aerosol. Modern on-line instruments offer not only a very high time resolution with sampling intervals down to seconds and essentially real-time analysis of the chemical and physical parameters of aerosol particles but can also be deployed with little effort at very remote locations.

Currently, two types of aerosol mass spectrometers are commonly used. Instruments based on thermal desorption electron ionization offer a bulk analysis of the chemical composition of the non-refractory aerosol. Laser desorption ionization mass spectrometers can analyze the composition of single aerosol particles including soot, sea salt and mineral dust that cannot be vaporized using thermal desorption methods.

Most aerosol mass spectrometers using thermal desorption electron ionization are based on a common instrument platform and because of this, results from these instruments can generally be easily compared (Canagaratna et al., 2007).

For laser ablation instruments the situation is more complex. Many such instruments are individual builds. Even the few commercial instruments in existence differ slightly in details.

Besides the differences in construction the lasers used for the ablation of particles in the individual instruments differ in wavelength as well as in pulse energy. This makes a comparison of results from various laser desorption ionization instruments more difficult.

Here we present a comparison of two different laser ablation instruments (Table 1). A newly developed, very compact single particle mass spectrometer (LAAPTOF; AeroMegt GmbH) that is commercially available is compared to a custom built system (LAMPAS 3; Hinz et al., 2011).

For the comparison of the two instruments we used a test set of aerosols comprised of several different chemicals including sodium chloride, ammonium sulfate, ammonium nitrate, soot and mineral dust as well as different sizes of polystyrene latex particles. The measurement setup for both instruments was identical, using the same constant output atomizer (TSI 3076) and diffusion dryer (TSI 3062).

Aerosols having different composition were either atomized, nebulized or suspended in air. All test aerosols were dried prior to sampling. The whole range of chemicals was measured by both instruments. Additionally, spectra for each chemical makeup were recorded at different pulse energies for the ablation laser, to investigation the variability as well as the wavelength and energy dependence of the resulting ions and spectra.

Table 1. Specifications of LAMPAS 3 and LAAPTOF.

	LAMPAS 3	***LAAPTOF***
sizing laser, λ	532 nm	405 nm
ablation laser, λ	337 nm	193 nm
max. irradiance	$5 \cdot 10^9$ W/cm^2	$1 \cdot 10^9$ W/cm^2
mass resolving power	400 M/ΔM	800 M/ΔM

The results allow not only a direct comparison of both instruments for the tested compounds but can be also applied to field measurements as well as show the best instrument configuration for inter-comparison. Further investigations of the spectra collected at different pulse energies might be helpful for investigation of aerosol particles at different locations, e.g., to select the best energy for measurements at marine, rural or urban locations.

Complexation of transition metal ions by organic and inorganic ligands in size-segregated atmospheric aerosol particles in Melpitz, Germany

S. Scheinhardt[1], K. Müller[1], D. van Pinxteren[1], K. Fomba[1], A. Grüner[1], G. Spindler[1], H. Herrmann[1]

[1]Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany

Presenting author email: scheinhardt@tropos.de

Transition metal ions (TMI) like Fe, Cu and Mn are important species in atmospheric liquid phase reactions since they can take part in various redox reactions. Notably, they influence aqueous HO_x chemistry and participate in photochemical oxidation processes of organics. The chemical form under which TMIs are present has a huge influence on their photochemical properties, but so far their speciation remains unclear.

Therefore, size-segregated aerosol samples have been taken at a well-characterised rural background site in central Europe (Melpitz; Spindler, 2010) by means of a five-stage Berner impactor. After sampling, the impactor foils were extracted with water and the resulting aqueous extracts were chemically analysed (cf. Figure 1): TMIs were determined by totalreflection X-ray fluorescence (TXRF), inorganic ions by ion chromatography (IC) and capillary electrophoresis (CE), and small mono- and dicarboxylic acids by capillary electrophoresis. Additionally, the pH of the extracts was measured.

Together with meteorological parameters like humidity and temperature, these measurements allowed us to calculate the aerosol water content using the E-AIM Model (Wexler, 2002). Thus, the molar concentrations of dissolved TMIs, potential ligands and H^+ in the aqueous phase of atmospheric particles could be obtained.

Next, sampling days have been allocated into four case groups, depending on the season and the air mass origin during sampling: Summer West (SW), Winter West (WW), Summer East (SE) and Winter East (WE). In each category, the mean composition of the aqueous

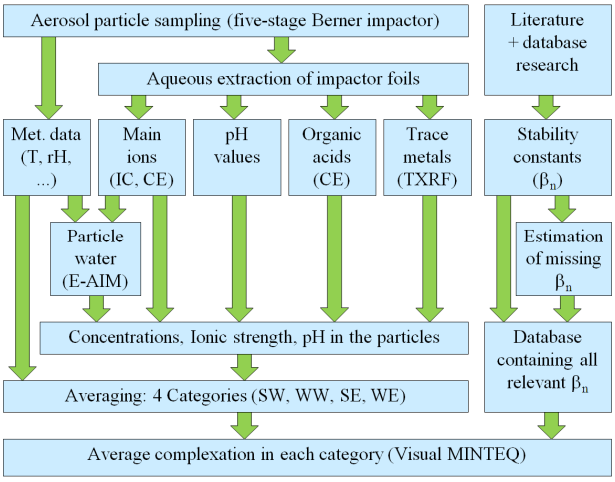

Figure 1. Scheme illustrating the strategy of the present study.

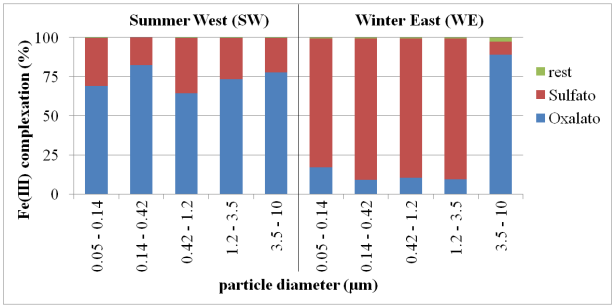

Figure 2. Calculated average complexation of Fe(III) in aerosol particles collected in Melpitz.

particle phase has been calculated (average of the corresponding sampling days). These average molar concentrations have finally been used as an input for the chemical speciation model Visual MINTEQ (Gustafsson, 2011), which allowed us to calculate the equilibrium complexation of TMIs by organic and inorganic ligands in the aqueous particle phase. Stability constants were ionic strength corrected using the Davies equation.

In this way, the mean TMI complexation in Melpitz has been calculated for the 4 categories. The results show that TMI complexation by organic compounds is important even in very acidic particles (pH~1). As an example, Fig. 2 shows that, in the SW case, Fe(III) is mostly present in the form of oxalato complexes, while in the WE case, Fe(III) is rather complexed by sulphate ions (due to higher sulphate loadings in this case). Mn(II) and Fe(II) are mainly complexed by sulphate and nitrate, while Cu(II) is, like Fe(III), complexed by oxalate, sulphate and additionally by nitrate (data not shown).

This is the first time that the complexation of TMIs in size-segregated aerosol particles is determined.

The organic carbon and total protein concentrations in atmospheric aerosol of Southwestern Siberia boundary atmospheric layer

A.S. Safatov[1], G.A. Buryak[1], S.E. Olkin[1], I.K. Reznikova[1], V.I. Makarov[2] and S.A. Popova[2]

[1]FBRI SRC VB "Vector", Koltsovo, Novosibirsk rgn, 630559, Russian Federation

Presenting author email: safatov@vector.nsc.ru

Literature data show that atmospheric aerosol always contains a certain amount of organic (OC) and elemental carbon (EC) as well as components of biological origin. The aim of this study was to analyze long-term data on ground level concentrations of atmospheric aerosol in Southwestern Siberia and those of OC and total protein (TP, universal marker of components of biological origin).

Aerosol sampling was performed by pumping the air at the volumetric rate of 13 m^3/h for a day through fiber filters of AFA-HA-20 type and glass fiber filters. A series of observations for each season lasted for 30 days (4 series per year).

The weight of deposited aerosol was determined by the gravimetric method.

The concentrations of OC and EC were determined by the thermal method (reaction gas chromatography) as described in (Popova *et al*, 2007). The method of reaction gas chromatography allows us to determine the concentrations of OC and EC by their high-temperature separation in an inert atmosphere. Each component is oxidized to CO_2, converted into CH_4 and recorded by a flame ionization detector. The organic substances that are vaporized at heating the sample (to 700 ° C) in an inert atmosphere are defined as organic carbon, and when all substances are burned in an oxidizing atmosphere - as elemental carbon.

The weights of total protein in the samples were determined using a fluorescent dye (You *et al*, 1997).

Tables 1 and 2 show the results of measurements carried out in 2001-2010. The analysis of results demonstrates that, as a whole, the average annual concentration of aerosol tends to increase with a slight reduction during recent years of observations. The average annual concentration of OC in the atmosphere also tends to increase, whereas the average annual concentration of TP remains nearly constant, Table 1. At the same time, the portion of OC in the total mass of aerosol particles also tends to increase during the observation period, while the portion of TP remains practically constant.

Normalization of the values by the corresponding average annual values reveals their seasonal variation. In the cold season, the concentrations of aerosol, the OC and TP are lower than in the warm one. Aerosol concentrations and OC reach their maximums in spring, and TP does it in summer, Table 2.

Table 1. Average annual concentrations of aerosol, OC and TP (all in μg/m^3) in Southwestern Siberia (mean values ± 95% confidence interval).

Year of observation	Values		
	Aerosol	OC	TP
2001	38.6 ± 4.7	4.79 ± 0.90	0.11 ± 0.02
2002	31.4 ± 4.3	5.27 ± 0.98	0.31 ± 0.06
2003	28.9 ± 3.0	4.58 ± 0.74	0.59 ± 0.09
2004	35.2 ± 5.5	4.00 ± 0.63	0.78 ± 0.20
2005	32.2 ± 3.0	4.13 ± 0.47	0.35 ± 0.06
2006	52.1 ± 6.8	6.50 ± 1.14	0.89 ± 0.21
2007	47.9 ± 6.4	4.94 ± 0.68	0.69 ± 0.15
2008	49.6 ± 4.2	7.01 ± 1.20	0.39 ± 0.06
2009	44.6 ± 5.7	8.20 ± 2.25	0.49 ± 0.08
2010	36.8 ± 3.1	6.68 ± 0.91	0.35 ± 0.06

Table 2. Seasonal variation of the concentrations of aerosol, OC and TP normalized by the corresponding average annual values. Averaging over 2001 - 2010, the mean values are presented in increments of 1 ± their 95% confidence interval.

Year of observation	Values		
	Aerosol	OC	TP
Весна	1.41 ± 0.11	1.62 ± 0.19	1.40 ± 0.15
Лето	0.86 ± 0.04	0.80 ± 0.04	1.62 ± 0.12
Осень	0.80 ± 0.05	0.83 ± 0.07	0.72 ± 0.07
Зима	0.91 ± 0.04	0.73 ± 0.05	0.18 ± 0.02

The comparison of these data with those published in Safatov *et al* (2010) for the altitudes of 500 - 7000 m reveals an essential difference between them. For the atmospheric layer at 500 - 7000 m during the same period, aerosol concentrations and those of TP in it tend to decrease, while the portion of TP in the total mass of aerosol increases during the same period. This is probably explained by the influence of local bioaerosol sources, and the difference in the movement of air masses in the boundary atmospheric layer at the altitudes of 500 - 7000.

$PM_{2.5}$ and PM_{10} composition in São Paulo city Atmosphere – Summer and Winter campaigns

P.C. Vasconcellos[1], B. Oraggio[1], P.V. Veiga[1], A. Soreira[1], E. G. Alves[1], J.B De Andrade[2]

[1]Department of Chemistry, University of São Paulo, São Paulo, Cidade Universitária,05508-000, Brazil
[2]Department of Chemistry, Federal University of Bahia, Salvador, Campus de Ondina, 40170-290, Brazil
Keywords: air pollution, aerosols, organic and inorganic pollutants.
email: perola@iq.usp.br

PM_{10} and $PM_{2.5}$ samples were collected in São Paulo city (Brazil) at a site located into the University of São Paulo (SPA site). This site is impacted by miscellaneous emissions sources, including biogenic emissions from a local small forest. Summer campaign took place from October 2009 to March 2010, and the intensive winter campaign in June 2010. Polycyclic aromatic hydrocarbons (PAH) and n-alkanes were determined by gas chromatography after extraction by Soxhlet and fractionation in silica column. The water soluble ions were determined by ion chromatography.

In the summer campaign (wet and warm season) total water soluble ions concentration averaged 7266 ng m^{-3} for $PM_{2.5}$.

In the winter campaign, when events of air pollution were observed, these species averaged 9039 ng m^{-3} for $PM_{2.5}$ and 10307 ng m^{-3} for MP_{10}. The most abundant species were sulphate, nitrate and ammonium in both PM_{10} and $PM_{2.5}$ samples. Sulphate and oxalate didn't present good correlation indicating different formation processes and emissions sources of the precursors. In the winter back trajectories showed air masses coming from regions where sugarcane burning occurs. Except fumarate, all species are more abundant in the fine particulate. $PM_{2.5}$ contributed from 50 to 100% to PM_{10} (Figure 1). According to World Health Organization, the ratio of 0.5 is characteristic of the urban areas of developing countries and corresponds to the lower limit of the range found in urban areas of developed countries (0.5 - 0.8).

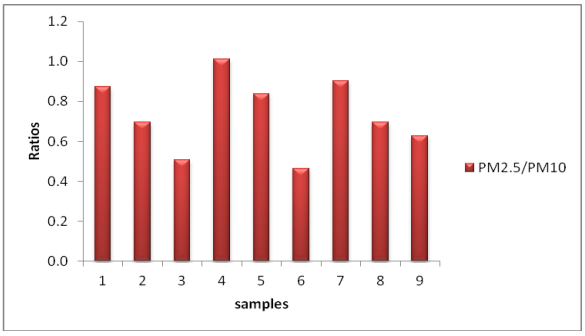

Figure 1. $PM_{2.5}/PM_{10}$ ratios during winter campaign.

The average SO_4^{2-}/NO_3^- ratio were about two times higher in the summer campaign (2.5) than at winter one (1.2). The volatilization of nitrate in the aerosol has been reported in the literature and the winds bringing sulphate derived from sea salt can increase these ratios.

Fourteen PAH (from phenanthrene to indenopyrene) and C_{16}-C_{30} range alkanes were determined. In summer, the most abundant PAH were pyrene, chrysene and benzo(e)pyrene; BeP/BaP ratios (<1) indicated that local emissions are more important than the transport of pollutants. On the other hand, in the winter samples, the lighter compounds were more abundant (phenanthrene, anthracene and fluoranthene). Retene, compound present in biomass burning smokes (Vasconcellos et al., 2011) was present in all samples (av. 20 ng m^{-3}) and BeP/BaP ratios (2.3) indicate transport of air masses and photochemical activity influencing the PAH concentrations.

Between the n-alkanes, the odd-even distribution of the higher n-alkanes shows the biogenic influence and pristane and phytane, the fossil fuel contribution in both campaigns. Figure 2 show the alkanes distribution in a sample collected in the summer campaign.

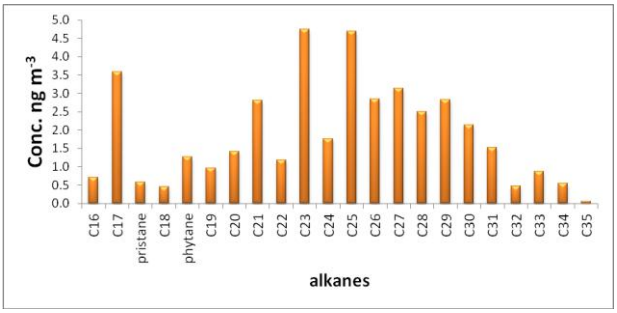

Figure 2. Mean concentrations of n-alkanes, pristane and phytane in samples collected during the wet campaign.

Conclusions

At SPA site, local emissions seem are more important to influence the air quality during the summer campaign, and transport of pollutants from areas with agriculture activities and local vehicular emission can impact the site during the winter time. $PM_{2.5}$ presented a large contribution to PM_{10}.

Aliphatic and aromatic amines in atmospheric aerosol particles

J. Ruiz-Jimenez[1], J. Parshintsev[1], T. Laitinen[1], K. Hartonen[1], T. Petäjä[2], M. Kulmala[2], M.–L. Riekkola[1]

[1]Laboratory of Analytical Chemistry, Department of Chemistry, P.O. Box 55, FI-00014 University of Helsinki, Finland;
[2]Division of Atmospheric Sciences, Department of Physics, P.O. Box 64, FI-00014 University of Helsinki, Finland

Keywords: Aliphatic amines, aromatic amines, aerosol particles, LC-MS, SMEAR II
Presenting author email: jose.ruiz-jimenez@helsinki.fi

Although the chemical composition of atmospheric aerosols has been extensively studied during the last decades, only a few papers have focused on the determination of chemical composition of ambient nanometer sized particles. Recent studies have demonstrated the relevance of the nitrogen compounds in the aerosol chemistry and their participation in particle growing processes.

The most common and abundant nitrogen containing organic compounds found in the atmosphere are the low-molecular weight aliphatic amines with one to six carbon numbers, and from aromatic amines especially aniline, amino acids and amides with biogenic and anthropogenic sources. The most common biogenic sources are the degraded biomolecules and biopolymers, and the cellular metabolism. Waste combustion, sewage treatment, automobile exhaust, vulcanization fumes, fish processing plants, fish stands of city markets and industrial animal farms can be regarded as the main anthropogenic sources.

The sampling of atmospheric aerosol particles is a highly challenging task, especially in the case of size segregated ultrafine particles. Two different devices such as, impactors and differential mobility analyzers (DMA) can be utilized, but unfortunately the collection efficiency of the former tend to be poor for particles significantly smaller than 100 nm due to evaporation processes.

The size-separated particles can be collected on the impactor plate or on a suitable filter, extracted and analyzed with chromatographic techniques utilizing mass spectrometric detection or directly transferred to a mass spectrometer. It is well known that a significant amount of gaseous compounds can be adsorbed on the filter, causing overestimation of particulate concentration of compounds, especially in the case of nanometer-size aerosols. Two different approaches can be used in order to avoid or limit the presence of these artefacts. The first one is based on the removal of gas phase compounds before the collection of the particles in the filter using classical denuders. The second involves the use of new sampling systems based on particle size separation using a DMA and simultaneous collection of gas-phase zero samples allowing the quantification of these artefacts.

The determination of nitrogen containing compounds in aerosol particles is mainly based on chromatographic techniques such as gas chromatography (GC), ion chromatography (IC) and high performance liquid chromatography (HPLC), although other separation techniques such as capillary electrophoresis (CE) has also been employed. However, the derivatization is generally mandatory in the case of GC and LC to improve the separation efficiency and the detection sensitivity of the analytes.

A tedious derivatization step is also almost mandatory for the sensitive analysis of amines by liquid chromatography. An adequate optimization procedure and/or the use of an auxiliary energy such as, ultrasound can minimize the time needed for the derivatization, the amount of expensive reagents, and analyte losses. Unfortunately the derivatizations reagents are suitable only for primary and secondary amines but not for tertiary amines. Fortunately the hyphenation of LC to mass spectrometry (MS) allows the analysis of the underivatized analytes, although most of the methods reported in the literature include a derivatization step in order to facilitate the separation and improve the sensitivity. The selection of the most suitable MS ion source in terms of sensitivity, linearity, repeatability and reproducibility is a key factor in the method development.

In this study, a complete LC-MS methodology was developed for the determination of aliphatic and aromatic amines in atmospheric aerosol particles after dansyl chloride derivatization. This new method was applied for the determination of 19 amines (ten aliphatic and nine aromatic amines) in 16 ambient aerosol particle samples collected at the SMEAR II station.

Several relevant aspects related to the performance of the developed method such as (1) the use of ultrasounds to avoid analyte losses due to evaporation and to hinder the formation of reaction by-products during the derivatization process; (2) the advantages and drawbacks of the use of different approaches in order to limit or avoid gas phase artefacts; and (3) the selection of the more adequate ionization source in terms of sensitivity, linearity, repeatability and reproducibility will be described.

Finally, the developed method was fully characterized and validated using different sample matrices. The results obtained from its application to atmospheric air samples were in a good agreement with those provided by other methods found in the literature.

Organic composition of fog: transformation between liquid and interstitial phase

S. Schüttauf[1], J. Matschullat[1], D. van Pinxteren[2], Y. Iinuma[2], H. Herrmann[2]

[1]Institute of Mineralogy, Technical University Bergakademie Freiberg, Freiberg, 09599, Germany
[2]Chemistry Department, Leibnitz Institute for Tropospheric Research, Leipzig, 04318, Germany
Keywords: aerosol chemistry, dicarboxylic acids, fog water, interstitial phase, SOA, VOC (s)

e-Mail: stephanie.schuettauf@ioez.tu-freiberg.de

Fog and cloud water may significantly alter the organic composition of aerosols. The liquid phase enables chemical reactions that do not exist in the gas phase. Furthermore, fog and cloud water are media for new particle formation and reformation. The extended residence time of fog near ground level supports several chemical reactions. Hence, fog and cloud water are important media, which considerably influence aerosols, their composition and properties in the atmosphere.

There is a large demand in understanding the transformation of organic compounds by fog and cloud water. We report measurements of the chemical composition of fog and interstitial aerosol samples from two different sites at the Erzgebirge summit: a) Zinnwald, 877 m asl, eastern Erzgebirge, and b) Fichtelberg, 1,214 m asl, highest elevation of the German Erzgebirge. The Erzgebirge (Ore Mountains) was chosen because it was one of the most polluted forested mountain ranges in Central Europe. The most important source of pollution was the highly-industrialized Northern Bohemian Basin (200–300 m asl) with a major concentration of Czech Republic's lignite power plants, petrochemical and heavy industry.

Passive string collectors were used for fog water sampling, as described in Lange *et al.* (2003). Interstitial aerosol was collected using an aerosol sampler, based on impaction principles and operating with quartz fiber filters. We determined pH-values, electrical conductivity and the concentration of major ions, trace metals and carbonaceous material. TOC (OC-/EC), carboxylic acids, sugar and sugar derivatives and nitrophenols were in focus of the organic analysis.

First results showed nine different sugars and sugar derivatives in the fog water. While levoglucosan and arabitol were the most prominent compounds at both sites, Fichtelberg was dominated by mannosan and Zinnwald was dominated by mannitol (Figure 1). The observed concentrations at both sampling sites were relatively low: 0.02 to 0.2 mg L^{-1}. This is surprising, especially for levoglucosan. Twenty-two carboxylic acids were detected, belonging to six different groups (aliphatic functionalized, aromatic and nitric aromatic monocarboxylic acids and aliphatic non-functionalized, aliphatic functionalized and aromatic dicarboxylic acids). The chemical composition of fog water differs considerably between the two sites. Zinnwald, a "polluted" site with high concentrations of sulphate, nitrate and ammonium, was dominated by levulinic, benzoic, adipic and 7-oxoocatanoic acid (0.98 µmol L^{-1}, 0.25 µmol L^{-1}, 0.15 µmol L^{-1}, 0.09 µmol L^{-1}). Fichtelberg, much less influenced by air pollution and dominated by chloride and sodium, showed the highest concentrations for 2-isopropylmalic, azelaic and suberic acid (0.08 µmol L^{-1}, 0.06 µmol L^{-1}, 0.05 µmol L^{-1}). Photochemical processes are the most expected sources for these carboxylic acids. Other possible sources remain uncertain and need further investigation.

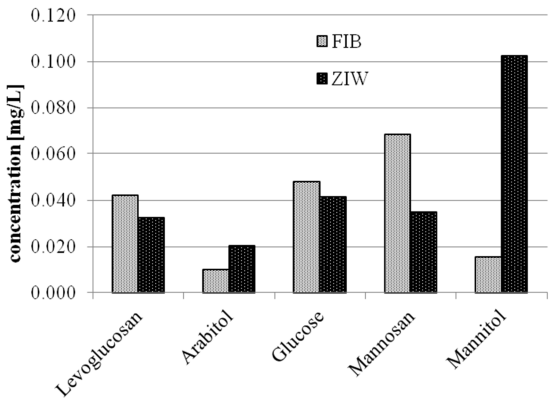

Figure 1. Sugar concentrations in Zinnwald (ZIW) and Fichtelberg (FIB)

In Milan, one of the largest cities in Italy, strong atmospheric stability conditions cause prolonged periods with high pollution levels exceeding the EU threshold limits. In many winter episodes secondary aerosol prevails on primary aerosol (Vecchi et al., 2004) but the mechanisms which cause secondary aerosol formation are not completely clear yet.

In this work, we present the results obtained in two different winter campaigns (2006 – 2007). PM10 was sampled in parallel on quartz fibre and PTFE filters with 4 hour and 8 hour time-resolution.. A detailed chemical characterisation (with quantification of elements, inorganic ions, OC/EC fractions, WSOC, and levoglucosan) was carried out on the samples.

The data analysis presented here is mainly focused on the secondary aerosol formation occurring during foggy days.

In the first campaign (November/December 2006 – 4 hour resolution) we used the Hydroxymethanesulfonate (HMS) as a tracer for heterogeneous chemical reactions (Dall'Osto et al., 2009) as it is a product of the aqueous reaction between dissolved SO_2 and HCHO. HMS was detected in more than 90% of our samples. HMS concentration ranged between 12 ng m^{-3} and 3500 ng m^{-3} and increased during the fog events as shown in figure 1. HMS concentrations resulted well correlated with sulphate values. This shows that sulphate is probably formed in cloud droplets (Choularton and Bower, 2001).

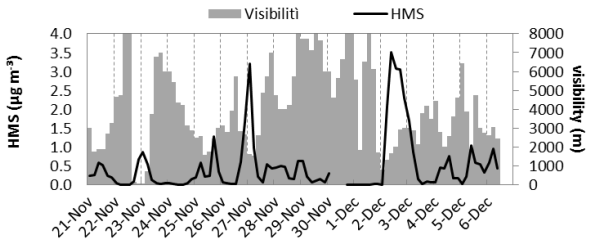

Figure 1. comparison between trend of HMS and visibility.

During the second field campaign (February 2007 – 4 and 8 hour resolution) we investigated the secondary nitrate formation. As shown in figure 2, the nitrate concentration increased from 20 to 110 µg m^{-3} in about 36 hours during the fog event. In the same period, an increase in WSOC (water soluble organic compounds), concentration and relative humidity levels was also detected. During the fog event, we also observed an increase of HMS concentration (concentration up to 700 ng m^{-3}), which was fostered by the low solar radiation. This day was also characterised by a high OC/EC ratio.

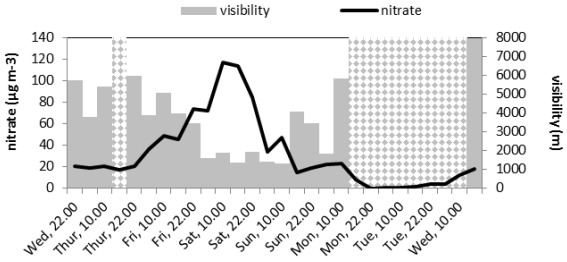

Figure 2. comparison between trend of nitrate and visibility.

In order to evaluate the acidity of the WSOC, we also quantified the organic carbon extracted at two different pH values (2.5 and 5.5). The concentration trend of the compounds extracted at lower pH is well correlated to the K^+ concentrations. K^+ is known to be related to wood burning. Therefore, this source is probably an important source of organic acid compounds too. On the other hand, the concentration of compounds extracted in less acidic solution increased during the night. The insoluble organic compounds are well correlated to the primary components of particulate matter.

The Barcelona metropolitan area has a serious environmental problem concerning air quality. In the last years, new Directives on Air Quality are becoming more restrictive, requesting for a lowering in atmospheric pollutants. In the case of Barcelona, a serious problem is observed for NO_2 and particulate matter, with a high number of exceedences of the Air Quality standards across most of the metropolitan area. Estimations of contributions from different sources show that road transport in the main pollution source increasing the loads of atmospheric pollutants (NO_x and particles) in this region, but also an important contribution is coming from the harbour area (8-9%). The APICE (Common Mediterranean strategy and local practical Actions for the mitigation of Port, Industries and Cities Emissions) project pretends to reduce harbour emissions to the atmosphere by adopting mitigation strategies. In the harbour area, a number of emission sources are polluting the atmosphere, being ships one of them.

In this work we show the results from an intensive sampling campaign (7th November 2011 to 5th January 2012) carried out in the harbour area. During this campaign we deployed two low volume samplers for collecting PM_{10} every day (from 10 to 10), resulting in 59 consecutive days of successful campaign. The monitoring site was in the terrace of the 8th floor in the World Trade Center, a business building located in the northern border of the harbour area, just few meters from the cruise area. The aim of the study was to capture, as much as possible, fresh shipping emissions. This would happen when winds blow from the south (which is relatively usual) and there are cruises in the harbour. The fingerprint of these fresh shipping emissions may serve as inputs for subsequent receptor modelling that will be carried out in order to determine the contribution from ships to ambient PM_{10} levels in the Barcelona city.

Before and after sampling, quartz fibre filters were conditioned and weighted to determine PM_{10} concentrations. Thereafter, filters were treated in laboratory following procedures described in Pey *et al* (2010). Finally, concentrations of major and trace elements and compounds were determined (OC, EC, SO_4^{2-}, NO_3^-, NH_4^+, Cl^-, Al, Fe, Ca, Na, K, Mg, P, Ti, Mn, Sr, Rb, Zn, Cu, Sb, Sn, Pb, V, Ni, Co, among others, including typical tracers of shipping emissions.

Mean PM_{10} concentration was 33 $\mu g/m^3$: carbonaceous particles (33%), unaccounted material (30%, mostly water), mineral matter (15%), sea spray (10%), sulphate (6%), nitrate (4%) and ammonium (2%). At the beginning of the campaign, extremely high levels of PM_{10} were recorded owing to typical winter pollution episodes. PM_{10} composition during these events was dominated by secondary aerosols, both organic and inorganic. After these few polluted days, Mediterranean cyclones provoked heavy rains and strong winds over Barcelona area, which diminished secondary pollutants in the atmosphere in opposition to sea spray, which increased drastically. Sporadic and low-intense African dust episodes were also registered before and after autumn storms. Finally, from end November to the end of the campaign, sunny and warm days prevailed, which favoured the development of weak sea breezes during the day. Thus, Southern winds blown over the monitoring site bringing, a number of days, fresh emissions from ships. As seen in Figure 1a, V and Ni (typical tracers of shipping emissions) levels increased a number of days. Because shipping plumes are usually mixed with urban and industrial emissions, the identification of these fresh plumes is not direct. We have used the ratio V/Cu (Cu is a typical urban tracer – traffic- coming from tires and breaks abrasion) to distinguish which shipping emissions are fresh (with low Cu levels) and which are mixed with urban pollution (Figure 1b). As seen in Figure 1, the highest record of V, on 4th December 2011, was coincident with very low Cu levels, which is assumed to be of a dominant ship origin. Thus, the chemical profile of PM_{10} for that day may be deduced as a typical ship-signature.

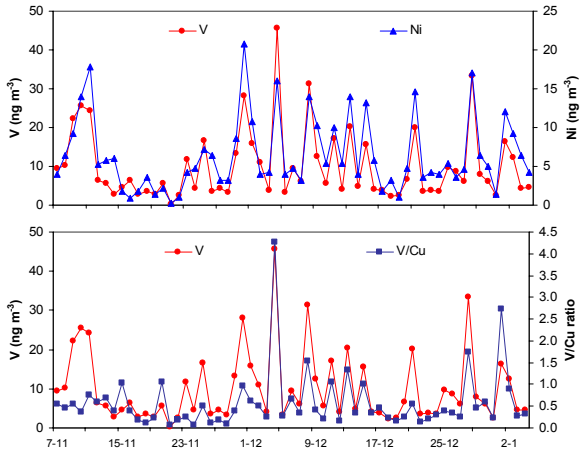

Figure 1. Daily variation of: a) V and Ni (ng m^{-3}); b) V and V/Cu, in PM_{10} during the campaign

Characteristics of surface ozone over Qinghai Lake area in Northeast Tibetan Plateau, China

Zhenxing Shen[1], Xin Wang[1], Junji Cao[2], Zhuzi Zhao[2]

[1]Department of Environmental Sciences and Engineering, Xi'an Jiaotong University, Xi'an, China
[2]SKLLQG, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China
Key words: Ozone formation, meteorological factor, NO_x, back trajectory
Presenting author E-mail: zxshen@mail.xjtu.edu.cn

One year continuous measurements of surface ozone over Qinghai lake area (36°58′37″N, 99°53′56″E) in Northeast Tibetan Plateau, China was presented in this study. Daily average O_3 ranged from 11.1 ppbv to 33.3 ppbv with an annual average of 20.9 ppbv. Seasonal average of O_3 followed a decreasing order of summer > autumn > spring > winter. The diurnal variation in O_3 shows low concentrations during daytime and high concentrations during late night and early morning.

Table 1 O_3 level in Qinghai Lake area

	O_3 level (ppbv)	
	Average	Range
Spring	19.8	12.7-28.9
Summer	24.9	3.1-33.3
Autumn	22.2	14.2-30.8
Winter	17.7	11.1-25.6

An intensive campaign on Aug 13 to 31, 2010 was conducted to investigate the correlation among meteorological factors and chemical condition with surface ozone. It was noted that solar radiation had a poor relationship with ozone level. Moreover, high wind speed was always coincided with the high ozone level. In addition, insufficient NO_x in atmosphere was observed in Qinghai Lake area. Such results revealed that local photochemical reaction process contributed limitedly to surface ozone, while intrusion of stratospheric O_3 and distance transport should be the main sources of surface ozone in this rural area. Back-trajectory analysis further indicated the contribution of long distance transport of air mass from northwest to the surface ozone in Qinghai Lake area. Moreover, transport of ozone-rich air masses from the stratosphere to the troposphere is also important.

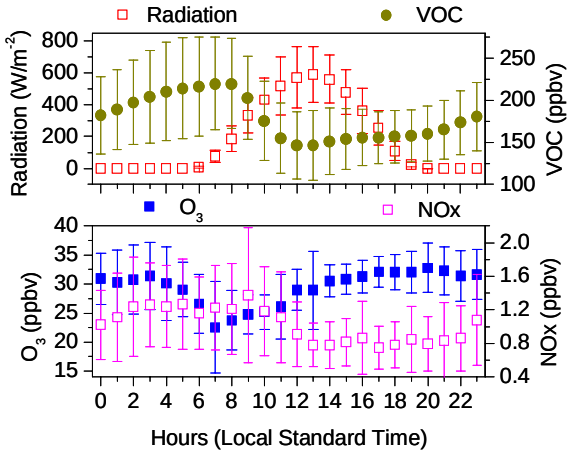

Figure 1 Diurnal cycle of solar radiation, NO_x, VOC, and O_3 levels in Qinghai Lake area during the strengthen campaign period

Seventeen carbonyls in urban ambient air were quantified in summer (June 2009) and winter (January 2010) in an urban site located in Xi'an, China. Formaldehyde, acetaldehyde and acetone were the three most abundant carbonyls in the atmosphere with the concentration 6.54±2.38 ppbv, 2.08±1.07 ppbv and 2.74±1.14 ppbv in summer (from 14th to 24th June, 2009), respectively. In winter, the concentrations were 4.46±1.74 ppbv, 6.52±3.88 ppbv and 3.87±2.33 ppbv respectively from 4th January, 2010 to 10th January, 2010. Most carbonyls had higher concentrations in winter than in summer. And majority of the species had higher concentrations in daytime than in nighttime, indicating photochemical oxidation/human activities played an important role in diurnal variation. Formaldehyde/acetaldehyde ratios (F/A) in summer of 2.14 was much higher than 0.47 in winter, showing significant effect of photochemical oxidation in the urban air during summer. Acetaldehyde/propionaldehyde (A/P) average ratio was 12.2 in wintertime, implying anthropogenic emission was the major source of carbonyls in Xi'an. In addition, the ratio of acetone to methylglyoxal (A/M) is used to determine the impact of photochemistry in the atmosphere. The average acetone/methylglyoxal ratio (10.3±2.3) in summer was lower than that in winter (21.3±5.1) in Xi'an. Strong correlations among some carbonyls imply that they came from the same pollution sources. Formaldehyde and acetaldehyde play a very important role in photochemical smog formation. Methylglyoxal and glyoxal also have significant contribution to ozone formation potential.

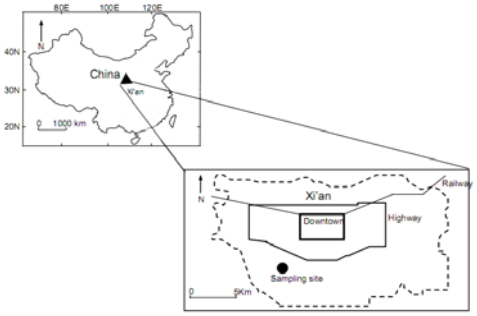

Fig. 1. A geographical map showing the location of Xi'an in China (upper plot) and sampling site IEECAS (black spot in bottom plot).

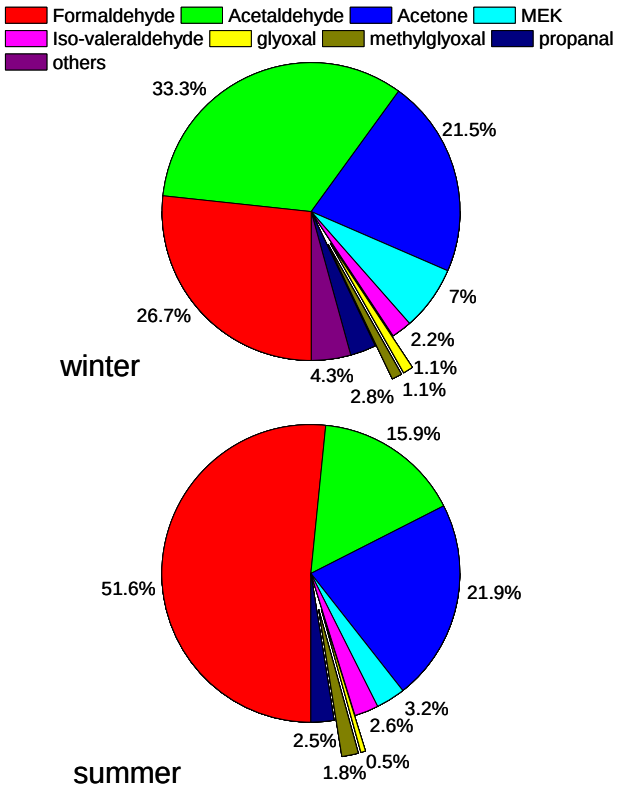

Fig. 2. Molar compositions for carbonyls in summer and winter in Xi'an.

Keywords: MOUDI, conversion ratios, episode day, non-episode day.
Presenting author email: jhtsai@mail.ncku.edu.tw

Ions species in airborne fine particulate matter was investigated in southern Taiwan during episode event and non-episode periods. A Micro Orifice Uniform Deposit Impactor (MOUDI) and a nano-MOUDI were employed to take PM samples. Ambient concentrations of HNO_3 and SO_2, and particulate NO_3^- and SO_4^{2-} were determined in daytime and nighttime. Conversion of these inorganic species into airborne particulate matter, especial in the accumulation mode, was discussed in this study. High humidity atmosphere was observed in this study area.

NO_3^- partition between gas and particulate phases strongly depends on temperature, relative humidity, and ammonia concentration. The conversion ratios of Fn and Fs for NO_2 to nitrate and SO_2 to sulfate in particulate matter, respectively, are defined as follows (Kadowaki, 1986; Khoder, 2002; Lin et al., 2006):

$$F_n = \frac{[PNO_3^-]+[GNO_3^-]}{[NO_2]+[PNO_3^-]+[GNO_3^-]}$$

where $[PNO_3^-]$ is the particulate-nitrate concentration in the accumulation mode ($\mu g/m^3$ NO_2), $[GNO_3^-]$ is the gaseous-nitric acid concentration ($\mu g/m^3$ NO_2), and $[NO_2]$ represents the ambient NO_2 concentration ($\mu g/m^3$).

$$F_s = \frac{[PSO_4^{2-}]}{[PSO_4^{2-}]+[GSO_2]}$$

where $[SO_4^{2-}]$ is the particulate-sulfate concentration in the accumulation mode ($\mu g/m^3$ SO_2), and $[SO_2]$ is the ambient SO_2 concentration ($\mu g/m^3$). Atmospheric H_2SO_4 is neglected in this work.

Table 1 shows the information of NO_2, SO_2, PNO_3^-, GNO_3^- PSO_4^{2-}, Fn and Fs during the sampling periods. The NO_2 conversion factor at daytime and nighttime during the episode days was about 1.4 and 4 times higher than that during the non-episode days, respectively. The daytime data are higher than that reported in winter in Japan and Egypt, and are similar to those observed in autumn and winter in central Taiwan. Results of the non-episode nighttime were consistent with what were observed in the other studies in winter (Kadowaki, 1986; Khoder, 2002; Lin et al., 2006). On the other hand, the highest value of Fn during the episode nighttime was higher than that found by previous studies, and the Fn values during episode days were higher than those during non-episode days. In addition Fs of both daytime and nighttime during episode periods were about 1.5 times higher than that of non-episode periods.

High Fn and Fs in episode days indicated that ratio of SO_2 oxidation to sulfate and ratio of NO_2 oxidation to nitrate were relative high. Mass of sulfate and nitrate in accumulation mode particle during episode days were higher than those in non-episode days. This result suggests that the effect of gas-to-particle conversion plays an important role in the increment of airborne fine particulate matter concentration in southern Taiwan during air pollution episode days.

Table 1 Conversion of NO_2 to NO_3^- and SO_2 to SO_4^{2-} in Southern Taiwan

Compounds	Episode day		Non-episode day	
	Daytime (n=7)	Nighttime (n=8)	Daytime (n=12)	Nighttime (n=11)
NO_2 ($\mu g/m^3$)	49.35±4.90* (43.86-55.16)	61.04±9.64 (45.48-77.03)	15.73±14.33 (3.39-44.96)	20.38±14.80 (7.40-60.38)
SO_2 ($\mu g/m^3$)	34.09±8.02 (23.02-43.07)	21.54±8.09 (8.95-33.11)	10.98±9.83 (1.79-30.69)	6.49±5.56 (1.60-20.29)
PSO_4^{2-} ($\mu g/m^3$)	17.61±5.57 (12.78-28.91)	16.93±5.29 (7.23-22.87)	2.93±2.30 (0.32-6.76)	3.94±3.14 (0.86-9.82)

Regional contributions of arsenic species in Southwestern Spain

González-Castanedo Y[1], Sánchez-Rodas D.[2], Sánchez de la Campa A.M.[1], Fernández-Camacho R. [1] de la Rosa J. D[1]

[1]Associate Unit CSIC-UHU "Atmospheric Pollution", CIQSO, Campus El Carmen, 21071 Huelva, Spain
[2] Department of Chemistry and Materials Science, Campus El Carmen, Univ. of Huelva, 21071 Huelva, Spain
Keywords: regional background, heavy metals, arsenic speciation
Presenting author email: yolanda.gonzalez@dgeo.uhu.es

In the last decade, aerosols have been intensively studied in Southwestern Spain (SWS) for the purpose of assesing the air quality in Huelva. These studies indicate that the local population of the city is exposed to high concentration of a trace metal cocktail (As, Cu, Zn, Ti, Bi and Pb) related to the impact of several industrial emissions situated in the surroundings (Sánchez de la Campa, 2011). The presence of the arsenic in the samples is related to the influence of the near-by copper smelter considered the largest one in Spain (Fernández-Camacho, 2010). Arsenic is recognised to be a carcinogenic element which toxicity depends on the oxidation state and molecular form in which this element is included.

The present work is the first one reporting total mass and chemical composition PM2.5, arsenic speciation included, from a regional background site in SWS. For achieve this aim, simultaneous sampling of PM10 and PM2.5 were carried out at two stations (an urban background station (UB, Campus) situated in Huelva city and in a regional background station (RB, El Arenosillo) placed about 30 Km to the NW) in order to compare results of the same days and evaluate the influence of local and regional sources in the background PM composition.

Trace metal content of 71 and 54 synchronic samples, of PM10 and PM2.5 respectively, taken during 2006-2007 was determined by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Moreover, speciation analysis was performed using High Performance Liquid Chromatography coupled to Hydride Generation and Atomic Fluorescence Spectrometry (HPLC-HG-AFS) with those samples (34 filters) with total arsenic content higher than 2 $\mu g/m^3$ so as to characterize the distribution of arsenic species in this area. This methodology has previously employed for determination of inorganic As (III) and As (V) species in airborne particles (Sánchez-Rodas, 2007).

According to the chemical composition of PM (Table 1), high levels of metals (e.g. As, Se, Bi, Cu, Zn, Pb) were found in PM10 and especially in PM2.5 at RB and UB. This fact indicates that there is an industrial contribution in both stations which will depend on the meteorological sceneries. The impact of the industrial sources emissions plumes on the city of Huelva occurs with wind directions from the third quadrant (34% during whole sampling period) while fourth quadrant winds (30% during whole sampling period) will bring metal-rich plumes at RB station.

Table1.Trace metal and arsenic species concentration in PM_{10} and $PM_{2.5}$ at regional (RB) and urban background (UB) station during 2006-2007.

	PM_{10}		**$PM_{2.5}$**		**$PM_{2.5}$ /PM_{10}**	
	UB	**RB**	**UB**	**RB**	**UB**	**RB**
$\mu g/m^3$	40	31	20	17		
ng/m^3						
Cu	49.0	15.0	37.5	8.42	0.8	0.6
Zn	39.0	37.6	28.5	33.6	0.7	0.9
As	7.03	4.89	5.38	4.45	0.8	0.9
Se	1.76	1.29	1.10	0.87	0.6	0.7
Pb	13.9	11.9	14.0	11.4	1.0	1.0
Bi	0.86	0.53	0.63	0.49	0.7	0.9
As	11.4	6.64	9.79	6.04	0.9	0.9
AsIII	0.43	0.39	0.41	0.25	1.0	0.7
AsV	13.1	7.83	12.4	6.76	0.9	0.9

The behaviour of arsenic species is akin to that of total arsenic and the rest of the trace metals. The speciation analysis (Table 1) show that arsenate (As (V)) is the main arsenic species found in both stations, urban (13.1 $ngPM10/m^3$ y 12.4 $ngPM2.5/m^3$) and regional background (7.83 $ngPM10/m^3$ and 6,76 $ngPM2.5/m^3$). In spite of the low mean concentrations of arsenite (As (III)), the proportion of the most toxic specie, is similar at UB and RB ambient. As (III) varies between 3-5% in PM10 and 3-4% in PM2.5. In the same way, the mean As (V) contribution varies between 95-97 % in PM10 and 96-97% in PM2.5. The results indicate that arsenic species as well as trace elements (PM2.5/PM10=0.7-1) accumulate in the finer particles which may be transported long distance from the source emission.

A significant percentage of organic matter (between 40 and 60%) in atmospheric aerosols consists of a numerous but still poorly understood class of hydrosoluble compounds known as water soluble organic carbon (WSOC). WSOC can significantly decrease the surface tension of aqueous solutions, affect the hygroscopicity of aerosols, and may be important in determining the ability of particles to serve as cloud condensation nuclei (CCN), with consequences for climate, optical properties of the atmosphere and air quality. The scientific activity performed at Ny Alesund during the 2010 campaign had the aim of better understanding the formation, the chemical composition and the transport processes of aerosol towards the arctic zone.

Eighteen samples were collected from March to September 2010, sampling was performed using an high volume cascade impactor (TE 6000 series, Tisch Environmental Inc.) at the Gruvebadet supersite (78 55 07 N, 11 53 30E) (stage parameters: 10.0 – 7.2 µm (Stage 1), 7.2 – 3.0 µm (Stage 2), 3.0 – 1.5 µm (Stage 3), 1.5- 0.95 µm (Stage 4), 0.95 – 0.49 µm (Stage 5), < 0.49 µm (back up)).

The following analytes were determined: levoglucosan (Bourcier et al 2010) and methoxy phenols (vanillic acid VA, isovanillic acid IVA, homovanillic acid HA, syringic acid SyA, conyferil aldehyde CAH, ferulic acid FA, syringaldehyde SyAH, p-coumaric acid PA) (paper in preparation) as biomass burning tracers, acrylamide (antropogenic) (Zangrando et al 2011) and trace elements (TE) were analysed to better understand transport processes. Seasonal trends were obtained.

Instrumental analysis in WSOC employed an Agilent 1100 series HPLC system (Agilent, Waldbronn, Germany) coupled to an API 4000 triple quadrupole mass spectrometer (Applied Biosystems/MDS SCIEX, Toronto, Ontario, Canada).

For levoglucosan the highest levels were observed in back up filters in a range of concentration between 4 pg/m^{-3} and 682 pg m^{-3} (average 71± 166 pg m^{-3}). The analysis of slotted filters revealed in stage 4 the highest levels at 5.8 pg m^{-3}.

The presence of acrylamide in arctic aerosols was episodic. Significant concentrations were determined in ultrafine aerosols (< 0.49 µm) in some samples that range from 32 fg m-^{3} to 127 32 fg m^{-3}, average concentration was 37 ± 50g fg m^{-3}. In fine and coarse aerosols (stage 1 to 5) in general acrylamide was not detected, except in some samples, but with a very low concentration. Moreover we noticed that the atmospheric concentrations were highest in ultrafine particles, so we can attribute the presence of acrylamide mainly to long range transport although for some samples we can hypothesized a local source.

The determination of methoxyphenols in fine and ultrafine aerosols (< 0.49 µm) was performed on back up filters. In Arctic particulate matter total concentration of methoxyphenols determined range between 16554 and 1998 fg m^{-3}, average 5469 ± 3376 fg m^{-3}. The compounds mainly present are VA, HA and PA, average percentage 28.4%, 27.0% and 38.6% respectively. While SyA (3.5%), SyAH, IVA, CAH and FA are presents only in minor concentration, globally at average percentage of 6%. The analysis of slotted filters showed that in stages 3 and 4 are present the highest levels of methoxyphenols similar to that observed in the back up filter.

TE analyses were carried out using a Sector Field Inductively Coupled Plasma-Mass Spectrometer (SF-ICP-MS, Element2 Finnigan-MAT, Bremen, Germany), coupled with a cooled cyclonic spray chamber (ESI-PC3). Samples were acidified with 2% ultrapure nitric acid and directly analysed. The quantification of TE was carried out by external calibration method. Preliminary results of TE analyses in two back up filters (GB9 and GB15) have highlight higher concentrations in GB9 sample for all the elements analysed probably due to a local burning event.

Aerosol-fog chemical interactions: a case study in the Po Valley (Northern Italy)

L.Giulianelli[1], S. Gilardoni[1], M. Rinaldi[1], S. Decesari[1], M. Paglione[1], C. Carbone[1], S. Fuzzi[1] and M.C. Facchini[1]

[1] Institute of Atmospheric Science and Climate (ISAC), CNR, Bologna, Italy
Keywords: aerosol chemistry, aerosol cloud interaction, chemical composition, droplets, multiphase processes.
Presenting author email: l.giulianelli@isac.cnr.it

Fog represents a multiphase system that play a significant role in the formation, distribution and removal of trace atmospheric components. Fog droplets form by condensation of water vapour onto condensation nuclei in supersaturation conditions, therefore the chemical composition of the aerosol particles acting as condensation nuclei influences the initial chemical composition of the fog droplets. Particles scavenging and the chemical reactions occurring in the aqueous phase determine changes in the composition of both fog droplets and residual aerosol particles resulting after fog dissipation. Since fog forms at the ground level, the interactions between fog droplets and particulate matter by the chemical and physical processes mentioned above can have a deep impact on the local air quality.

The frequency of the fog events and the high level of particulate matter in the air makes the Po Valley (Northern Italy) the perfect place to observe the relations between fog droplets and aerosol particles, Facchini *et al* (1999).

In order to investigate these processes fog samples were collected within the ARPA-Supersito Project field campaign (15^{th} - 30^{th} November 2011). The measurements took place in the field station of San Pietro Capofiume, a rural place in the Eastern Po Valley. Aerosol samples were collected before, during and after fog events that frequently occurred during the campaign, as well as fog droplets. Samples were collected with a day/night frequency for aerosol and bulk samples for each fog event. During two very dense fog events (15^{th} and 17^{th} of November) the sampling strategy changed in order to have higher time resolution samples: one fog sample every hour and one aerosol sample every 4 hours. The purpose is to investigate the evolution in the chemical composition of both fog droplets and size segregated aerosol particles during the whole fog event.

The campaign provided both online measurements by Aerosol Mass Spectrometer (AMS) and aerosol size segregated samples on tedlar and quartz substrates for offline analysis. An automated string collector was used to collect fog droplets, Fuzzi *et al* (1997). Ionic composition of the samples was determined by Ion Chromatography. Carbon and nitrogen analysis were performed to determine the amount of organic compounds (soluble and insoluble) and soluble organic nitrogen content. The distribution of the main species (NH_4^+, $SO_4^=$, NO_3^-, soluble organic compounds, etc.) between fog and aerosol particles and the variation in the chemical composition of aerosol samples allow us to investigate the partitioning process occurring into this multiphase system.

Scavenging of PM1 particles during fog formation is well illustrated in Fig.1, where the different trends of liquid water content (LWC) and particle mass concentration are reported. Detailed results of the chemical characterization of the multiphase system and the study of interactions occurring between particulate matter and fog droplets will be presented.

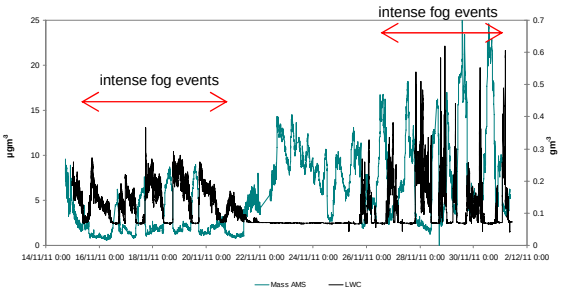

Fig. 1. Submicron particle mass concentration (μgm^{-3}, green line) measured by AMS and LWC (gm^{-3}, black line) trend during the field campaign.

This research was conducted as part of the Supersito Project, which was supported and financed by Emilia-Romagna Region and Regional Agency for Prevention and Environment under Deliberation of Regional Government n. 428/10.

For several decades, control of air quality is a main concern of public health. Further, the determination of chemical composition of Particulate atmospheric Matter (PM) is increasingly important in order to understand their atmospheric behavior and their impact on climate change. With this respect, the interest in the individual organic constituents of PM has grown, all the more since most of them can also be used as tracers in source apportionment models.

Particularly, the Sulfur containing Polycyclic Aromatic Hydrocarbons (PASHs) are considered as both pollutants and as markers of many sources emissions. Indeed these compounds are emitted in the atmosphere by combustion processes and they have already been identified on particulate organic matter. Due to their chemical stability, they are also distributed to other environmental compartments. In recent years, several studies have identified thiaarene in exhausts from combustion processes (Lemieux et al., 2004), in aquatic environments (Ni et al., 2008), and in ambient air (Becker et al., 1999).

Usually, PASHs have been used to distinguish emissions from exhaust diesel and coal tar. In fact thiophenes and benzothiazoles derivatives are mainly used respectively as molecular markers of diesel emissions and tire wear.

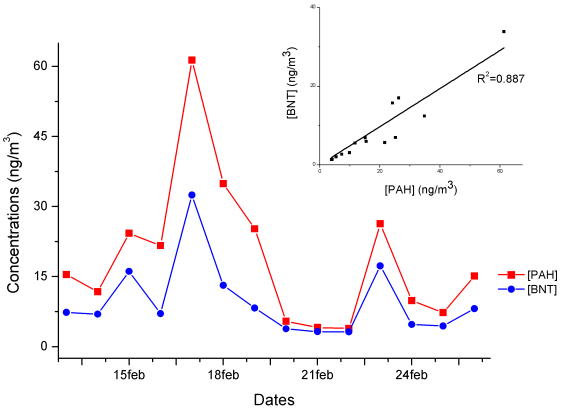

Figure 1: Temporal evolution and correlation between concentrations of PAHs and BNT in the particulate phase of aerosols in winter 2010 in Passy.

In this study, the identification of thiophenes and benzothiazoles has been achieved on aerosol samples from several experimental sites. The first sampling site is largely influenced by traffic, due to its localization near a highway around Grenoble; (Echirolles-Grenoble, France). A second sampling site was located in an Alpine valley with a strong industrial activity and crossed by an important main highway (Passy, France). At both sites, PM10 were collected on quartz filters and the gas phase was trapped on PUF with a high-vol sampler ($30.m^3.h^{-1}$). Each daily sample was analysed for EC-OC and organic speciation. Thiophenes and benzothiazoles were quantified by GC-MS analysis, together with several other source tracers (levoglucosan, hopanes, PAHs...).

Benzothiazole, as a tire wear tracers, has been detected next to the highway and mainly in the gas phase but not at the Alpine industrial valley site. Thiophenes were not identified on the kerbside site despite the proximity of vehicular emissions. The highest concentrations of thiophenes in particulate phase of aerosols were found in the Alpine industrial valley site. Benzo[b]naphtha(2,1-d)thiophene (BNT(2,1)) concentrations ranged from 1.32 to 33.84 ng/m^3 in winter 2010 and 1.30 to 16.40 ng/m^3 in spring 2011. Figure 1 shows that thiophenes and PAH's concentrations are rather well correlated with in the particulate phase at this site.

These results show that BNT(2,1) cannot be considered as marker of vehicular emissions. This result can be related to the decrease of sulfur concentrations in fuel. Measurements on bench test of vehicular emissions will allow to confirm it (test forseen within the PM Drive program funded by ADEME in France). Moreover, their presence on the Alpine industrial valley site indicates their potential as markers of industrial activity.

The new interest of these compounds as tracers will be discussed, focusing on their application in several receptor models such as Chemical Mass Balance (CMB) for aerosol source apportionment and multivariate regression model for HAP source apportionment.

The city of Cordoba is one of the most populated cities of the Guadalquivir Valley (Andalusia, South of Spain), exhibiting an admissible air quality as stated by the Regional Environmental Agency of Junta de Andalusia. In this work, we focuses on the Geochemistry and source contribution on PM10, in the Lepanto monitoring station (urban background) of the Air Quality Network of Andalusia.

Tourism is considered one of the most important economical activities in Córdoba. Moreover, Zn-Cu smelter and jewellery industry is localized in the western part of the city. Also, domestic furnaces of jewellery are placed in downtown of Córdoba.

Mean total mass and chemical composition of PM10 were obtained by sampling on filter using EU reference methods between 2007 and 2010. Sixty-five inorganic chemical compounds and elements were analyzed by ICP-MS (trace elements), ICP-OES (major elements), Ion Chromatography (ions) and Elemental Analysis (Ctotal) techniques. Geochemical results of PM10 in Lepanto were compared with others monitoring stations of Spain and Andalusia referenced by Querol et al (2007) and de la Rosa et al (2010). Chemical analysis of Ag were performed in PM10 at Córdoba, and compared with another urban background monitoring station (Principes) of the city of Seville. Ag can be used as a tracer of jewellery industry emissions.

The highest annual average PM10 was obtained in 2007 (44 µg/m³). This value is higher than the average value limit proposed by 2008/50/CE Directive. In the same way, the daily limit value (VLD) for this year was exceeded 26 days. During the rest of the study period, the levels decreased to meet the Directive acceptability criteria (40 µgPM10/m³ and 35 VLD, respectively).

Since annual PM10 levels and chemical composition point of view, Lepanto can be considerer as a urban background monitoring station, compared with other monitoring station of Spain (Querol et al 2007) and Andalusia (de la Rosa et al 2010). However, high geochemical anomalies of Zn (206 ng/m³), Cu (83.3 ng/m³) and Cd (0.81 ng/m³) suggest as the Córdoba is influenced by the impact of Zn-Cu smelters emissions.

Also, Ag high concentrations of Ag have been analyzed in the city of Córdoba compared with the city of Seville (urban monitoring station of Príncipes). SEM-EDS images show the presence of irregular particles of 1.5 µm size.

The contribution of the main sources to PM10 in the monitoring station was quantified by receptor modelling techniques (Thurston & Spengler, 1985) (Fig. 1). The major contributor to the total mass for PM10 (54%, 20.3 µg/m³) is the crustal source (mainly Rb, La, Li, Ca, Al_2O_3, Mg, K, Mn, C total and V), which are considered a mixture of natural and anthropogenic mineral material that is deposited in urban areas and continuously suspended by the traffic and the wind. The traffic (NH_4^+, NO_3^-, Ti, Ni and Sb) and the industrial source contribute the same mass proportion (6%, 2.2 µg/m³). The composition of the industrial source is Cu, Zn, Cd, Bi, which is coincident with the composition of Zn-Cu smelter emissions. The fourth factor that defines the PCA is the Regional, mainly composed by sulphate and V (4%, 1.4 ng/m³). And last, there is a fifth source characteristic of this zone that accounts for a 3% (1.3 µg/m³) of PM10 total mass, composed mainly of Ag and Cd. This source presents a chemical profile related with emissions from silver smelting of the jewellery industry.

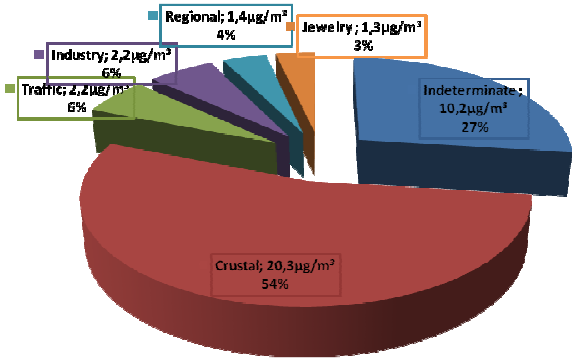

Figure 1. Source contribution to PM10 in Lepanto (city of Cordoba) during 2007-2008.

Fog is a multiphase system in which water droplets, aerosol particles and atmospheric gaseous species interact. This phenomenon occurs at the ground level, close to all the anthropogenic emissions which are involved in the chemical and physical transformations within the system.

The study of the fog multiphase system is an interesting topic in the area of the Po Valley (Northern Italy) due to several factors, first of all the frequency of this phenomenon during the fall-winter season. Furthermore the Po Valley is a densely inhabited region characterized by high level of pollution due to industrial and agricultural activities and intense vehicular traffic. High aerosol loading is often registered in this area. The field station of San Pietro Capofiume in the Eastern Po Valley thus represents a perfect point for the fog droplets sampling and characterization and possibly for the observation of particulate matter - fog droplets interactions.

The collection and study of fog samples began in the early 80s, Fuzzi *et al*. (1983). Initially fog droplets were sampled occasionally, then, at the beginning of the 90s field campaigns through all the fog season were carried out, Fuzzi *et al* (1992, 1996). During these field campaigns an automated sampling procedure was set up, Fuzzi *et al* (1997), and from 1997/98 the same sampling procedure has been carried out each fall-winter season until today. All these measurements allowed the collection of a nearly 30 years long database which is now available to investigate possible time trends of physical and chemical parameters, as frequency of fog events, liquid water content (LWC), acidity, chemical composition (NH_4^+, $SO_4^=$, NO_3^-, soluble organic compounds, etc.). Concentration ranges found in the Po Valley fog samples are 0.03-27.87, 0.02-16.90, 0.04-25.04 µeq/l and 2.70-163.00 mgC/l for NO_3^-, $SO_4^=$, NH_4^+ and water soluble organic Carbon (WSOC) respectively. pH values are very variable, ranging from 2.44 to 8.83.

Preliminary results of the database elaboration suggest a decreasing trend of the $SO_4^=$ concentration in the fog samples from the 80s up to now. This is consistent with the policy of reducing SO_2 emissions. Another trend regards the acidity of the samples: mean pH values are higher now than twenty years ago. During the 90s mean pH values ranged from 4.7 to 6.2, while values ranged from 5.7 to 7.1 from 2000 to 2011. Connections between these two trends will be investigated. No evident trends have been pointed out for NO_3^- and NH_4^+. Fig.1 shows the increasing trend of $NO_3^-/SO_4^=$ ratio due to the decreasing amount of $SO_4^=$ in the fog samples. WSOC and WSON (Water Soluble Organic Nitrogen) data are available since season 1997/98 and 2004/2005 respectively. The results of the elaboration of these data will be presented.

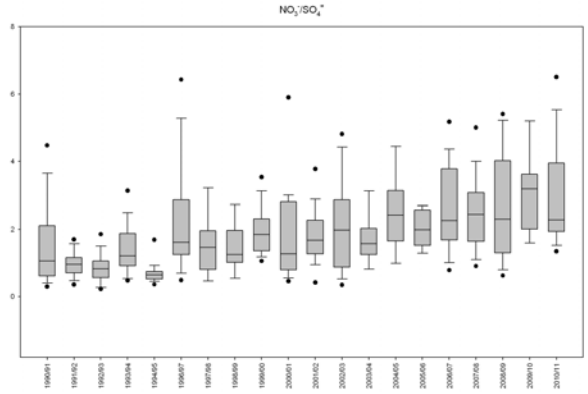

Figure 1. Increasing trend in the $NO_3^-/SO_4^=$ ratio from 1990/91 to 2010/11, due to the decreasing concentration of sulphate in fog samples.

Presenting author email: ink22@cam.ac.uk

Biogenic volatile organic compounds (BVOCs) play an important role in atmospheric chemistry and give rise to secondary organic aerosols (SOA), which have effects on climate and human health. On a global scale, BVOCs account for about 90% of VOC emissions (Guenther *et al.*, 1995). A substantial fraction (20-90%) of atmospheric fine particulate matter is comprised of organic compounds (Kanakidou *et al.*, 2005), which cover a wide range of polarities, volatilities and masses. Our knowledge on the organic chemical composition of atmospheric aerosols is rather limited; only about 20-30% of the organic matter has been characterised at the molecular level. Because of this limitation, recent efforts have focused on methods that classify bulk organic aerosols. For instance, ultra high resolution mass spectrometry (UHR-MS) allows determination of thousands of individual organic aerosol constituents at once, providing their elemental formulae from accurate mass measurements (Nizkorodov *et al.*, 2011).

In this study, we applied UHR-MS for the analysis of the separate day and night PM_1 aerosol samples that were collected during a two week summer period (August, 2011) at a boreal forest site, SMEAR II station in Hyytiälä, southern Finland. Prior to mass spectral analysis, all aerosol samples were analysed for organic carbon (OC) and elemental carbon (EC) using a thermal optical transmittance (TOT) technique. Depending on the OC load of the aerosol sample, a portion of the filter was extracted in methanol, filtered, evaporated to dryness and resuspended in methanol – water (20:80 v/v) or acetonitrile – water (20:80 v/v) mixtures. The extracts were analysed using an LTQ Orbitrap Velos fitted with a chip-based electrospray ion source, TriVersa NanoMate®. In addition, pooled day and night samples were analysed using liquid chromatography/mass spectrometry (LC/MS). The mass spectra were recorded in positive and negative modes over the mass range *m/z* 50-1200 with a mass resolving power of 100,000 (m/Δm). Background peaks were subsequently eliminated by subtraction of peaks present in blank samples. The remaining peaks were assigned probable empirical formulae assuming that ions contain only ^{12}C, ^{1}H, ^{16}O, ^{14}N, ^{32}S and ^{23}Na (only in the positive mode).

Almost for all samples negative ionisation spectra contained significantly more ions than those of positive, and the majority of these ions were found below 350 Da. More than 1000 elemental formulae were assigned in both modes, and no apparent diel variations in the elemental compositions were observed. The majority of the peaks were attributed to oxygenated or nitrogen containing compounds. The peak assignments were examined using van Krevelen approach, which allows describing the evolution of functional groups in organic aerosol (OA). Figure 1 shows a van Krevelen diagram for a typical daytime sample from Hyytiälä, Finland.

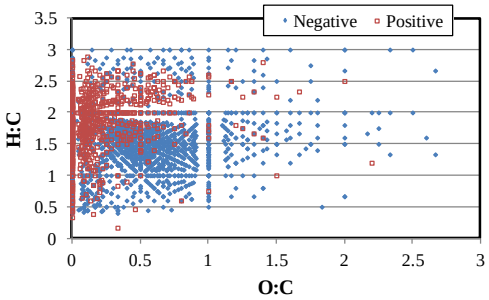

Fig. 1. Van Krevlen diagram for a typical sample collected at Hyytiälä, on 24 August, 2011. Blue and red markers corespond to data from negative and positive ion modes, respectively.

On average O:C ratio was found to be around 0.5 and 0.2 in the negative and positive modes, respectively and stayed constant throughout the sampling campaign. During two days an increased O:C ratio was observed, which could be explained by a change in the air mass back trajectories. In general, the O:C ratio was within the range obtained for SOA generated in laboratory experiments with a number of BVOCs, e.g., α-pinene (Shilling *et al.*, 2009) and isoprene (Nguyen *et al.*, 2011). The LC/MS analysis revealed more than 30 species mainly attributed to oxidation products of BVOCs (i.e., α-,β-pinene) supporting the results from the analysis of the bulk OA.

The work at the University of Cambridge was supported by a Marie Curie Intra-European fellowship (project # 254319).

Nucleation and Aitken mode atmospheric particles in relation to O_3 and NO_X at semirural background in Denmark

Q.T. Nguyen[1,2], J.K. Nøjgaard[1], M. Glasius[2] and L.L. Sørensen[1]

[1]Institute for Environmental Science, Aarhus University, Roskilde, DK-4000, Denmark
[2]Department of Chemistry, Aarhus University, Aarhus, DK-8000, Denmark
Keywords: atmospheric particles, oxidants, nucleation mode, Aitken mode, source apportionment
Presenting author email: quynh@chem.au.dk

In order to study the formation, transformation and loss of atmospheric particles, it is beneficial to examine particle size distributions in relation to atmospheric oxidizing species. Atmospheric oxidants (O_3, NO and NO_2) and particle size distributions (6-700 nm) were studied at Lille Valby, a semi-rural background location in Denmark during 2009 to evaluate the sources of particulate matter. Particles were grouped into different size bins, including lower Aitken mode (< 30 nm), upper Aitken mode (30-110 nm) and accumulation mode (110-700 nm). The lower Aitken mode also covered the nucleation mode (6-19 nm).

Both upper Aitken mode particles (30-110 nm) and accumulation mode particles (110-700 nm) either showed no correlation O_3 or anti-correlated with O_3. In contrast, the lower Aitken mode particles (<30 nm), which typically peaked around noon from April to September correlated positively with O_3. This indicated that photochemistry was likely to be responsible for most of the nucleation mode particles in this period of the year (Hamed *et al.*, 2007).

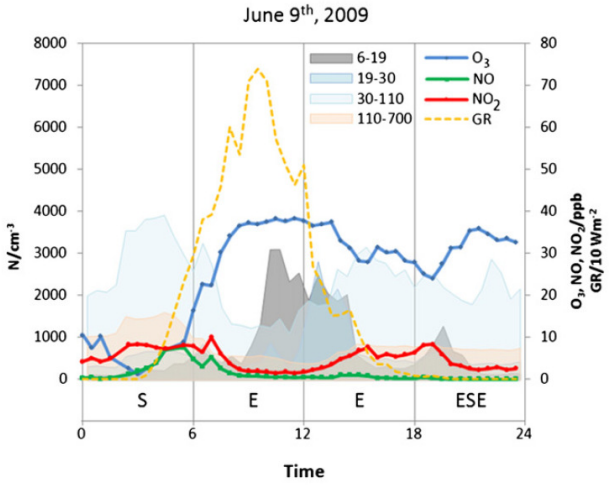

Figure 1. Diurnal plot example of atmospheric oxidants, particle number concentration according to particle mode, global radiation and wind direction.

In the months with lower global radiation (October-March), the lower Aitken mode correlated positively with NO_2, which typically showed peaks in the morning and afternoon on working days, indicating that traffic is the most important source of nucleation mode particles in that period of the year. A strong correlation was observed for Aitken mode particles and NO_2 throughout the year, which suggested a common traffic source (Hussein *et al.*, 2004; Ketzel *et al.*, 2007). Growth of Aitken mode particles was also observed during high NO_X episodes.

While photochemistry and traffic were major sources to Aitken mode particles, an additional source apportionment analysis using Constrained Physical Receptor Model (COPREM) (Wåhlin, 2003) identified Secondary Inorganic Aerosols (SIA) as the largest source to PM_{10} (36% including secondary marine aerosols) in the semi-rural background troposphere in Denmark. It was found that ammonium nitrate was a larger source than ammonium sulfate to the SIA mass fraction, where particulate nitrate exceeded that of sulfate by 2.6 times on a molar basis. Such results indicated that NO_2, as a precursor for e.g. ammonium nitrate is probably more important than SO_2, as a precursor for ammonium sulfate, in the formation of SIA. Subsequently, NO_2 from anthropogenic emissions and its following conversion to particulate nitrates thus appeared to influence semi-rural atmospheric particulate matter in both the Aitken mode and mass wise in PM_{10}.

This work is based on data from the Danish Air Quality Monitoring program and the Particle Project 2008-2010, which are financially supported by the Danish EPA.

Vehicle emissions have been linked to detrimental health effects with children thought to be more susceptible (See e.g., Ryan et al 2005). In an urban environment a major source of organic aerosols (OA) are vehicle emissions. The ambient concentration of OA is dynamic in nature and the use of an aerosol mass spectrometer can achieve the necessary temporal resolution to capture the daily variation of OA (Jimenez et al 2009). Currently there is a limited understanding of effects of long term exposure to traffic emissions on children's health. In the present study, we used an aerosol mass spectrometer to monitor OA and determine children's potential exposure at school to traffic emissions.In this paper, we present the preliminary results of this investigation. The study is a part of a larger project aimed at gaining a holistic picture of the exposure of children to traffic related pollutants, known as UPTECH (www.ilaqh.qut.edu.au/Misc/UPTECH%20Home.htm).

A compact time-of-flight aerosol mass spectrometer (AMS) was operated at four schools in different suburbs in Brisbane, Australia (S01, S04, S11 and S12). The AMS was housed within a classroom and the outdoor air was sampled using a minimum length of tubing. Sampling was carried out for 2 weeks at S01, S11 and S12 and for 3 weeks at S04. Sampling interval was 5 minutes alternating equally between PTOF and MS modes. The AMS was calibrated for ion efficiency (IE) and particle size at the beginning of the sampling and the IE calibrations also done in the middle and at the end of sampling. AMS data analysis was conducted using the standard software (Squirrel v1.51 in IGOR Pro v6.22).

The average diurnal variation of the total organic concentration for each school was determined. In general during school hours (9am – 3pm) the concentrations were lower compared to the rest of the day at all four schools. Peaks in the concentration of OA were observed in the morning around 6-8am and in the evening around 8pm at each school with varying intensities.

The diurnal variation observed at S04 (Figure 1) and S11 showed a large peak in morning and a smaller peak in the evening. The morning peak would suggest a traffic influence as it coincides with peak morning traffic. The average mass spectrum at this time for both schools more resembled the hydrocarbon-like organic aerosol (HOA) as described in Ng et al (2010). However, the m/z 44 was found to have a mass similar to that for m/z 41 and 43, which meant that the aerosols were partially oxidised and so were not fresh traffic emissions. Notably, there was no peak observed at around 5-6pm as would be expected due to peak evening traffic. Instead the evening peak was observed later and with different oxidation levels. At S04 it had a similar spectrum to the morning peak, which further suggests that this was due to slightly aged traffic emissions. At S11 the spectra was more like low-volatility oxygenated organic aerosols (LV-OOA) (Ng et al. 2010) meaning that this peak can be attributed to an increase in aged and highly oxidised OA concentration.

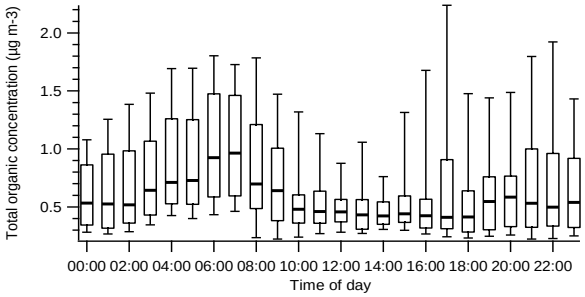

Figure 1: Average diurnal variation of total organic concentrations for S04.

In S12 the dominant peak was in the evening and these OA were LV-OOA in nature and so were highly aged and oxidised. The presence of m/z 60 and 73, which are attributed to levoglucosan, a marker for biomass burning (Ng et al 2011) means that the origin was biomass burning. At S01, there was little variation observed apart from a very large peak that was observed at 7am and we suspect that this was due to the use of fuel powered gardening equipment, possibly a leaf blower at the school.

At each school the lowest concentrations of OA were observed during school hours with peaks associated with traffic occurring outside school hours, which would indicate that, at these schools, children had limited direct exposure to traffic emissions during the sampling period.

Keywords: Pb isotope, PM10, Geochemistry, Iberian Pyrite Belt

Presenting author email: jesus@uhu.es

Pb isotopes have been using as an interesting tool in order to trace the sources and distribution of atmospheric aerosols and their impact in the environment (Chow and Johnstone 1965). Combustion of leaded gasoline, mining and smelting are the main sources of Pb in the air.

In this work, we present preliminary analyses of Pb isotopes ($^{206}Pb/^{207}Pb$ and $^{208}Pb/^{206}Pb$) of atmospheric aerosols (PM10) in the Iberian Pyrite Belt (IBP, SW Spain), in which isotope ratios can be used as a fingerprint of sources, and may discriminate the impact of the abandoned mining waste in the air.

IBP is considered as one of the most important mining district of the world, displaying geochemical anomalies of Cu, Zn, Pb and As among other toxic elements.

Since March 2009, a sampling of PM10 is performed using MCV high-volume captors (1-2 samples every week) in the town of Nerva (IBP) (3,000 inhabitants). Sampling and geochemical analysis of major and trace elements and compounds are described in Sánchez de la Campa et al. (2011).

Geochemical analyses of PM10 (op.cit.) have permitted the quantification of the contribution of resuspended particles from mining waste in the air, which can contribute toxic elements (e.g. Bi, As, Cu, pb, Cd, Zn and Sb). Town placed around the abandoned mining centres can receive the impact of those toxic elements.

The lead isotope analyses were done using ICP-MS (Agilent 7700) technique. Previously, filters were digested using a mixing of HF and HNO3 (see details Querol et al. 1999). Calibration of the ICP was done using a standard solution of NIST-981. During the calibration the masses 206, 207 and 208 were determined, with a R.S.D better than 1%. To monitor the drift of the ICP-MS, the standard solution (NIST-981) was analysed between batches of samples..

Marcoux (1998) has analyzed Pb isotope ratios from the main sulphide deposits in the Iberian Pyrite Belt. These analyses have been plotted in a $^{208}Pb/^{206}Pb$ vs $^{206}Pb/^{207}Pb$ diagram of PM10 with representative samples of atmospheric aerosols of Nerva, Iberian Peninsula aerosols (Bollhöfer and Rosman, 2001) and petrol aerosols (Erel et al., 1997). We have classified the aerosols from Nerva taking in account the air masses origin using backtrajectory analysis of HYSPLIT software (Draxler and Rolph, 2003). Under the influence of saharian air masses, the aerosols display an isotope signature similar to petrol aerosols. However, under scenarios of Atlantic air masses, the aerosols show similar isotope ratios than IPB rocks.

Atmospheric aerosols can be incorporated in the water by precipitation, modifying the isotope composition of water (Fernández et al. 2005). This conclusion is supported by the similar isotope composition of groundwater samples (op. cit.) and PM10 in the IPB.

Metals and trace element characterization of weather condition - air quality relationships due to event based measurements of particulate matter

Silvia Leise, Frank Zimmermann, Jörg Matschullat

Interdisciplinary Environmental Research Center, Technische Universität Bergakademie Freiberg, Brennhausgasse 14, D-09599 Freiberg, Germany
Keywords: Aerosol chemistry, air quality, weather conditions, trace elements
Presenting author email: silvia.leise@ioez.tu-freiberg.de

The chemical composition of the atmosphere and the involved processes depend partly on temperature and humidity besides other meteorological conditions like mixing layer height. Consequently, climate change will affect the future composition of the atmosphere (Hedegaard et al. 2008). Atmospheric circulation has a major effect on air quality by controlling local meteorological conditions (Flocas et al. 2009). One of the most relevant air pollutants is particulate matter (PM). The effect of changing meteorological parameters on aerosols furthermore depends on the PM component (Jacob et al. 2009). PM from natural sources such as secondary organic aerosol or crust material is believed to be influenced much more by changing weather conditions (Carslaw et al. 2010) than by anthropogenic aerosols. We already showed the relation of air quality in Eastern Germany to large scale weather patterns in a study of a ten year time series of PM data (EAC 2011),. The intensity of the relationship strongly seems to depend on the type of air pollutant.

The ongoing study aims to characterize the aerosol composition at three different sites (DD (112m asl.): urban background, M (87m asl.) and OBB (735m asl.): rural) in Eastern Germany. Three five-stage LPI cascade impactors are used to collect size segregated aerosol samples on an event basis. At all three sites 24 hour samples are taken concurrent depending on the large scale synoptic weather conditions. Samples are analyzed by ICP-MS on metals and trace elements. This study focuses on crust elements and trace metals.

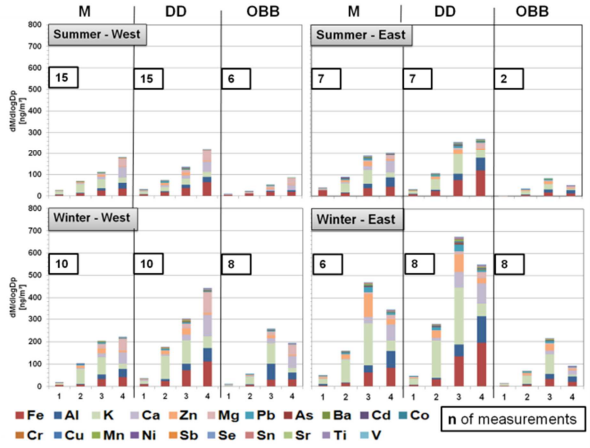

Fig. 1: Overview of element concentrations for the three sites M, DD and OBB. Four stages are taken into account (0.049 – 3.5 µm). Categories are based on the calculation of 96 hour backward trajectories

First results show that the magnitude of the correlation of PM compounds and weather patterns differs. Similar characteristics can be seen for all three sites (Fig. 1). In general, the summer categories are less polluted than the winter categories, due to more stable weather conditions (inversions) and due to additional sources in winter half year (heating period). Categories with air masses from eastern directions (continental air masses) are more polluted. The winter-east category shows higher concentrations for the third stage, which is likely due to a longer residence time of the aerosols in the atmosphere during this category.

Yet, particles in the accumulation mode show a stronger differentiation between the different weather patterns than fine or coarse particles. Large-scale synoptic weather patterns have a stronger influence on particles affected by long-range transport. The dependency of PM components to weather patterns is strongly related to sources and transport pathways of the components. Compounds that are dominated by local sources such as Ni or Cr, demonstrate almost no segregation between the weather patterns. Compounds like As, Zn or Pb demonstrate a stronger dependency. Crustal elements like Al, Fe or Ti are also influenced by air mass origin.

Author email: kissgy@almos.uni-pannon.hu

Humic-like substances (HULIS) constitute a considerable fraction (often the majority) of the water-soluble organic matter present in atmospheric aerosol. Consequently, this complex organic mixture significantly influences the physical and chemical properties of the aerosol particles as well as their biological effects. Several studies have dealt with the sources and characterisation of humic-like substances leading to considerable knowledge on their potential formation mechanism, elemental composition, molecular weight range, spectroscopic features, higroscopicity, CCN ability, etc. However, information on the size distribution of HULIS is very limited (Peng et al., 2010) although knowledge of this feature provides important information on possible sources and formation mechanisms in the atmosphere.

In this work humic-like substances isolated from aerosol particles of different size ranges were characterized. Aerosol samples were collected in the 0.0625-16 μm size range with an 8-stage Berner impactor at a rural site (K-puszta) in Hungary, an urban site (Zagreb) and a coastal site (Martinska) in Croatia. Humic-like substances were isolated from the aqueous extracts of each stage and their carbon content was determined by TOC analysis. The UV absorbance and fluorescence properties as well as the mass spectra of the constituents of the aqueous extracts and those of the isolated HULIS were studied. Approximately 90% of fluorescing compounds (EX=235nm/EM=410nm) were found in the 0.0625-1 μm size range which indicated that humic-like substances occurred in the fine fraction. This was confirmed by the results of carbon analysis and mass spectrometric investigations: the mass spectrum of the organic matter isolated from the particles in the 0.0625-1 μm size range resembled that of humic-like substances while the mass spectrum of the low amount of organic matter isolated from bigger particles differed significantly. Specific UV and fluorescent properties indicated that the chemical composition of particles within the 0.0625-1 μm size range is diverse. In order to confirm this finding the isolated humic-like substances were analyzed by ultra high resolution mass spectrometry (FT-ICR-MS). Elemental composition (obtained from FT-ICR-MS), UV absorbance and fluorescent properties of HULIS isolated from aerosol particles of different sizes will be shown for aerosol samples collected at different sites.

A multi-tracer approach to better understand Secondary Organic Aerosol sources and (trans)formation processes in the Mediterranean region

J. B. Nicolas[1], J. Sciare[1], R. Sarda-Estève[1], N. Mihalopoulos[2], G. Kouvarakis[2] and F. Dulac[1]

[1]Laboratoire des Sciences du Climat et de l'Environnement (LSCE), CNRS-CEA, Gif-sur-Yvette, 91191, France
[2]Environmental Chemical Processing Laboratory (ECPL), Univ. of Crete, Heraklion Voutes, Greece
Keywords: SOA, oxalate, methanesulfonate, Aethalometer model, Mediterranean region.
Presenting author email: jose.nicolas@lsce.ipsl.fr

The Mediterranean region exhibits amongst the highest Particulate Matter (PM) loadings in Europe (Putaud *et al.*, 2010), inducing complex effects on regional climate, air quality and possibly on human health. Thus, a better understanding of PM sources and properties in this area is compulsory, since recent studies have shown it is one of the most sensitive regions to world climate changes.

Secondary Organic Aerosol (SOA) represents one of the major part of fine PM. Its origins and concentrations are still hardly predictable, pointing out the need for a better characterization of SOA in the Mediterranean, focusing on their sources and (trans)formation processes.

A 2-month field experiment (Sept-Oct 2011) was performed in the Eastern Mediterranean at the Finokalia atmospheric station (Crete Island, Greece), within ChArMEx (the **Ch**emistry-**Aer**osol **M**editerranean **Ex**periment) and ACTRIS (**A**erosols, **C**louds, and **T**race gases **R**esearch **I**nfra**S**tructure network) projects. A multi-tracer approach was carried out during this campaign, when photochemistry offers conditions to investigate different oxidation states of SOA.

Methodology

Fine aerosol ($PM_{2.5}$) real-time measurements of Organic Carbon (OC) and Water-Soluble Organic Carbon were performed by EC-OC Sunset field (every 2 hours) and PILS-TOC (every 4 min) instruments. Submicron measurements of major anions (sulfate, nitrate, chloride) and specific organic tracers (oxalate, methanesulfonate) were obtained every 12 min by a PILS-IC technique.

Co-located Black Carbon (BC) measurements were conducted with a 7-λ Aethalometer (Magee Scientific) enabling to separate the BC of wood burning origin from the fossil fuel fraction.

Filter samples (R&P Partisol Plus; every 6 hours) and liquid vials (BMI-PILS; every 30 min) were also collected in order to provide complementary organic speciation (by LC-MS/MS), tracing in particular wood burning and biogenic emissions.

Results

Co-variations were observed between oxalate and sulfate (Fig.1), and between oxalate and OC (Fig.2), indicating the major role of in-cloud processing in the formation of SOA (Yu *et al.*, 2005).

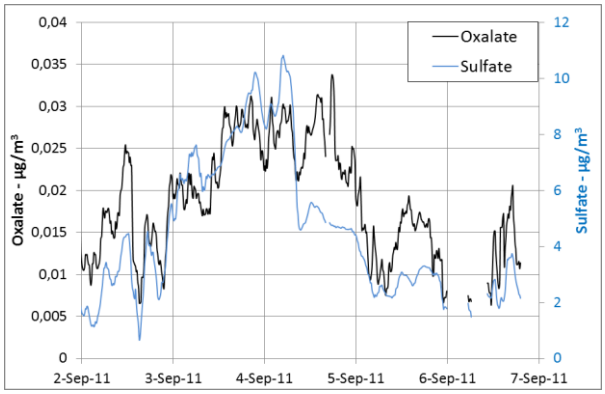

Figure 1. Co-variations between oxalate and sulfate.

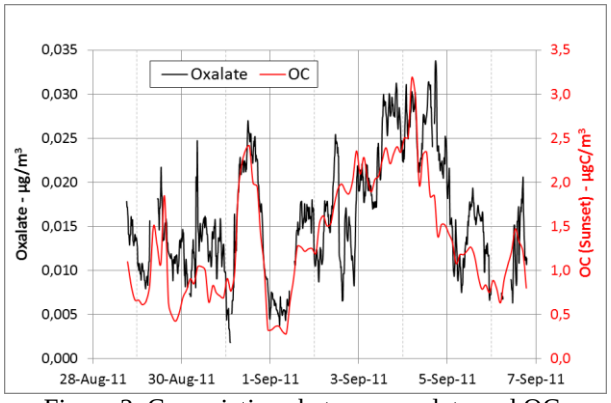

Figure 2. Co-variations between oxalate and OC.

These results will be compared with those from similar observations to be performed in the Western Mediterranean (Corsica Island) in summer 2012. It will allow us to investigate the differences between the two basins in terms of biogenic/anthropogenic sources and atmospheric processes, which are expected to be significant providing the major discrepancies observed in their fine aerosol compositions (Nicolas *et al.*, 2011).

This research was funded by ChArMEx, EU-FP7-ACTRIS (2011-2015), ADEME, CNRS and CEA. The FORTH (Heraklion and Patras) teams are thanked for their help and collaborative work during the campaign.

Presenting author email: h.su@mpic.de

Soot particles are regarded as the most efficient light absorbing aerosol species in the atmosphere, playing an important role as a driver of global warming. Their climate effects strongly depend on their mixing state, which significantly changes their light absorbing capability and cloud condensation nuclei (CCN) activity. Therefore, knowledge about the mixing state of soot and its aging mechanism becomes an important topic in the atmospheric sciences.

The size-resolved (30–320 nm diameter) mixing state of soot particles in polluted megacity air was measured at a suburban site (Yufa) during the CAREBeijing 2006 campaign in Beijing, using a Volatility Tandem Differential Mobility Analyzer (VTDMA). Particles in this size range with non-volatile residuals at 300 ℃ were considered to be soot particles. On average, the number fraction of internally mixed soot in total soot particles (*F*in), decreased from 0.80 to 0.57 when initial *D*p increased from 30 nm to 320 nm. Further analysis reveals that: (1) *F*in was well correlated with the aerosol hygroscopic mixing state measured by a CCN counter. More externally mixed soot particles were observed when particles showed more heterogeneous features with regard to hygroscopicity. (2) *F*in had pronounced diurnal cycles. For particles in the accumulation mode (*D*p at 100–320 nm), largest *F*in were observed at noon time, with apparent turnover rates ($k_{ex \rightarrow in}$) up to 7.8% h^{-1}. (3) *F*in was subject to competing effects of both aging and emissions. While aging increases *F*in by converting externally mixed soot particles into internally mixed ones, emissions tend to reduce *F*in by emitting more fresh and externally mixed soot particles. Similar competing effects were also found with air mass age indicators. (4) Under the estimated emission intensities, actual turnover rates of soot ($k_{ex \rightarrow in}$) up to 20% h^{-1} were derived, which showed a pronounced diurnal cycle peaking around noon time (Fig. 1). This result confirms that (soot) particles are undergoing fast aging/coating with the existing high levels of condensable vapors in the megacity Beijing. (5) Diurnal cycles of *F*in were different between Aitken and accumulation mode particles, which could be explained by the faster size shift of smaller particles in the Aitken mode.

To improve the *F*in prediction in regional/global models, we suggest parameterizing *F*in by an air mass aging indicator, i.e., $F\text{in} = a + bx$, where *a* and *b* are empirical coefficients determined from observations, and *x* is the value of an air mass age indicator. At the Yufa site in the North China Plain, fitted coefficients (*a*, *b*) were determined as (0.57, 0.21), (0.47, 0.21), and (0.52, 0.0088) for *x*(indicators) as $[NO_z]/[NO_y]$, [E]/[X] ([ethylbenzene]/[m,p-xylene]) and ([IM] + [OM])/[EC] ([inorganic + organic matter]/[elemental carbon]), respectively. Such a parameterization consumes little additional computing time, but yields a more realistic description of *F*in.

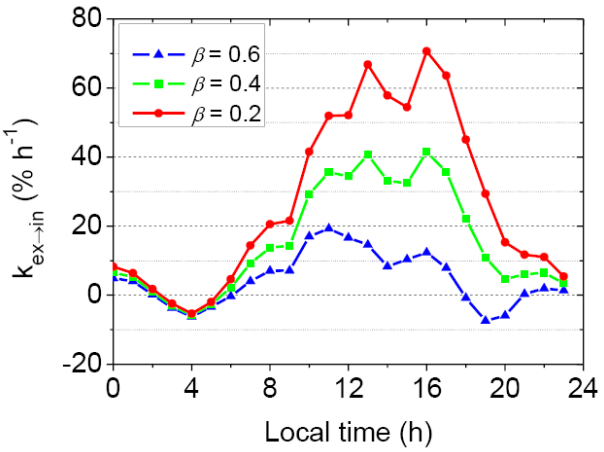

Fig. 1: The actual turnover rate of soot, $k_{ex \rightarrow in}$, under different emission factor β (number fraction of internally mixed soot particles to total soot particles).

This research aimed to identify major atmospheric pollutant risks on selected cultural heritage items (limestone, polychromes) in the city of Granada (Southern Spain) with respect to their *preventive conservation*. This nowadays popular approach to safeguard our cultural heritage involves to characterize the historical item itself, monitoring its microclimatic and atmospheric exposure conditions, and to study the interactions at the interface aerosol-item substrate. In this context we have performed two types of field measurements: a) indoor and outdoor air quality was assessed in La Alhambra and Generalife located on top of the Sabika hill overlooking the city of Granada, and the monastery of San Jerónimo placed in the city center of Granada and surrounded by busy streets; b) a two-year term ageing test performed on a building limestone used in monuments and civil buildings in Granada, under different urban conditions to assess its cultural heritage sustainability with respect to its black soiling process.

Valuable information about concentrations of atmospheric gaseous pollutants as well as chemical and mineralogical composition, size, and morphology of particulate matter, their concentration, trends, major sources and the threatening effects on the artwork items is provided and discussed. Complementary micro- and nano-analytical techniques were applied to chemically characterize the pollutants: ion chromatography (IC) and UV-Vis spectrophotometry for analyzing gases, and electron probe microanalysis (EPMA), scanning electron microscopy with energy-dispersive X-ray analyzer (SEM-EDX), transmission electron microscopy (TEM), X-ray Fluorescence (XRF), X-ray diffraction (XRD), Raman microscopy (RM) and the novel tandem technique EPMA-RM for characterizing bulk and single particles. The soiling process (surface blackening) was monitored through lightness and chroma changes using colorimetry and spectrophotometry techniques.

Results reveal that soil dust particles (aluminosilicates, calcite, dolomite, quartz and clay minerals from the surrounding geological materials) and soot particles (black carbon) are the most abundant particles in the Granada air, intensifying stones and paintings darkening. Sea salts (chlorides) reacting with the urban atmosphere produce a mixture of particulates with diverse chemical composition (aged salt particles such as Na-nitrates, sulfates and ammonium-rich salts) that further promote discoloration of polychromes through mineral transformation, as noticed in the Alhambra artworks. Also fly ash particles (Si-Al rich) were found and the contribution of Saharan dust events to the composition of the mineral aerosol content. Blackening of surface decorative materials is fostered by particle re-suspension due to improper cleaning habits in the monastery of San Jerónimo, and cultural events and detailed curvatures and relief in the Alhambra polychromed artworks which results in uneven blackening (more offensive than a gradual blackening). Heave metals were found to originate from diesel exhaust (V and Ni) and tire tread emissions (Cu, Cr, Pb and Zn). High summer concentrations for O_3 (up to 229 $\mu g.m^{-3}$) were detected at the Alhambra differently to lower O_3 levels in the monastery of San Jerónimo in winter. Here average NO_2 concentration (32 $\mu g.m^{-3}$) is higher than in the Alhambra monument (15.4 $\mu g.m^{-3}$).

Black carbon (BC) concentration is around an average of 2$\mu g.m^{-3}$ (ranging from 0 to 15$\mu g.m^{-3}$) inside the Alhambra and the Gate of Pomegranates, the original access to the monument closed to traffic at present. BC concentration is expected to rise up to 8$\mu g.m^{-3}$, as found at a similarly steep and nearby street, with dense traffic in the Albayzín (values = 1 to 23$\mu g.m^{-3}$).

On limestones exposed to the Granada urban air, black soiling and gypsum crust formation were noticed after the first year of exposure. The effective area coverage, EAC, surpassed the 2% value considered to be the limit perceptible for the human eye (values ranging from 7.8 to 20.4%). The calculated soiling coefficient based on BC concentration was $8.0–9.9\times10^{-3}$ $days^{-1/2}$ $\mu g^{-1/2}m^{3/2}$, which are comparable to values obtained for other limestones placed in urban conditions in Atlantic and continental climates. This type of research should help restorers to be aware of the most vulnerable areas for architectural stones and polychromed artworks in polluted cities. Also these data can be potentially used as a first approximation for planning efficient cleaning policies and to define targeted strategies with respect to traffic access.

Characterisation of nasal spray drug delivery

K.Inthavong[1], M.C.Fung[1], W.Yang[2] and J.Y. Tu[1]

[1]School of Aerospace, Mechanical, Manufacturing Engineering, RMIT University, Bundoora VIC, 3065, Australia

Keywords: drug delivery, atomisation, nasal spray.
Presenting author email: kiao.inthavong@rmit.edu.au

A commercial nasal spray device was tested under a constant flow in order to better understand its spray formation and characteristics. External characteristics such as the spray cone angle define the shape of the atomized spray that exits from the device, while the internal characteristics such as the droplet size distribution help to determine the likelihood of inertial impaction within the nasal cavity. The experimental method makes use of particle image velocimetry (PIV) and particle/droplet image analysis (PDIA) to obtain droplet diameters and spray velocities in different spray regions. Image processing techniques were applied to enhance visualization and a droplet concentration field.

Figure 1 shows an image at the near-nozzle region. The liquid is forced through the nozzle orifice under the action of a swirling centrifugal force. The interaction between the swirling liquid sheet and the surrounding air creates instabilities in the form of rapidly propagating waves produced on the liquid surface.

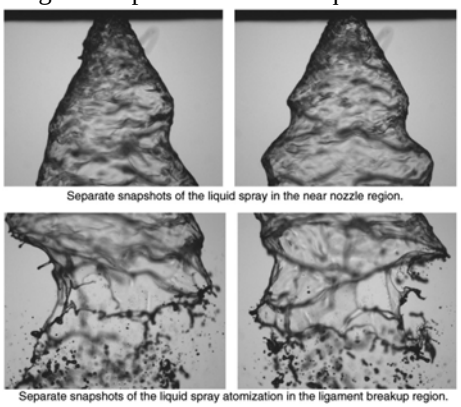

Figure 1. Two sets of images separated by in time showing the spray particle formation at the near-nozzle region and at the ligament breakup region

The spray outline shows the liquid oscillating in a sinusoidal pattern. Also on the surface, the liquid has sinusoidal wave patterns, suggesting the movement of the liquid '*rolling*' downstream in waves. The growth and amplitude of these waves are thought to be a function of the surface tension, aerodynamic forces, and liquid viscosity (Dombrowski and Johns 1963), and the sheet disintegrates into ligaments once the unstable waves reach a critical amplitude.

Time dependent spray formation was also captured which shows the swirling action of the spray as it is atomised (Figure 2) and the four modes described by Lefebvre (1989) can be seen.

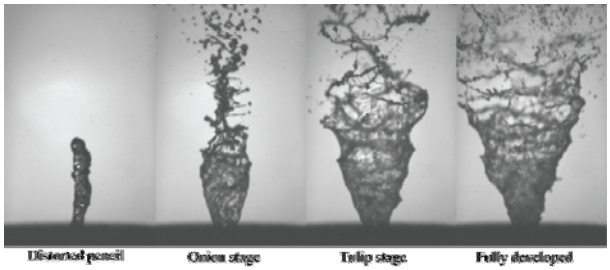

Figure 2 Spray development stages of nasal spray device

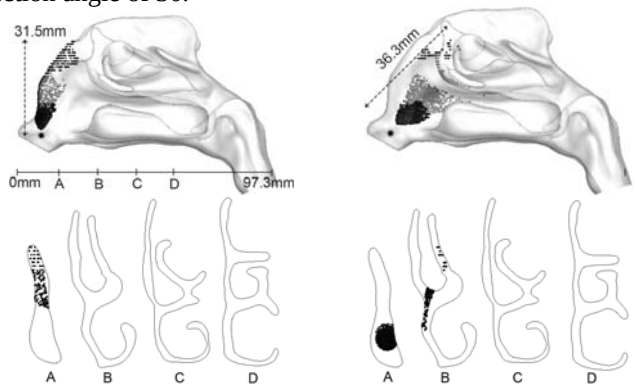
The results can be applied through Computational Fluid Dynamics (CFD) for a practical pharmaceutical application. A computational model of a human nasal cavity is used and initial conditions of the droplets described based on the shape of the measured spray plume are applied. By tracking the droplets, the wall deposition patterns and the spatial locations of the droplets as they pass through cross-sectional slices labeled A to D can be shown. Injection angles, 90 , and 45, are evaluated. The results in Figure 3 showed that the spray plume maximum length reached 47 mm for an injection angle of 30.



90° spray injection 45° spray injection

Figure 3 Visualisation of the unaffected experimental spray placed inside a human nasal cavity model. 100µm particles are delivered just inside the nasal cavity. Subsequent particle deposition onto nasal cavity walls are marked with small black dots.

Evolution of droplet size distribution during nebulization of liposomes

T.R. Sosnowski

Faculty of Chemical and Process Engineering, Warsaw University of Technology,
Waryńskiego 1, 00-645 Warsaw, Poland
Presenting author email: t.sosnowski@ichip.pw.edu.pl

Aerosolized liposomes can be used as drug carriers in inhalation drug delivery to improve drug transfer to the cells and/or provide a method for the sustained drug release (e.g., Zaru et al. 2007). The droplets of colloid which contain drug encapsulated in liposomes can be generated by a variety of nebulizers, providing that the vesicles are not considerably destructed by atomization.

This study is focused on analysis of the evolution of size distribution of droplets released from liposome colloids using selected pneumatic and vibrating-mesh nebulizers.

Multilamellar liposomes were prepared by hydration of lipid film formed after solvent evaporation from lecithin/chloroform solution (10 mg/ml). The lipid film was hydrated with water (15 ml) to form large multilamellar vesicles (up to a few μm in size as observed microscopically). The resulting colloid was sprayed using MP1 pneumatic nebulizer (Medbryt, Poland) with RF6 nebulizing head (Flaemnouva, Italy) or using two types of vibrating-mesh devices: Aeroneb-Pro (Aerogen Inc., Ireland) and e-Flow Rapid (Pari, Germany). Droplet size distribution and its evolution with the nebulization time was measured using Spraytec diffraction spectrometer (Malvern, UK) with the inhalation cell operated at the 10 L/min airflow. The results obtained for liposome colloid were compared to the distributions measured for water. All experimental runs were triplicated.

Temporal evolution of the volume median diameter (VMD, i.e. Dv50) of droplets emitted from tested nebulizers are shown in Figure 1a-1c. For each vibrating-mesh device, the aerosol produced from liposome colloid is composed of smaller droplets than the aerosol formed of pure water. It can be explained by the fact that the colloidal system contains lecithin which is surface active while a decrease of surface tension promotes formation of finer droplets in such atomization systems (Sosnowski & Żołądkowicz, 2011). Size of droplets produced by Aeroneb from the liposome colloid is slightly decreasing with time, probably as a result of partial disruption of large vesicles what increases the concentration of free lecithin in the liquid and further lowers the surface tension. Such effect is not observed for e-Flow nebulizer, where the dominating effects may be attributed to droplet coalescence at the mouthpiece of this high-output device. In case of pneumatic nebulizer, VMD of water droplets slightly increases with time due to liquid cooling which is related to the rise of liquid viscosity and surface tension.VMD remains stable for the liposome colloid atomized with jet device as cooling effects may be compensated by the surface tension reduction due to increased content of lecithin liberated from vesicles. Observed differences in the quality of aerosol produced from liposome colloids by various nebulizers may be useful in the optimization of the inhalation delivery of liposome-encapsulated drugs.

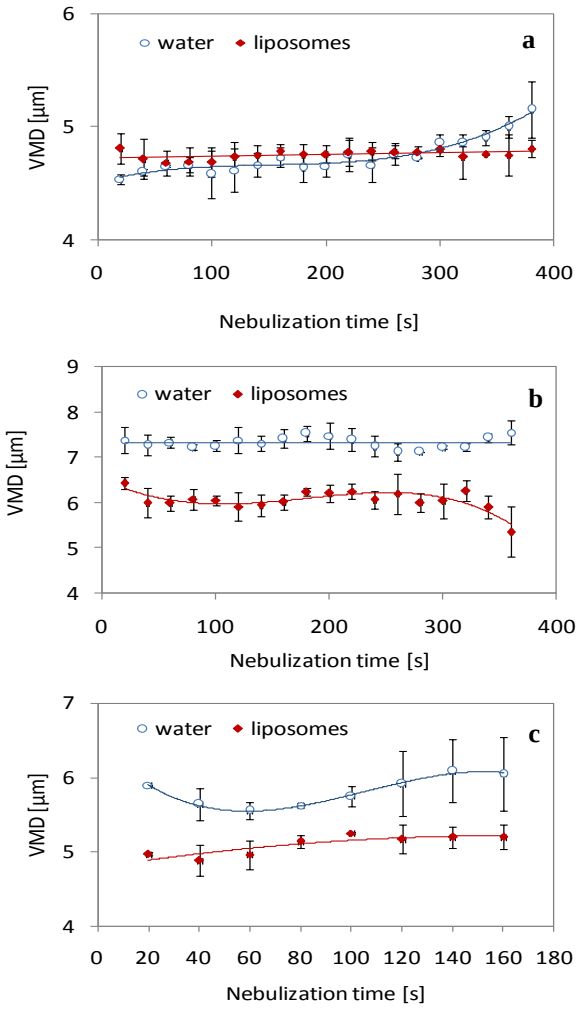

Figure 1. Evolution of droplet size distributions of water and liposome colloid emitted from different nebulizers: MP1-RF6 (a), AeroNeb Pro (b) and e-Flow Rapid (c).

Recently, delivery of various drugs to lungs has been of increased scientific interest and it has become a more and more common way to treat different diseases, not only respiratory diseases like asthma. According to computer simulations, electrostatic deposition of inhaler drug particles dominates in the lower lung regions (Balachandran et al. 1997), particularly in the alveoli where the most efficient systemic absorption exists. Earlier charge studies have focused on particle net charge measurements (Telko et al. 2007) since a method for measuring bipolar charge has not been available.

The Dekati® Bipolar Charge Analyzer is the first commercial instrument available for measuring aerosol particles' bipolar electrical charge as a function of particle size. The instrument consists of two main components: flow divider and electrical collection tubes. The flow divider divides the aerosol evenly to 6 branches. Each branch has an electrical collection tube consisting of an impactor which separates the particles based on particle size and two nested cylinders which measure the electrical bipolar charge of particles. The particles with different polarity drift to inner or outer tubes due to the electric field between the tubes. The bipolar charge of particles is measured as a current from the inner and outer tubes using electrometers. After the measurement the electrical collection tubes can be uncoupled and positive and negative particles can be covered and analyzed separately. Hence, the Dekati® Bibolar Charge Analyzer measures the electrical bipolar charge of different sized particles but if the particles are also analyzed, the bipolar charge in respect of mass can be assigned as well as the particles' composition in different size ranges.

Table 1. The particle sizes collected to the branches in the Dekati® Bipolar Charge Analyzer.

Tube	Particle size, µm
1	$D_p < 0.94$
2	$0.94 < D_p < 2.84$
3	$2.84 < D_p < 4.47$
4	$4.47 < D_p < 8.07$
5	$8.07 < D_p < 12.79$
filter	collects all the particles

Each one of five branches has a different impactor cutpoint and therefore different sized particles pass through the impactors (Table 1.) and the bipolar charge of different particle sizes are gained from the tubes. In the sixth branch, there is no tube or impactor but a filter instead. The filter is used to check the net charge of the particles but also the quality of the successful flow dividing. The nominal cut-sizes of the impactors match with the corresponding stages in the NGI-impactor at 60 lpm flow rate (Virgil. et al. 2003).

The electrical bipolar charge distribution of lactose particles is presented in Figure 1. Also the net charge of the particles is shown. The bipolar charge measurement has much more information compared to net charge of particles.

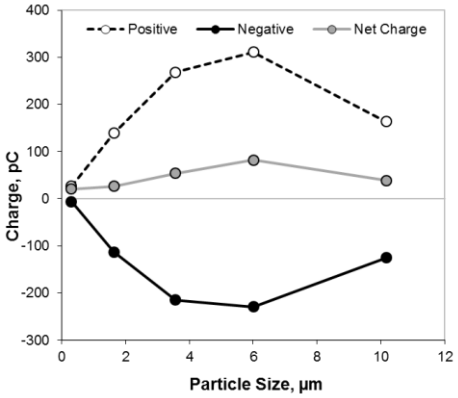

Figure 1. Positive, negative and net charge of lactose particles as a function of particle size

Each component of the instrument is calibrated separately: impactor stage collection efficiencies, the flow divider penetration and the tube particle collection efficiencies as a function of charge level and particle size (Yli-Ojanperä et al. 2012). The size distribution and net charge of Dekati® Bipolar Charge Analyzer are compared with the ELPI. The results are very comparable. The quality of flow dividing has been studied by net charges and analyzing the amount of particles in each branch. Particle deposition (losses) in different parts of the instrument has also been studied in detail.

The use of the respiratory tract for drug delivery has been proven highly successful for treating not only diseases of the lung, such as delivering bronchodilators to treat asthma, but also in the treatment of systemic diseases, such as delivering insulin to treat diabetes. The three main delivery systems currently available are metered-dose inhalers (MDIs), dry powder inhalers (DPIs) and nebulisers, where the mechanism by which each generates an aerosol is unique. Although each method is different, the aim is to be able to deliver the appropriate drug dose to the desired location within the lung. This is accomplished through tailoring the excipients in the starting formulation as a means to affect the size of the aerosol, thus allowing delivery it to the desired location in the lung. Although the correlation between aerosol size and deposition site in the lung are well studied, the rapid change in size of an aerosol in the humid environment of the lung is not. In this study, we examine the thermodynamic and kinetic factors that regulate the time-dependant size of droplets generated from commercial nebuliser formulations.

The hygroscopic properties of various nebuliser formulations were studied using two different electrodynamic balances, the standard double ring EDB (DR-EDB) (Hargreaves el al., 2010) and a concentric cylinder EDB (CC-EDB) (Davies et al., 2012). The DR-EDB was used to study the relative size change of the droplets as a function of relative humidity (RH), where time was given for the droplets to reach a thermodynamic equilibrium at each RH. The CC-EDB was used to study the rapid change in size of the droplet from the point of its generation to the point where it reaches equilibrium, with a time resolution on the ms time scale.

The formulations utilised in this study were saline (as a control), Flixotide, Salbutanol, Tobramycin and Ventaris. The rapid evaporation of droplets of each formulation was measured under relative humidity conditions of >90%, ~50% and dry.

The results for Flixotide are shown in figure 1, the data collected using the DR-EDB is shown in figure 1A while the data collected using the CC-EDB is shown in figure 1B.

In looking at the relative size change as a function of RH (figure 1A), the shape of the hygroscopic curve was found to be similar to that of NaCl - both have deliquescence and efflorescence points of 75% and 50% respectively, which is not surprising given that the formulations are primarily a saline solution. However, the overall mass change of the aerosol was found to be far lower than that of pure NaCl (data not shown), suggesting that the excipients in the formulation play a major role in the uptake of water by the droplet.

The size of the droplet as a function of time (figure 1B) clearly demonstrates the necessity in undertaking these studies; for most inhaled particles, the equilibrium size of the aerosol is never reached.

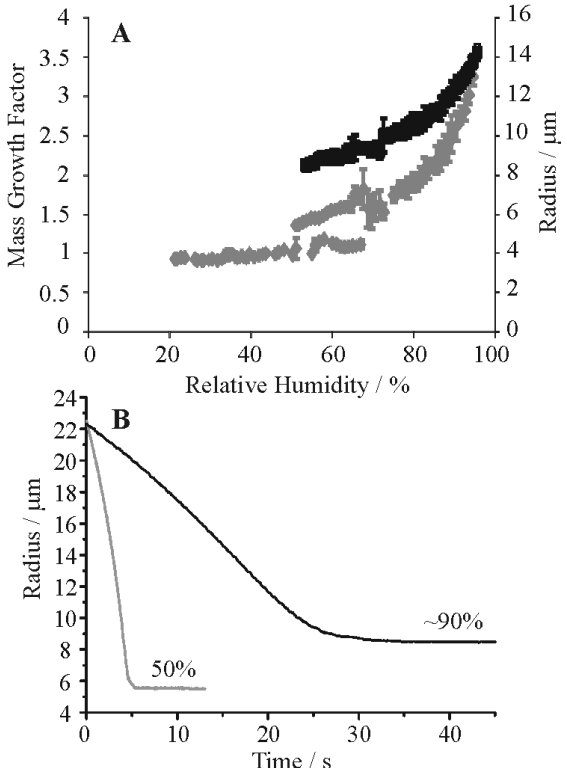

Figure 1. The relative size of droplets generated from a Flixotide formulation as a function of relative humidity (A) and time (B).

Additionally, the use of the two different EDBs was found to generate complimentary data. The ratio of the radii of the droplets at equilibrium between an RH of 95% and 50% for both instruments was ~1.5.

[5]Institute of Occupational Safety and Health, Council of Labor Affairs, Taipei, Taiwan

Keywords: carbon-nanotube, plasma, indoor, bioaerosol.
Presenting author email: shinhaoyang@ntu.edu.tw

Individuals spend an average of 87.2 % of their time indoors in the USA (Lance, 1996) and an average of 90 % of their time indoors in Taiwan, highlighting the increasing importance of indoor air quality. Bioaerosols induce various respiratory diseases and significantly impact indoor air quality (Eduard *et al*., 1993; Melbostad *et al*., 1994). Therefore, an increasing number of air-cleaning technologies remove indoor bioaerosols.

This work aimed to apply the carbon nanotube corona discharge plasma to remove bioaerosols. The nanotube carbon plasma device included two carbon nanotube discharge electrodes, a high voltage power supply, and a stainless steel mixing column. The carbon nanotube discharge electrodes were made by coating carbon nanotube on the stainless steel needles. Two carbon nanotube discharge electrodes connected with the positive and negative electrodes of the power supply.

The E-coli bioaerosols were chosen as the tested aerosols. The test bioaerosols were generated by using a Collison three-jet nebulizer (BGI Inc., Waltham, MA). The bioaerosol survival was measured by an Andersen single-stage impactor sampler (Andersen Samplers, Inc., Atlanta, GA) supplied with TSA plates. Figure 1 shows the components of the testing system. The test chamber made of stainless steel is 80 × 80 × 80 cm^3. Before experiments started, the chamber was well stabilized for 6 hr to achieve the demanded conditions. Two fans and a pump were utilized to retain a stable airflow and control the number of ACHs. The ACH is equal to the total airflow per volume of the tested chamber. Two ACHs, 0.5 and 1.0 (1/hr), were selected in this study. The air stream RH was modified by changing the ratio of flow rate of a dry gas stream to that of a humidified gas stream generated by a water vapor saturator.

Figure 2 plots the decay curves of *E-coli* bioaerosols in the testing system at a total ACH of 1.0 hr^{-1}, and RH of 30%. In the absence of the plasma system, the natural decay constant (kn) approached 0.135 min^{-1}. When the tesing system was equipped with a carbon-nanotube plasma system of 6 kV, the decay constant (ka) was 0.291 min^{-1}. The carbon-nanotube plasma system improved *E-coli* bioaerosols removal efficiency. This was due to the effects of inactivating of the carbon-nanotube plasma system. The plasma system using carbon nanotube electrodes had higher bioaerosol inactivation efficiency than the corona discharge system using stainless steel electrodes. The results further demonstrated that the inactivation efficiency increased as ACH and operating voltage increase.

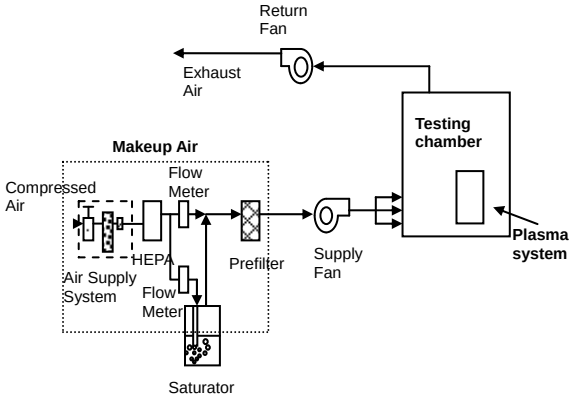

Figure 1. Schematic diagram of a small-scale testing system

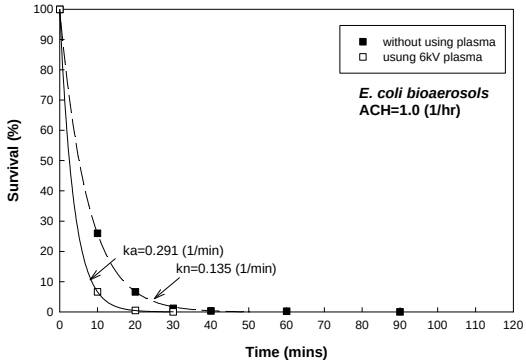

Fig. 2 Decay curves of the *E-coli* bioaerosols in the HVAC system with or without using plasma at ACH of 1.0 (1/hr).

Keywords: PM, COPD, urban areas, remote alpine sites.
Presenting author email: gianfranco.schiraldi@gmail.com

Increased concentration of particulate material (PM), mainly due to urban traffic, heating and industrial pollutants is likely to be responsible for a different incidence of respiratory complications and/or reduction of pulmonary function.

198 patients were recruited, on a casual and voluntary basis: 99 were recruited in Milan, Italy, i.e. a densely populated and polluted metropolitan area, the 99 in Aprica, a remote alpine site (1181 m.a.s.l), with low pollution, due to traffic or other pollution sources. PM_{10} (<10 μm)and $PM_{2,5}$ (<2,5μm) were measured by PM detection units during two 2 week-campaigns. Each group was classified in 2 subgroups. The former, aged 30 to 64 years, (n=72) the latter over 65 (n=27). All subjects, well matched for cigarette smoke, sex and age were in good health conditions, asymptomatic and with no previous history of respiratory chronic diseases. All of them underwent spirometry, with evaluation of the following parameters: FVC (forced vital capacity), FEV_1 (forced expiratory volume in 1 second), PEF (peak expiratory flow) and MEF_{50} and MEF_{25}, i.e. maximum forced expiratory flow at 50% and 25% of FVC, respectively. Data were expressed as the percentage ratio between measured and theoretical values (m/t%).

Results: m/t% of FEV_1 (index of bronchial patency), both in under 65 and over 65 subjects, was lower in Milan that in Aprica subjects (**Table 1** and **Table 2**).

Table 1: m/t% in subjects age 30-65 years

	Milan	Aprica	p (t test)
FEV_1 m/t%	96	103	<0.01
MEF_{50} m/t %	75	97	<0.0001
MEF_{25} m/t%	54	78	<0.0001

Table 2: m/t% in subjects age 65-89 years

	Milan	Aprica	P (t test)
FEV_1 m/t%	69	88	NS (p=0.052)
MEF_{50} m/t %	68	86	NS (p=0.073)
MEF_{25} m/t%	44	66	<0.0001

In particular, FEV_1 was <80% (value borderline between normal and abnormal data) in 20 out of 99 subjects in Milan (20,2%), whereas it was < 80% in only 8 out of 99 in Aprica (8,08%).

Evident differences were also observed in subgroups of different age: FEV1 resulted <80% in 8 out of 72 subjects under 65 years in Milan (11,1%) and in 2 out of 72 in Aprica (2,8%); and in 12 out of 27 (44,4%) and 6 out of 27 (22,2%) in subjects over 65 years, respectively (p<0,05), Allegra *et al* (2008).

Consistently, MEF_{50} and MEF_{25}, suggestive of the "smaller airway diseases", i.e. of a sub-clinical pathological entity somehow preceding chronic obstructive pulmonary diseases (COPD), were found (m/t%), both in under 65 and over 65 subjects, higher in Aprica than Milan inhabitants (**Table 1** and **Table 2**). In particular, in 30 out of 85 Milan subjects vs 18 out of 85 Aprica subjects, they were below the threshold (<65% for MEF_{50} , and <50% for MEF_{25}), which are considered borderline between normal and abnormal values (p<0,001) (**Table 3**).

Table 3: MEF_{50} and MEF_{25} changes (<65% and 50% respectively) Milan vs Aprica

MEF_{50}<65%, MEF_{25}<50%	Milan	Aprica
Total subjects	30 (35 %)	18 (21 %)
Subjects < 65y	17 (27 %)	3 (5 %)
Subjects >65y	13 (56 %)	15 (65 %)

Conclusion: Present data, even if preliminary, suggest that in the polluted metropolitan area of Milan, inhabitants are more prone to a progressive alterations of the respiratory function than in Aprica, a low pollution alpine site. In particular, not only in severely symptomatic subjects with evident respiratory diseases, but also in clinically asymptomatic individuals, it is possible to detect significant difference in respiratory function because of different levels of air pollution. Since PM related alterations are partly reversible because of repair and defense mechanisms of the host, Cetta *et al* (2009), periodical interruption of chronic exposure to metropolitan pollutants with exposure to a better environment (such as an Alpine site) could be of benefit.

A 4-years follow-up study of traffic related respiratory changes in school children in Milan , Italy

Important adverse effects on children health can be caused by exposure to air pollution, namely during the peculiar "susceptibility window" occurring during the first years of life, Clark *et al* (2010). In particular, traffic related pollution adversely affects lung function development.

Between 2007 and 2008, 228 children, mean age 8 years, were enrolled from 2 primary schools, located in different sites, in order to study pollution related respiratory symptoms and/or diseases in different places of Milan with a different traffic-related exposure. The former (School 1) was located near a large park, the latter was located downtown, close to main crossroads (School 2). Daily levels of PM10 and PM2,5 (diameter <10µm and 2,5µm) were measured both outdoor and indoor outside the schools (in the school garden) and within common places (corridors), for 7 consecutive days during 2 different campaigns (winter and spring-summer). Children underwent skin prick testing for inhaled allergens, analysis of exhaled nitric oxid (FeNO) and spirometry.

The distribution of FeNO values was significantly different (p=0,02) between the two schools. In particular, the percentage of children with FeNO values <5ppb in school 1 was higher (almost double) than in school 2. In 73% of children attending the school located downtown FeNO concentration was between 5 and 20ppb.

The percentage of asthma exacerbations in the previous 12 months was higher in children from school 2 (p=0.05). On the contrary, the prevalence of persistent allergic rhinitis in children allergic to grass pollen was higher in school 1 (p=0.03). In particular, the latter children also had a greater activity limitation, due to rhinitis and concomitant conjunctivitis (p=0.03). Interestingly, the highest recorded peak for PM10 occurred between 8:15 and 9:15 a.m., for 3 consecutive days, and was related to children arrival. This peak (>1000µg/m^3) (figure 1) didn't seem to produce specific health effects, likely because of the usual PM10 composition in a park site, with a lower content of toxic or reactive components.

Hospital admissions, because of lower respiratory tract diseases (bronchitis, bronchiolitis, pneumonia) were more frequent during the winter campaign and in school 2, whereas otitis and allergic rhinitis or conjunctivitis, together with asthma, were more severe during the spring-summer period and in school 1 (p<0,05).

Continuous monitoring for 3 years of both children and PM showed that: 1) short duration pollution peaks, even reaching concentrations 20 folds above the fixed limits, have no consequences on children health and were likely induced by children's arrival or movement; 2) there was an enormous daily variability in PM10 concentration, among the daily mean value results, from the average of values, with a very high standard deviation (+30,+1000µg/m^3) and with various peaks; 3) prolonged follow-up for 3 years in this selected group of children didn't show any evident difference in the occurrence of clinically relevant respiratory diseases. On the basis of FeNO values, different degrees of respiratory function and bronchial inflammation were found in the 2 groups.

Traffic could be responsible at least in part for the different air quality, but individual susceptibility and seasonal changes are also major determinants of clinical outcomes. In particular, early exposure during the first years of life could be responsible for future diseases occurring later, during adult life.

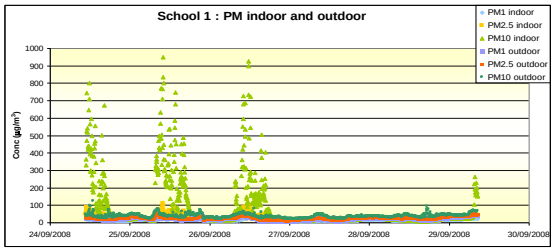

Figure 1. Concentration of PM10, indoor and outdoor, in School 1.

Urban traffic and environmental pollution are responsible for a different air quality in metropolitan areas vs less polluted sites and for a different incidence of respiratory complications and/or alteration of pulmonary function.

In the 2008 two groups of 99 subjects were recruited (n=198), on a casual and voluntary basis: the former in Milan, Italy, i.e. a polluted metropolitan area, the latter in Aprica, a remote alpine site (1181 m.a.s.l), with low pollution. PM_{10} (<10 μm) and $PM_{2,5}$ (<2,5μm) were measured by PM detection units during two 2 week-campaigns. Each group was classified in 2 subgroups. The former, aged 30 to 64 y (n=72) , the latter over 65y (n=27). All subjects, well matched for cigarette smoke, sex and age were in good health conditions, asymptomatic and with no previous history of respiratory chronic diseases. All of them underwent spirometry, with evaluation of the following parameters: FVC (forced vital capacity), FEV_1 (forced expiratory volume in 1 second), PEF (peak expiratory flow) and MEF_{50} and MEF_{25}, i.e. maximum forced expiratory flow at 50% and 25% of FVC, respectively. In addition, the thiol redox status, which is crucial to balance oxidative stress and ROS generation, facilated by air pollution, was also evaluated in 2 subgroups of subjects,: the former (n=38, age 82±9y) living in Milan, and the latter (n=42, age 70±8y) living in Aprica. HPLC analysis was performed on blood samples for the evaluation of thiols in plasma and erythrocytes (total and reduced forms PT, PR; ET, ER) and also in exhaled breath concentrate (EBC). In fact, thiol redox status contributes to contrast oxidative stress and ROS generation promoted by air pollution. Namely cystein (Cys), cysteinylglycine (CG), homocysteine (Hcy) and glutathione (GSH) were evaluated both in blood and in EBC.

FEV_1 resulted <80% in 20 out of 99 subjects in Milan (20,2%), whereas it was < 80% in only 8 out of 99 in Aprica (8,08%). Evident differences were also observed in subgroups of different age: FEV1 resulted <80% in 8 out of 72 subjects under 65 y in Milan (11,1%) and in 2 out of 72 in Aprica (2,8%); and in 12 out of 27 (44,4%) and 6 out of 27 (22,2%) in subjects over 65 y, respectively (p<0,05), Allegra *et al* (2008). Concerning thiol analysis, there was no evident difference in the GSH levels between the two populations. In fact, GSH alteration is usually a late event, occurring in severe imbalances and no subject in both groups had clinically evident diseases, Cetta *et al* (2009). On the contrary, PT Cys was 459,8 ±152,2 vs 286,3 ±74,8 (p<0,001) and ER Cys 2,5±0,8 vs 1,5 ±0,6 (p<0,001), respectively. Finally, data concerning thiol balance analysis from EBC showed: 1) a striking individual variability of the various chromatographic peaks; 2) low concentration of reduced species.

Conclusion: inhabitants of areas with different traffic volumes showed significantly different Cys, CG and Hcy levels, even if GSH remains unchanged, suggesting a greater- pro-oxidant effect in more exposed populations, affecting Cys, CG and Hcy levels, before GSH alterations. Analysis of thiol redox balance in plasma and erythrocytes is able to distinguish between more and less exposed subjects and could be a useful diagnostic tool for early detection of subjects at higher risk of health effects from environmental pollution. In particular, thiol analysis in EBC could be a very early marker of redox imbalance, and be used to detect early alterations in predisposed subjects. Air pollutants are weak pollutants, which at usual concentration in Western countries, in the absence of increased individual predisposition to respiratory or cardiovascular diseases do not determine clinically evident health effects after short-term exposure. In particular, PM related diseases are likely due to progressive accumulation of biological and tissue damage, because of oxidative stress and other injuries to human cells. These alterations are likely to be reversible and could be repaired by endogenous repair and defense mechanisms of the host.

Periodical interruption of chronic exposure to metropolitan pollutants with exposure to a better environment (such as an Alpine site), could be of benefit in all subjects with prolonged exposure to PM.

Many therapeutic approaches for lung diseases rely on delivery of drugs directly to lungs via inhalation. The efficacy of the therapy will depend on the amount of the delivered drug, the location of its deposition and its bioactivity. Hence, quantification of drug amount and its spatial distribution in lungs are indispensable factors in the validation of any drug in pre-clinical research.

Fluorescence and bioluminescence imaging in the visible range is a promising method for *in vivo* determination of dose, spatial distribution and bioactivity of drug dose in the lungs. However, the biological tissue interacts strongly with the visible light. Due to absorption and especially scattering of the light, quantification and mapping of the drug dose is difficult. We, therefore, use Cryo-Imaging (Steyer et al, 2009) of fluorescent substances in an excised lung as the experimental method for determining the factors like, attenuation coefficient of the lung tissue and as a reference method for the pulmonary drug dose and distribution.

Cryo-Imaging involves imaging and slicing of the specimen in an alternate manner. It requires a conventional cryomicrotome to be fitted with an imaging unit capable of recording fluorescence signals at multiple wavelengths (fig. 1). The specimen block is first imaged then sliced by a defined thickness. This procedure is repeated until the whole specimen is recorded.

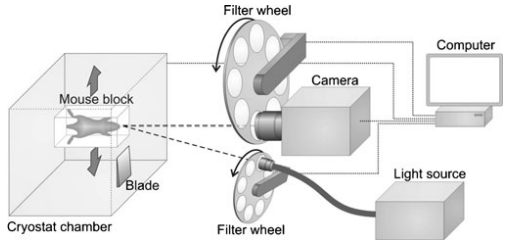

Figure 1. Schematic depiction of the Cryo-Imaging setup. As a first step the whole mouse instead of the excised lung is used. After each block face image the slicing takes place. The excitation light is provided by a filtered light source and the emission light is captured with a camera (Sarantopoulos et al, 2011)

Since each block face image not only contains light from a single slice, but also contains the fluorescence signal emanating from deeper layers of the specimen. The net fluorescence for a given slice is derived by taking into account the fluorescence images of deeper slices, modelling light propagation, and correcting for their contribution on the top layer. The corrected slices are stacked together to reconstruct a 3D distribution of the fluorophore. The sum of the net fluorescence from all the slices gives the total amount of fluorophore present in the specimen. The advantage of this method lies in its ability to obtain quantitative images with high spatial resolution and high sensitivity for the fluorescent signal.

A known amount of fluorescent polystyrene particles (diameter 450nm, excitation @ 670nm; emission @ 710nm) was instilled intratracheally to the lungs of a mouse, which was sacrificed immediately after the application. The lung was removed, fixed in an OCT solution (for fixation of the tissue) and snap frozen. The frozen block was then cryo-imaged with a slice thickness of 100 µm. A 3D distribution of the fluorophore in the lungs was reconstructed with an image processing routine written in MATLAB. Figure 2 shows a single slice of the reconstructed volume of three separated lobes of a mouse lung containing fluorescent polystyrene particles.

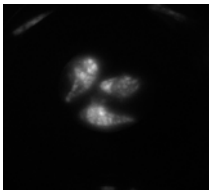

Figure 2. A fluorescence image of three separated lobes of a mouse lung taken with the Cryo-Imaging setup. The lungs contained fluorescent polystyrene particles (diameter 450nm, excitation @ 670nm; emission @ 710nm)

Stochastic rat lung dosimetry for radon progeny: A surrogate for the human lung

M.Hussain[1,2], R. Winker-Heil[1], and W. Hofmann[1]

[1]Department of Materials Research and Physics, University of Salzburg, 5020, Salzburg, Austria

Keywords: lung deposition, stochastic analysis, radon decay products

Experimental data on lung cancer risk in rats (Cross 1988; Chameaud et al. 1984) indicate that the mean lifetime risk coefficients per unit exposure are consistent with the epidemiological findings for uranium miners under various exposure conditions. The laboratory rat as a human surrogate to assess the associated risk following exposure to radon progeny has shown promising results (Monchaux et al. 2002), indicating that the rat is a suitable animal for lung cancer risk assessment.

Studies by Hofmann et al. (1999) have shown that airway diameters are more appropriate morphometric parameters to classify local particle deposition patterns and hence dose distributions across the human and the rat lung. In our present study, dose distributions from inhaled radon progeny are therefore computed by previously developed stochastic morphometric models of the human and rat lungs.

Dose estimation for inhaled radon progeny in mine environments are based on one percent of unattached fractions characterized by an activity median diameter (AMD) of 1 nm and attached fractions of 0.3µm (AMD) with a mean density of 2.7 g cm^{-3} and a geometric standard deviation (GSD) of 2.2. For dose calculations, the breathing parameters for the rat are derived from the data collected by Costa and Tepper (1988) with an average tidal volume of V_T = 2.0 mL and a breathing frequency of f = 117 min^{-1}.

Deposition patterns and hence doses delivered to bronchial airways as a function of airway diameter for radon progeny are shown in Figs 1 and 2.

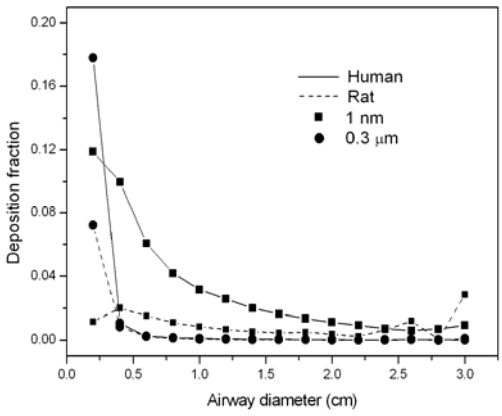

Fig 1: Deposition fractions of unattached and unattached radon progeny in the human and rat lungs.

Deposition in the trachea of the rat lung for the unattached fraction is higher than for the human lung, but is consistently lower in most of the conductive airways. However, doses delivered by the unattached fraction in both lungs do not show significant variations. In contrast to unattached fraction, attached fractions penetrate deeper into the lung with higher deposition fractions. The deposition distributions for the attached fractions in both species are nearly identical with relatively higher deposition in the trachea of rat lung. The doses delivered to the rat lung by the attached fraction are relatively higher in the deep lung. The average bronchial doses per unit exposure in the rat lung are 0.43 and 11.3 mGy WLM^{-1}, whereas in the human lung the corresponding doses are 0.55 and 7.1 mGy WLM^{-1}.

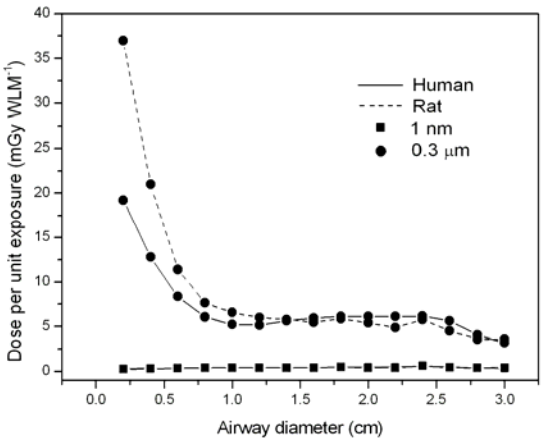

Fig 2: Doses per unit exposure for unattached and unattached radon progeny in the human and rat lungs.

The results presented above suggest that the rat lung diameters are an appropriate human surrogate model for human radon lung dosimetry.

Avian influenza virus (AIV) A subtype H5N1 is an object of researches conducted worldwide in connection with frequent cases of mass death of wild birds and poultry as a result of influenza spread in recent years and high fatality of some strains of this pathogen for humans.

According to some authors, chickens are infected via the fecal-oral route i.e. through gastrointestinal tract. Recently Kwon and Swayne, 2010 reported that chickens and ducks were more susceptible to the H5N1 virus when exposed by intranasal as compared to alimentary routes of inoculation. Some authors also do not exclude the aerosol way of transmission of this disease in chickens (Antarasena *et al* 2006; Shortridge *et al* 1998). Previously we also demonstrated the possibility of the aerogenic way of AIV transmission for these avian species (Safatov *et al*, 2007).

The goal of the work was to study the infectious properties of different AIV strains A subtype H5N1 for chickens, the degree of sensitivity of respiratory and gastrointestinal tracts of this avian species to the given pathogen as well as the dynamics of AIV dissemination in the organism of chickens infected via respiratory route.

Eight highly-pathogenic AIV strains A/H5N1 (intravenous pathogenicity index, IVPI - from 2.7 to 3.0) isolated in Russia and CIS countries were used in this work. All the strains at the 2nd -3rd passages (from the source of isolation) were cultivated on chicken embryos to the concentration of 7.5 – 8.5 Log_{10} 50% embryonic infective doses in 1 ml (EID_{50}/ml) and stored in a refrigerator at -70 °C before they were used in experiments.

Hisex Brown cross chickens of Rhode-Island genetic line 1 weighing 280-340 g were used in the studies. All chickens used were free from antibodies to H5 influenza virus.

Experiments were conducted according to the procedures similar to one described in detail in Agranovski *et al* (2010) and Sergeev *et al* (2002).

Comparative studies of the chickens' susceptibility to different highly pathogenic AIV strains at aerosol infection were performed, Table 1.

For comparison, the ID_{50} of AIV (by the example of A/Chicken/Suzdalka/Nov-11/2005 strain) were determined at infecting chickens with 3 more different routes of infection. It was noted that the virus displayed a considerably higher virulence for chickens at the intranasal way of infection as compared with those at oral (by 15 times) and intragastral ones (by 300 times). The aerosol way to infect birds with this AIV strain had a higher efficiency as compared with intranasal one (by 30 times).

Table 1. Data on the virulence of AIV strains at aerosol way of infecting chickens. Averages ± confidence interval with the probability of 95%

AIV A subtype H5N1 strains	AID_{50}, $Log_{10}EID_{50}$
A/Turkey/Suzdalka/Nov-1/2005	1.0 ± 0.4
A/Chicken/Suzdalka/Nov11/2005	1.2 ± 0.5
A/Chicken/Kurgan/05/2005	0.9 ± 0.4
A/Duck/Kurgan/08/2005	0.8 ± 0.4
A/Chicken/Crimea/04/2005	0.8 ± 0.5
A/Chicken/Omsk/06	1.0 ± 0.4
A/Chicken/Krasnodar/02/06	1.2 ± 0.5
A/Chicken/Dagestan/06	0.3 ± 0.6

Note: AID_{50} = 50 % Aerosol Infecting Dose.

Data on AIV A/Chicken/Kurgan/05/2005 dissemination in chickens infected via aerosol and intranasal routes in the course of infection showed simultaneous appearance of the virus 30 hours post infection in blood, lungs and cloaca indicates that it most probably penetrates into these organs from nasal mucous membrane by hematogenic way, for example, through fenestrated endothelium of blood vessels in olfactory region. Later detection of the virus in trachea than in the lungs also confirms this supposition and demonstrates a low level of the probability of existence of a descending way of pathogen spread from nasal cavity along the chicken's respiratory tract.

The results obtained showed that aerosol of AIV strains A subtype H5N1 is very infective for chickens. It is much more infective than inoculation via other routes of infection studied. It is confirmed also by data on virus dissemination in infected via various routes chickens.

A better knowledge of causative pathophysiological mechanisms, in addition to proper markers of effects, as key tools for a deeper insight into health effects of air pollution

F. Cisternino[1], V. Guercio[1], M. Monti[2], F. Granato[1], B. Lorenzi[1], J. Martellucci[1], R. Zangari[1] and F. Cetta[1]

[1]Dept. of Surgery and Thoracic Surgery, University of Siena, Siena, 53100, Italy

Keywords: PM, markers of exposure and effect, causative mechanisms, transient and persistent alterations.
Presenting author email: cisternino2@unisi.it

Aim of the study: To focus on possible markers of effect and susceptibility and pathophysiological mechanisms for a better understanding of the health effects of air-pollution.

Methods: Between 2007 and 2011, a comprehensive approach to health effects of air pollution in Milan, Italy was designed (Prolife Project). In particular, the following studies were performed : 1) PM concentration measurement; 2) comparison between daily concentration of PM or other pollutants and acute hospital admission for respiratory or cardiovascular diseases (n= 53.514); 3) longitudinal studies in frail subpopulations, such as children attending primary school (n=440) and elderly people living in nursing homes (n=198); 4) "*in vitro"* and "*in vivo"* experiments concerning host particle interactions.

Results: Transient or persistent and severe alterations of respiratory or cardiovascular districts were observed, either in children or in old people, in addition to alterations of other system such as sperm-cell function or osteoarticular function. However, in people with similar exposure to pollutants, they depended at a greater extent on individual susceptibility of the host than on intrinsic toxicity of the pollutants. In particular, more severe alterations were observed in subjects with chronic infection, COPD, rheumatoid arthritis or varicocele. It was found that PM determines multiple effects, that cannot be explained by "pure" toxic mechanisms. Therefore, a single marker is insufficient to capture the complexity of host particle interactions. In fact, an ideal marker should reflect at least 2 different mechanisms: 1) the former, that is pollution related (i.e. due to concentration, composition or other intrinsic properties of PM). 2) the latter, that is host susceptibility related. However, pollution-related diseases are a no-threshold phenomenon, i.e. there is no threshold of PM concentration above which the effect is detectable in all individuals, and no level below which there is no effect. Therefore, to capture these complex interactions, other markers should be chosen, partly related, but also partly not related to the presumed intrinsic toxicity of pollutants. These markers should measure individual susceptibility, vulnerability and the overall response of the human being as a whole.

Discussion: 1) A "stepwise approach", based on levels or degrees of evidence in the mechanistic causative role of PM and other airborne pollutants for the occurrence of clinically evident diseases or death in humans; 2) the need for markers of effect, which should be graded, on the basis of the level or degree of possible, transient, persistent or definitive damage. These markers can be classified as phase 1 or molecular markers (molecular alteration, or biological changes such as oxidative stress, ROS production, DNA adduct formation, which should be repaired by usual cellular mechanisms); phase 2, or cellular markers; phase 3, or markers of permanent tissutal damage and phase 4, or markers of clinically evident disease, or permanent function impairment of one organ or apparatus. Finally, a cumulative score is required, which takes into account both these mechanisms: particle related and host related. The measurement of this final score will also be variable, because it is arbitrary the weight that is given to each end-point and marker: oxidative stress, genetic mutation, inflammation, individual ability to repair damage, risk for autoimmune response. The weight of the various components should also be compared with current knowledge concerning the various diseases of interest. The weight will be greater for the "particle related toxic mechanism".

When evaluating diseases with low to no evidence for autoimmunity in their pathogenesis. And for the "host related mechanism", when dealing with clinical outcomes or diseases, for the occurrence of which (rheumatoid arthritis, asthma) autoimmunity is a well known causative factor. Markers of the toxic mechanism will be the following molecules related with oxidative stress and ROS generation or genetic polymorphisms in drug metabolizing enzymes (GSMT, NADH), which can be responsible for repair capacity. In addition to these markers we have to select markers expressing host cellular immunity and general markers of good health, in addition to specific markers for each function or district of interest.

The final picture of the various markers of interest will be more complicated, and to provide a proper model will be more complex. But, it will be more adherent to what actually occurs in real world. In particular, misleading inferences from epidemiological studies could be prevented.

Aerosolization system for experimental inhalation study of metal oxides nanoparticules

attoui@univ-paris12.fr

Respiratory effects of nanoparticles (NP) represent a major concern. However, no current data is available in the literature regarding health effects in human beings. Welders are a population of workers susceptible to be exposed to NP. Indeed, welding fumes are a complex mixture of particles and gases that is highly variable. It is estimated that 90% of welding is performed with mild steel, which is composed of mostly iron (Fe) and some manganese (Mn) to strengthen the steel (Antonini et al.2005; Morini & Viti 2009). In terms of particles number per cubic centimetre, 80 % of the generated particles are below 30 nm.

We therefore designed a study aimed to expose mice to aerosols of NP representative of that found in welding fumes, in order to assess the respiratory effects of such NP. In this paper we describe the aerosolization system with particles 20 nm particles size of Iron and Manganese produced with a home made spark generator. Filtered dried and compressed air is used as carrier gas to produce oxides in the hot plasma. Electrodes (6 mm OD) of Mn and Fe from Goodfellow (99.99 % purity) are used. The aerosol produced by the spark generator is pushed in an inhalation chamber with a flowrate of 10 lpm. Two SS spark generators and two inhalation chambers have been designed for each metal to prevent contamination. Each spark chamber and each inhalation chamber is used for one metal aerosol.

The spark generator is characterized in terms of size distribution and stability with a TSI SMPS with a long DMA column. Morphology and chemical analysis of the particles are performed with TEM deposition system. A high resolution TEM equipped with a field emission gun and Xray energy was used. For chemical composition XEDS and Electron Energy Loss Spectrometry EELS measurements are programmed. The figures 1 and 2 gives the size distribution of Fe and Mn particles produced by our spark generator in air.

It has been proposed that the toxicity of low-solubility nanomaterials is mainly dependent of the specific surface area of the particles (Oberdörster *et al* 2005). There has also been an increased availability in instrumentation for measuring the surface area of small-sized airborne particles. There is, however, still questions on to what extent the surface area of structurally complex dust particles from powders can be measured and how these measurements differ from data converted from size distributions from mobility and aerodynamic particle classification. Finally it is uncertain whether there is a reliable link between specific surface area of bulk powders and the surface area of the airborne particles as well as filter-collected respirable dust. Such a link would be crucial for the potential use of data on powder materials as well as future strategies in work-place monitoring and procedures in risk assessment.

Dustiness test using the small rotating drum (Schneider and Jensen, 2008) has been used in order to simulate industrial use of powders and thereby classifying them for risk assessments. This method was used with six chemically and structurally different materials stretching over a range of specific surface area from 0.03 to 225 m^2/g to produce test aerosols. Direct measurements on surface area were done using a Nanoparticle Surface Area Monitor (NSAM 3550, TSI) and an Aerotrak (9000, TSI). Additional size distribution measurements were done using a Fast Mobility Particle Sizer (FMPS 3091, TSI) and an Electric Low Pressure Impactor (ELPI+, Dekati). All size distribution data was recalculated with alveolar deposition to fit surface area instruments before being changed into surface area concentration assuming spherical shape. Respirable dust was collected for gravimetric measurements and analysis of surface area by off-line Small Angle X-ray Scattering (SAXS). Additional sampling of collection plates were done for analysis with Scanning Electron Microscopy.

Initial experiments showed a good agreement over the whole range of surface area concentrations for the two different surface area measurement instruments used. Figure 1 shows the calculated surface area measured using FMPS plotted against that measured using the surface area monitors. Despite some important deviations from 1:1 correlation, the dust surface area measured using FMPS generally appears to correlate well with that of the surface area monitors, throughout the whole surface area concentration range. The general disagreement between the methods increases slightly at lower surface areas, e.g., for TiO_2 measured using NSAM. It can also be noted that the Aerotrak seems to compare best against the FMPS, with the NSAM systematically giving slightly lower measurements, especially for higher levels of surface area concentrations. Similar comparisons between instruments for surface area measurements and ELPI initially show a systematic error and feeble agreement.

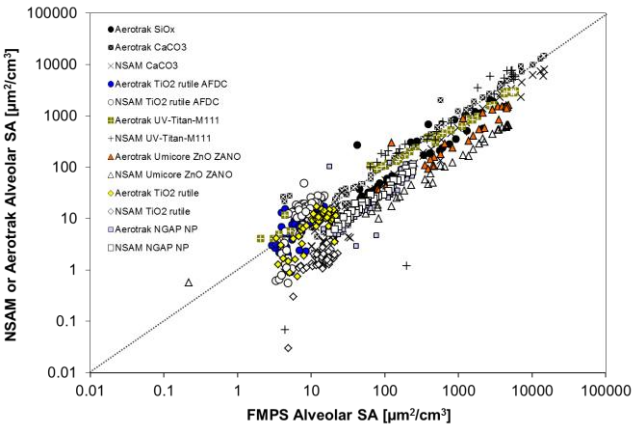

Figure 1. Correlation plot of time-series data on measured surface area using surface area monitors and FMPS. Dotted line indicates one-one correlation.

The administration of drugs directly into the respiratory tract has been used in a number of therapeutic area, including treatment of both lung and systemic diseases. The respiration of nano-sized particles gives some advantages with respect to the inhalation of micron-sized ones. First of all, the particles 10 to 20 nm in size deposit to the alveolar region about 4 times more efficiently than those of several microns in diameter. Moreover, the nanoparticles are easily transported across the membranes. In this paper we study the medical effect from inhalation of nanopaticulate nisoldipine (hypotensive drug) synthesized via the evaporation-condensation route. The male rats WISTAR and ISIAH were used as laboratory animals. The nose-only and whole body exposure chambers were used to study the inhalation effect. The chambers were designed and created in the Institute of Chemical Kinetics and Combustion, Russian Academy of Sciences.

The inhalation scheme includes a flow aerosol generator, inhalation chambers, filters, diluters, flow control equipment and aerosol spectrometer (Fig. 1). The evaporation - condensation aerosol generator consisted of a horizontal cylindrical quartz tube with an outer heater. Argon flow was supplied to the inlet and the aerosol was formed at the outlet. The particle mean diameter and number concentration were varied in the ranges 3 to 200 nm and 10^3 to 10^7 cm^{-3}, respectively, as measured by an Automatic Diffusion Battery. The Liquid Chromatography and X-Ray Diffraction methods were used to control the particle composition. The nose-only exposure chambers were used to determine the lung deposited dose and the particle deposition efficiency as a function of the mean particle diameter.

The medical effect was determined as the relative decrease of blood pressure P_i-P_f/P_i, where P_i and P_f are the blood pressures before and after inhalation (Fig. 2). The groups of five animals were used in each inhalation experiment. The inhalation time was 40 min. The mean diameter of inhaled particles is shown for each inhalation experiment.

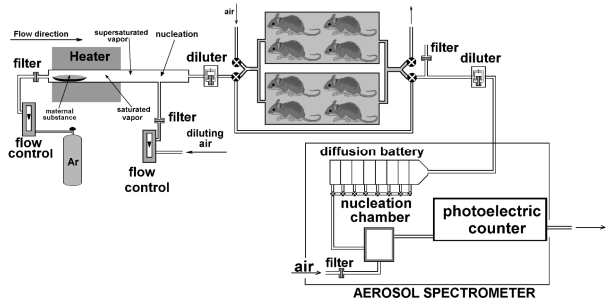

Fig. 1. Experimental set-up for inhalation experiments.

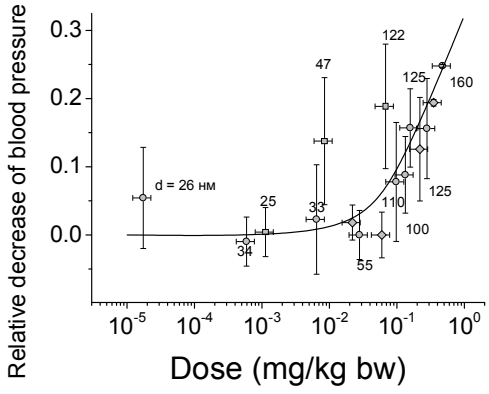

Fig. 2. Relative decrease of blood pressure vs. the inhaled or injected dose. Circles - inhalation (WISTAR), squares - inhalation (ISIAH), diamonds - injection (WISTAR).

Keywords: Indoor/outdoor particles, mass size distribution, chemical composition
Presenting author email: maskova@icpf.cas.cz

Aerosol particles are one of the major pollutants in outdoor and indoor air. They may negatively influence health, but also have negative effects on ecosystems and cultural heritage. Particulate matter (PM) can be harmful for works of art by causing soiling and chemical damage, depending on particle size and chemical composition (Hatchfield, 2005). The aim of this study was to investigate concentrations and sources of airborne PM in two types of indoor environment of the National Museum (NM): a) in an exhibition hall in the centre of Prague and b) in a depository in a small town Terezin.

The measurements have been done during two intensive campaigns and included particle number concentrations and size distributions determined by a Scanning Mobility Particle Sizer (SMPS 3936, TSI, USA) and an Aerodynamic Particle Sizer (APS 3321, TSI, USA). Both instruments sampled alternately from indoor and outdoor, covering the size range 14 – 20,000 nm. In NM Prague visiting hours took place every day from 10 am to 6 pm and the depository in NM Terezin is closed for public.

In the NM Prague the results showed visitors as a source of coarse particles and traffic in the outdoor environment as the most probable source of fine particles. In the NM Terezin the results indicated smoking in an adjacent office as an important source of fine particles. Average value for the indoor/outdoor ratio of the submicron particle number concentration had a maximum between particle diameters of 0.1 – 1 μm for both museums, which indicates a maximum penetration factor and low indoor deposition velocity of these particles. During a day windows in Prague were mostly opened which resulted in a higher penetration than in Terezin. During the visiting hours in Prague the average indoor concentration of coarse particles was even higher than outdoors, which confirmed visitors as a source of these particles (Fig. 1).

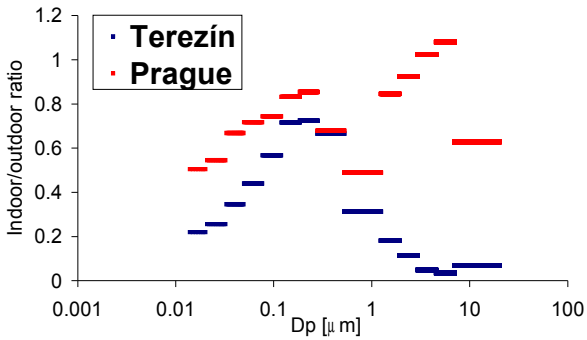

Figure 1. Indoor / outdoor ratios of particle number Concentration versus particle size in the NM Prague and Terezin.

Transport of particulate matter in the indoor environment of the National Library in Prague

J. Smolík[1], L. Mašková[1,2]

[1]Department of Aerosol and Laser Studies, Institute of Chemical Process Fundamentals ASCR, v.v.i.
[2] Charles University in Prague, Faculty of Science, Institute for Environmental Studies
Keywords: transport, particulate matter, indoor environment, brownian diffusion
Presenting author email: smolik@icpf.cas.cz

In order to determine sources of particulate matter (PM) inside the National Library in Prague, transport between indoor and outdoor environment, transport inside the Library and deposition on books and manuscripts, we measured size resolved particle number concentrations of PM using Scanning Mobility Particle Sizer (3936L, TSI, USA) and Aerodynamic Particle Sizer (3321, TSI, USA), sampling alternately indoors and outdoors of Baroque Library Hall. In parallel spatial distribution of PM was measured by four DustTrak instruments (8520, TSI, USA), located at different positions and heights inside the Hall. During the sampling air exchange rate was measured by Indoor Air Quality Monitor PS 32 (Sensotron, Poland) and size resolved PM was sampled with two Berner type Low Pressure Impactors (BLPI, 25/0.018/2, Hauke, Austria) for subsequent analysis. The deposition of particles on indoor surfaces was examined using Whatman filters located on the free shelf of the Library. All measurements were performed during three intensive campaigns in 2009.

The results showed, that visitors were the main source of coarse particles and atmospheric PM, penetrating from the outdoor environment, the main source of submicron particles. The average concentrations of size fractions 10 - 100 nm and 100 nm-1 μm of indoor PM were of the order 10^3 particles/cm^3 with quite uniform concentrations. The I/O concentration ratio had maximum at about 300 nm with the highes values observed during the winter probably due to higher air exchange rate caused by larger temperature difference between indoor and outdoor environment. The Ion Chromatography revealed that the major water-soluble inorganic component of indoor submicron particles was ammonium sulphate with maximum concentration also centred at 300 nm (Andělová *et al,* 2010).

The deposition experiments were focused predominantly on test if submicron particles can penetrate by diffusion between pages. For this purpose twelve bunches of Whatman filters, fixed in open Petri dishes, were placed on free shelf of Library. Bunches were gently loosed to increase the distance between filters and exposed for three, six, nine, and twelve months. Exposed filters were examined by Scanning Electron Microscopy (SEM) and Ion Chromatography (IC).

To estimate penetration of particles between filters and subsequent deposition on inner surfaces we modelled transport of particles as nonsteady Brownian diffusion between two parallel discs, put into the environment with constant particle number concentration 10^3 particles/cm^3. The diffusion equation was solved numerically for particle sizes 10, 100, and 1000 nm and gap between filters 1 and 5 mm. Simple model showed that submicron particles can penetrate by diffusion between two parallel sheets of filter, followed by deposition on filter surfaces. The particle penetration and deposition depended on particle size and width of the gap, with the depth of the penetration limited by parallel diffusional deposition on filter surfaces. Smaller particles penetrated faster and deeper resulting in higher particle number concentration of deposited particle but higher mass was transported by larger particles (Smolík *et al* 2011). SEM investigations of exposed filters showed variety of particles of all sizes deposited uniformly on the surface of the top (first) filters, and smaller particles deposited on subsequent filters with concentrations decreasing with the distance from the filter edge. Since up to 60% of mass of water-soluble part of indoor submicron particles was formed by ammonium sulphate (Andělová *et al* 2010), sulphate anion was used as a marker for deposited particles. Results of IC analyses, corrected for blank values, showed that the sulphate concentrations on all filters increased with time. Higher concentrations were found on top filters due to larger exposed area.

Conclusions

Measurements of indoor PM, performed in the National Library in Prague showed the main source of coarse particles were visitors and main source of submicron particles was atmospheric PM, penetrating indoors from the outdoor environment. The particles were uniformly distributed indoors and contained ammonium sulphate. Deposition experiments showed that submicron particles can penetrate into gaps between pages of books by Brownian diffusion.

Temporal evolution of pyrethroid aerosol concentrations after insecticide spray treatment in indoor atmosphere using a High Resolution Aerosol Time-of-Flight Mass Spectrometer (HR-ToF-AMS)

Aude Vesin, Nicolas Marchand, Etienne Quivet, Brice Temime-Roussel, Henri Wortham
Aix-Marseille Univ, CNRS, FRE 3416, Laboratoire Chimie Environnement, 13331 Marseille cedex 3, France
Keywords: pyrethroids, indoor atmospheres, HR-ToF-AMS, insecticide sprays.
Presenting author email: Nicolas.Marchand@univ-amu.fr

Providing high-time resolved monitoring of pesticide aerosol concentrations in the indoor atmosphere is necessary to accurately characterize the active substances behaviour after the use of household insecticide sprays. Due to the high time variability of the concentrations during these applications, the use of a high time-resolution instrument is relevant to supplement the state-of-the-art off-line methods (Berger-Preiss *et al*, 2009). Data on peak concentrations and kinetics are actually significant information in a perspective of human exposure evaluation.

The analytical method is based on the utilization of a High Resolution Aerosol Time-of-Flight Mass Spectrometer (HR-ToF-AMS) (Aerodyne Research), providing high-time resolved as well as size- and chemically-resolved on-line measurements of aerosols (Jimenez *et al*, 2003).

Materials/Methods

The HR-ToF-AMS, originally designed to measure the aerosol composition outdoors, provides chemical composition information about nitrate, sulphate, chlorine and total organic fractions. However, due to their known harmful health effects, it is found relevant to dissociate the contribution from the active substance relative to the additives to obtain precise concentration profiles of the pesticides alone. For that, the fragmentation tables were modified to follow pesticide concentrations alone instead of total organics.

Validation of this innovative data treatment is realized *via* the intercomparison of the HR-ToF-AMS pesticide concentrations obtained after fragmentation table modification with a more classical off-line sampling and analysis. Statistical analyses using the Chemical Mass Balance technique are also realised to validate data treatment.

Field measurements

Spraying experiments involving 5 different commercial insecticides containing permethrin, cypermethrin, tetramethrin, prallethrin, and/or piperonyl butoxide (PBO), mixed or not, were carried out under air exchange rate (AER) controlled conditions (around 0.5 h^{-1}) in a full-scale room, located in the "Mechanized house for Advanced Research on Indoor Air" (MARIA) experimental house, at the Scientific and Technical Center of Building (CSTB) research centre in Marne-la-Vallée, France. The insecticides were manually sprayed for 3 s. The air was monitored during and after application.

The presented concentration temporal profile (Fig.1) concerns a commercial spray containing permethrin, tetramethrin and PBO for which the peak concentrations are shown in Table 1.

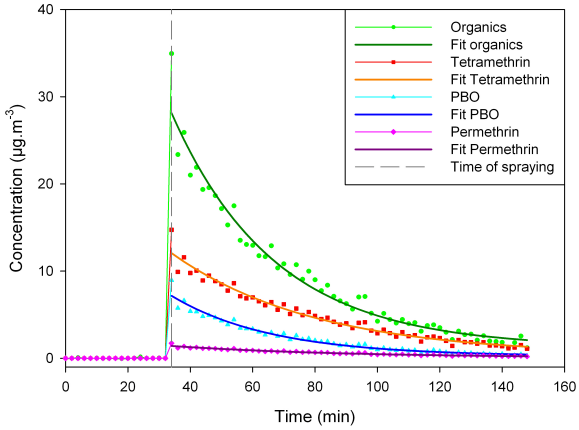

Figure 1. Concentration profiles after spraying

The time-dependent pesticide elimination kinetics is described in Eq. (1), assuming a well-mixed volume:

$$C(t) = C_{max}.e^{-K.t} \quad (1)$$

With t is the time (h), C(t) is the pesticide concentration (µg.m^{-3}), C_{max} is the maximum concentration (µg.m^{-3}), K is the elimination rate constant (h^{-1}).

Table 1. Characteristics of the temporal concentration profiles

	Peak concentration (µg.m^{-3})	Elimination rate constant (h^{-1})
Organics	35±6	1.8±0.2
Permethrin	1.7±0.3	1.1±0.2
Tetramethrin	15±3	1.3±0.2
PBO	9±2	1.9±0.2

The overall elimination rate constants (Table 1) are found to be far higher than the theoretical AER, therefore indicating that significant other elimination processes occur, such as particle deposition.

Particulate matter in school classrooms and outdoor air

C. Alves, T. Nunes, J. Silva, M. Duarte, C. Borrego

Centre for Environmental and Marine Studies (CESAM), Department of Environment, University of Aveiro, 3810-193 Aveiro, Portugal.

Keywords: indoor air quality, schools, PM_{10}, $PM_{2.5}$, OC/EC, water soluble ions.

celia.alves@ua.pt

EPA studies of human exposure to air pollutants indicate that indoor air levels of many pollutants may be 2-5 times, and occasionally more than 100 times, higher than outdoor levels. These levels of indoor air pollutants are of particular concern because it is estimated that most people, including children, spend as much as 90% of their time indoors. Over the past several decades, the exposure to indoor air pollutants is believed to have increased due to a variety of factors, including the construction of more tightly sealed buildings, reduced ventilation rates to save energy, the use of synthetic building materials and furnishings, and the use of chemically formulated personal care products, household cleaners, etc.

In January 2011, one kindergarten and eight elementary school classrooms were monitored (Table 1). The campaign included simultaneous measurements, indoors and outdoors, of comfort parameters, CO, CO_2 and particles. Automatic monitors using a light scattering technique were employed to measure PM_{10} continuously. During occupied periods, low volume samplers were used to daily collect $PM_{2.5}$ onto quartz fibre filters, which were subsequently analysed for carbonates, organic carbon (OC), elemental carbon (EC) and water soluble inorganic ions.

Table 1 School classrooms selected for the indoor air quality monitoring campaign in Aveiro, Portugal.

School	Characteristics	Nº of classrooms
Glória Elementary	Traffic City centre	3
Esgueira Elementary	Urban Residential	2
Esgueira Kindergarten	Urban Residential	1
Eixo Elementary	Rural	3

The daily average $PM_{2.5}$ concentrations obtained during the occupancy periods ranged from 44±5.0 μg m^{-3} to 111±16 μg m^{-3}. The highest values were obtained in the school with the highest occupancy rates. In addition, this school, located in a residential area, is the only one surrounded by an unpaved playground. Soil particles are tracked in on shoes or clothing from the outdoors, contributing to indoor-to-outdoor ratios (I/O) ranging from 1.8 to 3.2. I/O ratios between 1.5 and 2.0 were obtained in the other two schools, where comparable $PM_{2.5}$ concentrations have been measured. In the classroom with highest occupancy rates, the average PM_{10} levels for daytime and night-time periods were, respectively 362±84 and 111±36.9 μg m^{-3}. The corresponding $PM_{10}/PM_{2.5}$ ratios were 7.51±0.98 and 3.12±0.45. This suggests that high PM_{10} levels found in classrooms are probably due to resuspension of soil material or other coarse particles. The maximum concentrations coincided with the cleaning activities (Fig. 1).

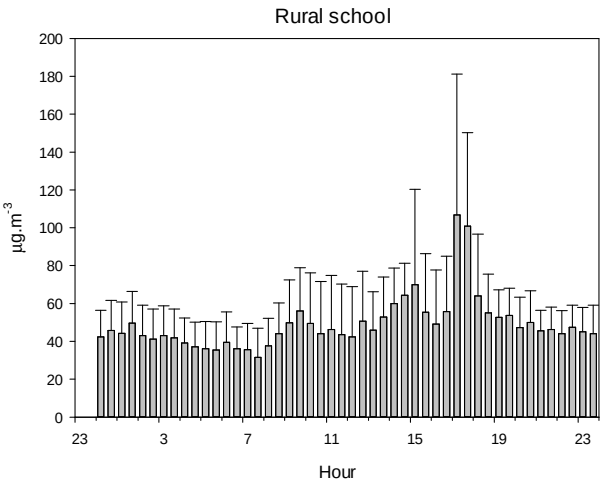

Fig. 1. Diurnal PM_{10} pattern in one of the classrooms.

The total of EC, OC and ions amounted to around 50% of the $PM_{2.5}$ in indoor air. A substantial contribution of calcium carbonate from chalk and/or soil dust to total particle mass was observed. Comparatively, the carbonate mass fraction in outdoor air is much lower.

CO_2 concentrations during school hours at a given day and classroom varied from 1300 ppm up to 7000 ppm, largely exceeding the limit of 1000 ppm stipulated in legislation. Regardless of classroom, the air exchange rates were not higher than 0.2 h^{-1}, showing an effective building tightness with closed windows that is responsible for the high levels of CO_2 and the extremely low outdoor air infiltration of not more than 0.4 L/s per person. The Portuguese legislation recommends a minimum outdoor airflow of 8.3 L/s per person.

This work was funded by the Directorate General for Health and Consumer Affairs (DG SANCO) through the "SINPHONIE - Schools Indoor Pollution and Health: Observatory Network in Europe" project.

Indoor and outdoor ultrafine particle characterisation in primary schools in Barcelona

Presenting author email: mar.viana@idaea.csic.es

Major knowledge gaps exist currently regarding the health hazardous effects of exposure to fine and ultrafine atmospheric particles of outdoor and indoor origin, in indoor environments. This is especially true for specific risk groups such as children. The early school years are considered an important window for brain development, but also a long period of vulnerability given that susceptibility to environmental threats is elevated.

Recently, research interest has been directed towards ultrafine particles (UFPs, particulates with aerodynamic diameter <0.1 μm). Epidemiological studies (Donaldson *et al.*, 2001) indicate that UFPs may have an even greater potency to cause adverse health effects than larger particles, given that they have increased deposition rates in the lower respiratory tract. UFP are enriched in organic carbon content as well as prooxidative polycyclic aromatic hydrocarbons (PAH) that promote oxidative stress and inflammation. There is little information on the trend in UFP in European urban atmospheres, but the increased load of diesel vehicles and recent data (Wichmann, 2000) suggest an upward trend.

Population exposure to both supra- and sub-micron particulate concentrations is usually considered to take place in outdoor environments. However, it is estimated that on average adults spend 60-90% of their time indoors. In the case of children, already 30% of their time is spent indoors during school hours, independently of other indoor environments.

While most of the available studies on UFP focus on particle mass, there is still very little information on the indoor/outdoor relationship for other parameters such as chemical composition and emission sources. The main goal of the present work is to characterise child exposure to chemically-characterised ultrafine particles of outdoor and indoor origin in schools, with special attention to the influence of outdoor emission sources (e.g., vehicular traffic) on indoor air.

To this end, indoor and outdoor sampling of UFP concentrations is currently being carried out at 38 primary schools in Barcelona, within the framework of the ERC Advanced Grant BREATHE. UFP are sampled by means of PCIS impactors (Sioutas Personal Cascade Impactors), using 37mm and 25 mm Pall quartz-fibre filter substrates. Three cut-off sizes are used: >$PM_{2.5}$, $PM_{0.25\text{-}2.5}$, and $PM_{0.25}$. The sampling duration is 8 hours per day (9-17h, school hours) over 4 consecutive days, amounting to a total of 32 hours per filter. The flow is set to 9 lpm. The cascade impactors will provide detailed information on the chemical composition of ultrafine particles (particle size <0.25 microns). The chemical characterisation will be complete (>65 elements and components determined). The meteorological variations between sampling days at different schools will be accounted for by analysing indoor/outdoor ratios, in addition to absolute particle concentrations. The ventilation conditions (e.g., open or closed windows) will also be taken into account.

Because of the large number of schools targeted (38 schools), preliminary results available at this moment refer mainly to the optimisation of the experimental setup (the results on the chemical characterisation of indoor and outdoor UFPs will be presented at the conference). Numerous sampling durations were tested in order to determine the minimum number of hours necessary to achieve enough UFP mass for the analytical determinations (32 hours). A custom-made mobile sampling unit was devised (Figure 1), to ensure instrument mobility and minimise noise-effects (sampling is carried out inside the classrooms filled with children). Laboratory procedures were also optimised and adjusted to the low UFP mass collected on the filters.

Figure 1. Mobile sampling unit for indoor and outdoor environments.

Introduction

Buildings in the developed countries are becoming increasingly airtight as a response to more strict energy efficiency requirements. These changes are likely to have impacts on exposure to indoor air pollutants in residential buildings. The indoor/outdoor (I/O) particulate matter (PM) ratios vary considerably due to the difference in size-dependent indoor PM emission rates, the geometry of the cracks in building envelopes, and the air exchange rates.

INSULATE project aims to assess of the impacts of building renovation on indoor air quality (IAQ). In the first stage of the project activities, the concentrations of PM together with other parameters were assessed before building renovation. In this study, the variations of particulate matter were presented as an average PM2.5 and PM10 mass and number concentrations in five buildings (Table 1).

Methods

Field studies are in process in two European countries (Finland and Lithuania), including 20 multi-family buildings per country. Five multifamily buildings have been measured in Kaunas city so far (approximately five apartments per building).

Measurements of size segregated PM were performed using the Lighthouse Handheld 3016 IAQ Optical Particle Counter (OPC, 6 channels, in a range of 0.3-10 µm). PM measurements were carried out both inside (preferable living room) and outside of the residence (e.g., balcony), OPC units were located at the same location during entire measurement period. Sampling duration in one apartment was approx. 24 hours, with a 1-minute measuring resolution for both indoor and outdoor PM measurements. Particle mass concentrations were calculated based on particle density of 1.5 g/cm^3.

Results

The calculated average PM2.5 and PM10 levels revealed substantial difference among different buildings (Table 1). The outdoor PM2.5 and PM10 concentrations were approximately 2 and 1.5 times higher compared to indoor concentrations. In 3rd and 4th building the highest PM concentrations were observed compared to the other buildings. This was likely influenced by changes in outdoor climatic conditions, namely, decreased temperature. Therefore, PM concentrations were likely to be influenced by biofuel burning in residential homes. During this measurement campaign outdoor PM2.5 mass concentration for each of the five buildings (outside of five apartments) ranged from 10.2±2.4 to 20.8±5.5, 10.2±4.3 – 19.9±4.8, 18.5±5.2 – 40.3±19.9, 29.5±5.7 – 49.2±14.8 and from 7.3±3.2 to 11.4±5.2 µg/m^3, respectively. PM10 mass concentrations varied in a similar pattern to PM2.5. Based on these data, spatial distribution of outdoor PM2.5 and PM10 mass concentrations were observed depending on the location of each apartment in the building, taking into account the proximity of streets.

Table 1. Daily indoor and outdoor particle mass concentrations of PM2.5 and PM10 in five Lithuanian multifamily buildings (average of 5 apartments).

	IN, µg/m^3		OUT, µg/m^3	
Building	**PM2.5**	**PM10**	**PM2.5**	**PM10**
1	9.8±1.7	19.6±2.6	15.9±4.5	20.8±5.3
2	4.9±1.7	17.4±13.5	14.6±4.5	27.4±1.7
3	12.9±4.1	22.0±8.9	30.0±10.3	36.0±12.1
4	18.1±9.6	23.1±9.5	37.0±9.9	55.8±19.4
5	6.4±4.5	14.3±8.6	9.4±2.1	13.1±2.8

Similarly to mass concentration, the highest number concentrations (PNC2.5) were assessed during measurement campaigns of buildings 3 and 4. Outdoor particle number concentrations ranged from 97.1±27.2 to 271.2±72.1 #/cm^3 for buildings 5 and 3, respectively.

Table 2. PNC2.5 number concentrations variation in five multifamily buildings (indoor and outdoor), expressed as # of particles per cm^{-3}.

Building	IN, #/cm^3	OUT, #/cm^3
1	95.4±20.2	159.2±39.6
2	51.6±17.8	130.9±58.5
3	135.7±22.7	271.2±72.1
4	204.6±115.4	264.2±35.2
5	58.0±24.1	97.1±27.2

Personal daily exposure of children to ultrafine particles and black carbon

C. Vargas Trassierra[1,2], S. Marini[1], L. Stabile[1], A. Russi[1], F. Fuoco[1], G. Buonanno[1],

[1]Dept. of Civil and Mechanical Engineering, University of Cassino and Souther Lazio, Cassino (FR) 03043, Italy

Keywords: children exposure, personal monitoring, ultrafine particles, black carbon
Presenting author email: c.vargas@unicas.it

Epidemiologic evidence indicates a relationship between particle pollution exposure and adverse respiratory and cardiovascular health effects, including decreased lung function, asthma, myocardial infarction and all-cause mortality (Brunekreef and Holgate, 2002). In general, the smaller the particle size, the greater its ability to penetrate into the lungs and thus to produce adverse effects on human health. For this reason, sub-micrometer particles and even more UFPs (diameter < 0.1 μm), show higher health care interest than other particle sizes. Anyway, while there is considerable toxicological evidence of potential harmful effect of UFPs on human health, epidemiological studies are still not sufficient for conclusions on the dose-response relationship concerning this aerosol fraction (WHO, 2005).

This study, which falls within the UPTECH international project, deals with the children's personal exposure assessment to UFPs and black carbon. BC was used as an indicator of exposure to diesel exhausts whose negative health effects (short and long-term cardiovascular, respiratory and neurodegenerative health effects) were reported in Baja et al., 2010; McCracken et al., 2010.

We considered children because they represent the most vulnerable group with regard to harmful effects of airborne particles exposure. This is due to: i) the higher dose of UFPs as function of the children lung size compared to adult one; ii) their developing organs and immunological system.

Air quality can be measured at four different spatial scales: i) “city scale”, the broadest and most common scale used to characterize air quality across several city blocks using remote measurements; ii) “outdoor scale”, representative of outside building grounds particle exposure; iii) “indoor scale”, within building rooms reflecting indoor-based exposure; iv) “personal scale”, using hand-held instruments carried as a personal monitor in order to assess their actual exposure.

The daily overall children exposure is dominated by particle concentration levels in three main microenvironments: home, school, and transport mode. Therefore, children attending the same school, can receive different doses.

In the present work personal exposure measurements were performed on a sample of about one hundred children aged 8 to 11 years who attend three schools (S_1, S_2, S_3) in Cassino (Italy). S_1 is a primary school located on traffic urban street; S_2 is a secondary school close to intersection of moderate and heavily trafficked urban street; S_3 is a primary school located in a rural area far away from urban traffic.

The personal exposure was monitored through: two hand-held particle counters (NanoTracer, Philips) and one BC monitor (Aethalometer-microAeth Model AE51, MageeScientific). These monitors have a high temporal resolution (1÷16 s for NanoTracer, 1 s ÷ 5 min for Aethalometer), are small and portable (750 g and 250 g, respectively) and do not require special training to use.

NanoTracer, which works by diffusion charging, is able to provide number concentration (in the range 10-300 nm), average particle diameter, and lung deposited surface area concentration measurements. An electrometer measures the current induced by previously charged particles collected on a filter inside a Faraday cage. The device is also able to evaluate the different fractions of the lung deposited surface area through a semi-empiric algorithm implemented by Marra *et al*., 2010.

The Aethalometer detects the changing optical absorption of light transmitted through an internal small teflon-coated borosilicated glass fiber filter where BC-particles are captured.

We monitored children for 24-h, they also filled in a diary reporting the main indoor and outdoor activities (such as studying, eating, transportation, sleeping), also indicating the length of each activity.

From data collected by NanoTracers it was found that school contribution on daily exposure to UFPs is about 15%-20%, with an average particle number concentration in the range $1.5\times10^4 – 5.3\times10^4$ part. cm^{-3}. The highest exposure intensity was measured during lunch time with a contribution of about 20% and particle number concentrations in the range 4.2×10^4-1.9×10^5 part. cm^{-3}.

For BC, as expected, the most contributing activity to personal exposure is transport with an average exposure of 12.4 μg m^{-3}, while lowest average exposure was found at home (4.4 μg m^{-3}).

Abstract

In conventional inhalation risk assessment, risk is assumed to be a function of hazard and exposure, where the potential hazard is expressed as a function of exposure in mass concentration. However, ultrafine particles (UFPs) are considered to be the most harmful fraction as concerns inhalation uptake (Seaton *et al* 1995). Thus, in the inhalation exposure assessment, size-fractioned concentrations fanging from around 10 nm to 10 μm are needed to estimate quantitative exposure. The exposure data should cover also particle number and surface area dose estimates so that dose-response relations of UFPs can be estimated.

Methods

In this study, we measured with airborne particle concentrations in TiO_2 production plant from following processes: jet milling, hammer milling, pelletizing, and packing. The concentrations were measured with mobility analyzers (SMPS, SMPS+C), aerodynamic analyzers (ELPIs), particle counters (CPCs), real-time mass analyzer (TEOM), and optical instrument (Dust Monitor 1.109). Particle samples were collected from air for electron microscopy analysis. The workers inhalation doses were analyzed as described in Koivisto *et al* (2012), where the workers regional inhalation dose rates was estimated by using the ICRP lung deposition model, and active surface area and mass concentrations were defined from the measured particle size distributions by using the particle mobility diameter and effective density.

Results

By interpreting particle size distribution time series and activity, we identified concentrations originating from combustion sources (soot) and manufacturing processes (H_2SO_4, TiO_2). Converted values were compared with the measured mass and active surface area concentrations. Figure 1b shows that forklifts and pressurized cleaning caused peak particle and mass concentrations respectively over 10^5 cm^{-3} and 1 mg m^{-3}. Mass concentration in Figure 1b correlates nicely with high coarse particle concentrations (Figures 1a and 1c). The workers total dose rates without use of respirator varied in particle number, active sirface area and mass form $0.2 \cdot 10^9$ to $5 \cdot 10^9$ particles min^{-1}, $0.8 \cdot 10^6$ to $20 \cdot 10^6$ μm^{-2} min^{-1}, and 1 to 50 μg min^{-1} (Figure 1d).

Conclusions

This study helps us understand the magnitude of the dose occurring in industry. It provides fundamental data for inhalation exposure risk assessment, regulations, dose metrics, the basis for defining metrics of dose-biological response. For risk assessment, the toxicity of particles should be known.

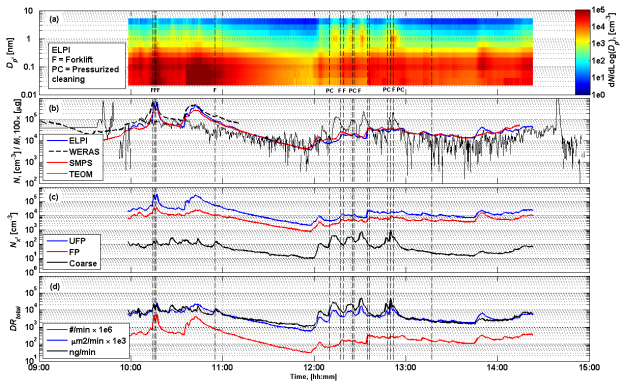

Figure 1: Packing of TiO_2 material: particle size distributions (a), particle and mass concentrations (b), fractions of UFP, FP and coarse particles (c), and dose rates (d). Figures (c) and (d) were calculated from particle size distributions in (a). Effective density was assumed to be 1 g cm^{-3}.

Semi-volatile partitioning effect on indoor PM: inorganic ions and PAHs.

G. Sangiorgi[1], M.G. Perrone[1], L. Ferrero[1], C. Lo Porto[1], B. Ferrini[1], S. Petraccone[1]

[1]Department of Environmental Sciences, University of Milan - Bicocca, Milan, I-20126, Italy
Keywords: indoor aerosols, gas-particulate partitioning, PM1, PM2.5.
Presenting author email: giorgia.sangiorgi1@unimib.it

The toxicity of PM is stronger for the fine particles and when are present species like PAHs and elements (Delfino *et al*, 2008; Saldiva *et al*, 2002). A little attention has been dedicated to the study of PM in offices, despite they are one of the most common workplaces all over the world.

The aim of the research was to investigate the PM1 and PM2.5 in four offices of Milan (Italy) and in the corresponding outdoor air, in order to highlight the changes of PMx composition. The offices were chosen because of their few and weak indoor sources of PM (i.e. computers, printers and photocopier machines). Smoking was forbidden, air supply systems were absent and the people movement was limited.

24-h PM1 and PM2.5 samples were collected simultaneously indoor and outdoor during two sampling campaigns (aug-oct 2007, jan-mar 2008). The concentration of inorganic ions and Polycyclic Aromatic Hydrocarbons (PAHs) were determined.

The indoor PMx level was 50-70% of the outdoor one: the indoor concentrations were always lower than outdoor, as expected from the low contribution of PM indoor sources.

The indoor (C_{in}) and outdoor (C_{out}) concentrations of PMx and of a particle-bound compound can be linearly related to roughly separate the indoor contributions due to 1) the outdoor fraction that enter indoor (infiltration factor, F_{INF}) and 2) the indoor-generated particle concentration C_{ig} (Hänninen *et al*, 2004):

$$C_{in} = F_{INF} * C_{out} + C_{ig} \qquad \text{(eq.1)}$$

For the analyzed chemical species, C_{ig} produced always negative or near zero values; comparing to the average indoor concentrations, it was <20%.

Table 1. Data of the measured infiltration factors, F_{INF}.

Season	PM1	PM2.5	NO_3^-	SO_4^{2-}	NH_4^+	4-ring PAHs	5-ring PAHs	6-ring PAHs
warm	0.49	0.50	0.19	0.95	0.45	0.92	0.88	1.17
cold	0.60	0.58	0.15	0.86	0.46	0.44	0.46	0.72

F_{INF} (Table 1 and Figure 1) showed the following patterns: I) the non-volatiles (i.e., SO_4^{2-}, present in the form of $(NH_4)_2SO_4$) had about the same F_{INF} during the two campaigns (~0.90); II) the semi-volatile inorganic compounds (i.e., NH_4NO_3) had always very low F_{INF} (NO_3^- ~0.17, NH_4^+ ~0.45); III) the semi-volatile organic compounds (PAHs) had a strong decreasing F_{INF} passing from the warm (~0.96) to the cold (~0.51) season.

When passing from outdoor to indoor, typically the temperature increases, most of all during winter. A semi-volatile molecule will tend to partition more on the gas phase, a process also favoured by the adsorption of the gaseous compounds onto the indoor surfaces (Weschler and Nazaroff, 2008). This effect was observed during the described campaigns.

It is likely that the real F_{INF} of the three inorganic ions was the same and close to the one of SO_4^{2-}, but once indoor a high portion of NH_4NO_3 rapidly had passed in the gaseous phase, thus reducing its particulate concentration and F_{INF}. Since the high vapor pressure of NH_4NO_3, a large fraction of NO_3^- suffered this process, whereas only the particulate NH_4^+ present as NH_4NO_3 passed in the gaseous phase.

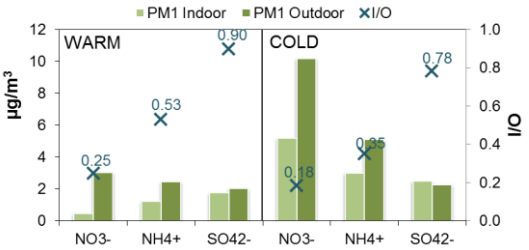

Figure 1. PM1 concentrations and indoor to outdoor concentration ratios of inorganic ions.

For all the PAHs, it was observed a decreasing F_{INF} passing from the warm to the cold season. This was likely due to the stronger difference of temperature between outdoor and indoor during winter.

The different seasonal trend of F_{INF} for the inorganic ions and PAHs could be explained by considering the very high vapor pressure of NH_4NO_3 ($3x10^{-3}$ mmHg) compared with the PAHs ($<4.5x10^{-6}$ mmHg): a very little increasing in the temperature could affect the ammonium nitrate, but not the PAHs partitioning equilibrium.

The results of the research confirm that a semi-volatile compound tend to redistribute in favor of the gas phase when entering indoor, where the conditions are warmer. Taking into account the semi-volatile partitioning effect, a change of the eq.1 is proposed.

Introduction

Children spend significant part of their time in schools. Therefore, indoor air quality affects children's health and ability to learn (Heinrich, J., 2011). Indoor air pollution and its control receiving increasing attention from scientists, health specialists, administrators and policy makers (Mejia et al., 2011).

Particulate matter (PM) is one of the most important air pollutants in indoor air. PM concentrations are regulated by mass concentrations in fractions $PM_{2.5}$ and PM_{10}. Diurnal variations of PM concentrations usually represent the daily school activities, while nighttime concentrations may represent the contribution of PM from outdoor environment.

Methods

The particulate matter was analyzed in indoor air in Kaunas primary school during winter time of 2011/2012. The indoor particulate matter were measured at five schools: School #1 representing residential multi-family apartment building area; School #2 representing residential multifamily apartment building area with heavy industrial influence; School #3 representing residential area, School #4, representing city center with heavy traffic, School #5, representing single family building residential area. All of these sampling sites representing different areas of Kaunas city. $PM_{2.5}$ and PM_{10} concentrations of indoor PM fractions were investigated during analysis period.

PM concentrations were measured using the Lighthouse Handheld 3016 IAQ Optical Particle Counter (OPC, 6 channels, in a range of 0.3-10 μm). PM measurements were carried out inside the classrooms, for five days in one sampling site. PM concentrations were logged with 1-minute resolution.

Results

The calculated 12 hour (6 am-6 pm) mean $PM_{2.5}$ and PM_{10}concentration in Schools are presented in Table 1. During the daytime $PM_{2.5}$ concentration comprised 12-16% of PM_{10} concentration, while during nighttime this contribution has reached 30-50%. The highest difference between $PM_{2.5}$ and PM_{10} concentrations was observed in School #4.

The concentration of $PM_{2.5}$ during day time was 2 – 3 times higher than night time. For PM_{10} differences between day time and night time was about 4 – 12 times. The highest differences were observed in School #5.

Table 1. The calculated 12 hour (6 am. - 6 pm.) mean $PM_{2.5}$ and PM_{10} concentrations in schools.

	Day time		Night time	
	PM2,5	PM10	PM2,5	PM10
School #1	13,28±2,80	38,88±33,30	16,35±4,14	19,63±4,78
School #2	6,88±3,88	50,95±47,62	4,62±20,7	13,87±10,28
School #3	11,19±2,19	78,69±47,89	6,32±0,96	10,22±8,72
School #4	23,11±6,17	178,86±99,76	11,99±4,04	31,68±29,48
School #5	9,70±3,98	58,14±40,27	3,15±0,79	4,67±1,61

5-day averaged $PM_{2.5}$ and PM_{10} concentrations in investigated schools during the sampling period are presented in Fig. 1.

The highest PM concentration in both fractions was measured in sampling site #4, which represents city center. Short-term PM_{10} concentration in schools #3, #4, #5 reached more than 100 $\mu g/m^3$.

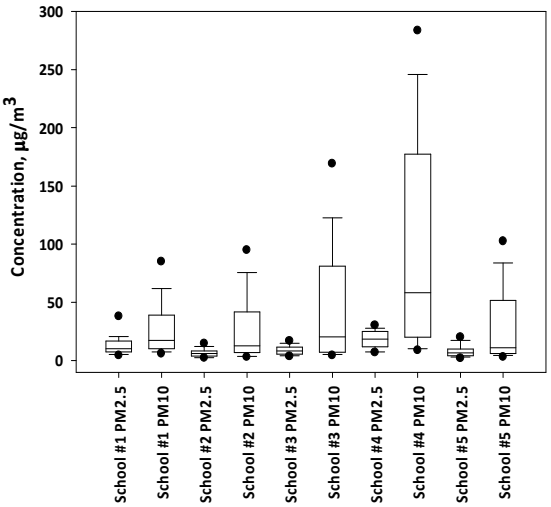

Fig. 1. Daily $PM_{2.5}$ and PM_{10} concentrations in schools of Kaunas, Lithuania. Median, interquartile range, 5th and 95th percentille and extremes are presented of 5-day data registered with 1-minute resolution.

Biomass burning source: Indoor - Outdoor comparison

Andriani E. [1], Dambruoso P. [1], de Gennaro G. [1], Demarinis Loiotile A[1], Di Gilio A. [1], Marzocca A.[1], Mazzone A. [1], Palmisani J. [1] and Tutino M. [1]

[1]Department of Chemistry, University of Bari, Bari, Apulia Region, 70126, Italy
Keywords: biomass burning, indoor, outdoor, particulate matter
Presenting author email: annalisa.marzocca@uniba.it

On the global scale, biomass burning represents an important source of atmospheric aerosols and greenhouse gases and, in recent years, the growing interest about biomass burning is due to its adverse effects on human health. In fact extensive studies (Nussbaumer, 2003) show that biomass combustion is responsible for high emissions of fine and ultrafine particles which are associated with increased morbidity and mortality. Therefore, more attention should be direct to the indoor biomass burning emissions. Exposure to indoor air pollution, especially to particulates, resulting from biomass burning (wood, charcoal, crop residues) has been implicated as a casual agent of respiratory and eye diseases. These effect are attributed to biomass burning sources, in particular to high levels of pollutants detected in indoor air when there is a fireplace.

The aims of this study are the chemical characterization of PM10 aerosols under the influence of biomass burning emissions and the assessment of the impact of this source on the levels and chemical composition of PM10, both outdoor and indoor environments. In particular, the impact of biomass burning source on the levels and chemical composition of PM has been evaluated in terms of PM10, metals, Polycyclic Aromatic Hydrocarbons (PHAs) and organic and elemental carbon (OC and EC) concentrations, by analysis of samples collected at a few meters from plume of a bonfire. The results of this monitoring have shown that the PM10 concentration (2164 ug/m^3) was about fifty times higher than PM10 collected at background site in no event conditions, and high concentrations of OC, K and PAHs, were observed. The analysis of collected data showed the relevance of organic and inorganic tracer species for interpreting the impact of biomass burning source on PM levels and allowed to determine diagnostic ratio for biomass burning sources. Moreover, higher OC, K and PAHs concentrations were determined in outdoor environments when combustion sources there were. In fact during an outdoor monitoring campaign in Apulia Region it can be possible to confirm that a little town in Apulia region denominated Torchiarolo and characterized by only agricultural activities, was not a regional background site such as it was defined by air quality network. The analysis of the sample collected at Torchiarolo site and trends of PM10, OC, EC, BaP and K concentrations (Fig.1) suggested the presence of an important local pollution sources. Moreover, as shown in Fig 2, PM10, OC and EC, K and PHAs concentrations at Torchiarolo were much higher than an other regional background site in Apulia Region; suggesting the relevance of biomass-burning sources in this area (Amodio et al, 2011), probably due to the presence of a great number of fireplaces used to domestic energy.

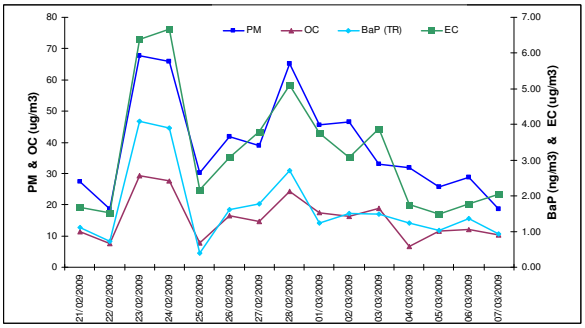

Fig.1: PM10, OC, EC, BaP concentration at Torchiarolo site

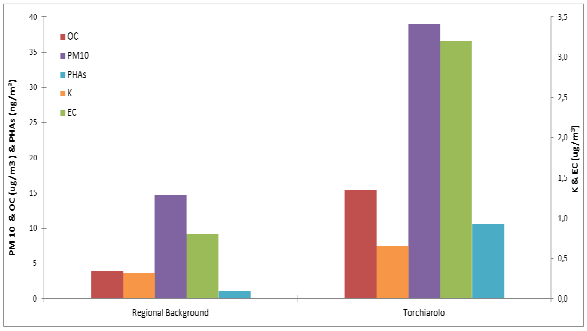

Fig.2 Comparison between two regional background sites in Apulia Region

Finally, the air quality of five houses where there was a fireplace, has been monitored. Every monitoring campaign was performed for three days and PM2.5 and PM10 concentrations have been determinated. The number concentration of fine and ultrafine particles has been detected by a optical particle counters (OPC) and a FMPS (Fast mobility Particle sizer), in order to obtain their dimensional distribution. The chemical characterization of samples was performed in order to determine elements, PAHs, OC and EC.

The preliminary information collected during these monitoring campaigns has allowed to evaluate the impact of biomass burning sources and in particular of fireplaces, on indoor air quality and the chemical composition of PM which people is mainly exposed.

Comparison of nasal deposition efficiency between Taiwanese and Caucasian adults

Y.M. Sun[1], C.W. Lee[2] and D.J. Hsu[2]

[1] Department of Occupational Safety and Health, Chung Hwa University of Medical Technology, Tainan 717, Taiwan

[2] Department of Safety, Health and Environmental Engineering, National Kaohsiung First University of Science and Technology, Kaohsiung 811, Taiwan

Keywords: Deposition efficiency, Human nasal passage, Nanoparticles.

Presenting author email: swimming@mail.hwai.edu.tw

Numerous studies on the removal efficiency of inhaled particles in the nasal region have been performed in the past decades, by using either replicate casts or human volunteers (Hsu and Chuang, 2012). Many empirical equations were also developed to characterize the deposition efficiency in this region. However, most of those studies were primarily based on a limited number of white male subjects (Kim and Hu, 2006). Kesavanathan and Swift (1998) pointed out that nasal anatomic and dimensional factor are important in determining the amount of deposition in the nasal passage and that particle deposition data from a demographically diverse group is important. An anthropometric study in Taiwan indicated that Taiwanese have a shorter craniofacial depth (i.e., distance between glabella and occiput) and longer craniofacial width (i.e., distance between two tragi) than Americans (Yu et al., 1996). Another US study suggested that Chinese workers have shorter face length, longer face width and smaller nose protrusion than Americans (Du et al., 2008). These differences in facial features are likely to affect the anatomical structure of the upper respiratory tract and, consequently, the characteristics of particle deposition in this region between the two ethnic groups. Thus, the experimental data of particle deposition in the respiratory tract reported previously will be less applicable to the Asians if the nasal particle deposition is different between two ethnic groups.

Four Taiwanese and two Caucasians adults were recruited to obtain the computed tomography (CT) scans of their respiratory tract extending from nostril/mouth to trachea. The images of the CT scans were used to build the 3D computer model. Then, based on the 3D computer models, the airway models were constructed with epoxy by a rapid prototyping machine (Sony Manufacturing Systems America, Inc., Lake Forest, CA, USA, Model SCS-8000). The human respiratory flow rates of 5, 10, 15, and 20 LPM were used and the particle sizes studied ranged between 14~500 nm. The particle size and number concentrations were measured by a Scanning Mobility Particle Sizer (SMPS) (TSI Inc., Shoreview, MN, USA).

Our results showed the deposition efficiency decreased with the increasing flow rate, and this trend conforms with the published data. Additionally, Figure 1 shows the deposition efficiency of both ethnic groups and Taiwanese adults had higher deposition efficiency than Caucasians. An empirical equation for Taiwanese adults was developed and is shown as follows:

$$\eta = 1 - \exp\left(-12.51 D^{2.970917}\, Q^{-0.40598} \right)$$

where D is the diffusion coefficient and Q the respiratory flow rate. The present study concludes that nasal structures is critical for nasal deposition and in vivo studies on Taiwanese adults should be conducted in the future, so as to provide the basis for the health risk assessment of exposure to particles

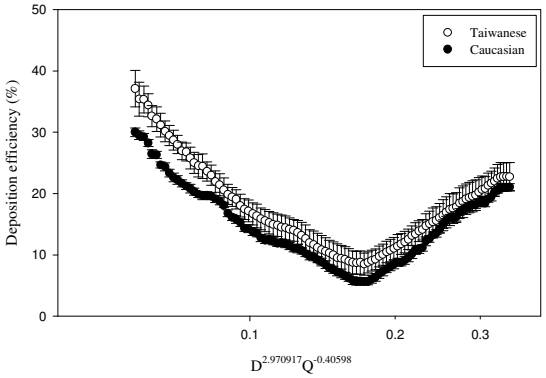

Figure 1. Comparison of nasal particle deposition efficiency between Taiwanese and Caucasian adults.

Lung deposition of charged aerosol particles – particle characterisation and experimental setup for a human volunteer study

M.D. Wright[1], M.F. Biddiscombe[2], J.C. Matthews[1], S.R. Underwood[2], D.L. Henshaw[1], O.S. Usmani[2] and D.E. Shallcross[1]

Presenting author email: matthew.wright@bristol.ac.uk

Electrostatic charge may increase particle deposition in the lung upon inhalation (Melandri *et al*, 1983), possibly leading to increased health risks associated with particulate matter. This study seeks to determine whether 100 nm and 200 nm particles which carry excess electric charge, compared to ambient charge-neutralised particles, show enhanced lung deposition efficiency in healthy human volunteers. The outcomes will help to determine the viability of the 'corona ion hypothesis' linking proximity to overhead high-voltage power lines with increased risk of childhood leukaemia (Fews *et al*, 1999) and will also provide important results relevant to the delivery of charged aerosol drugs to the lung.

The study comprises a characterisation stage, currently underway, and a human volunteer clinical study, planned for mid-2012. Figure 1 shows the basic experimental setup. We produce carbonaceous particles radiolabelled with ^{99m}Tc with Technegas (Cyclopharm) using the preparation method of Möller *et al* (2006), and apply increased charge using a corona charger. Enhanced deposition, or a change in the location of deposition, due to particle charge will be identified in a human volunteer study (8 volunteers, 4 study visits each) by direct comparison of inhaled and exhaled particle concentration using Mobility Particle Sizers (Grimm) and Electrical Low Pressure Impactor (Dekati), and via gamma scintigraphy (Usmani *et al*, 2005). We focus on particles of size 100-200 nm, since this is below the size range used in previous volunteer studies of charged particle deposition (Melandri *et al*, 1983). It is also the size range in which particles ordinarily deposit least efficiently within the lung, therefore the potential for electrostatic effects to enhance deposition is maximised.

The Technegas particle size distribution and charge at the output of the device and in the delivery system must be properly characterised to determine the expected dose (number and activity) received by volunteers. Typical number and mass size distributions, and total number concentration and mean particle diameter obtained each minute after actuation of the Technegas generator, are shown in Figure 2. To obtain the smaller particles, the generator chamber must be flushed into a dilution chamber soon after actuation, whereas for larger particles a holding period inside the generator is required to allow the particles to grow through coagulation, although number concentration drops significantly. Number concentration varies from run to run, with typical peak concentrations in the range 1-2 × 10^7 cm^{-3} (mass 1.5-5.0 mg m^{-3}) but the shape of the distribution is similar. The repeatability of the Technegas generator in producing particles of a given size distribution shape is good, but there is some variability in particle number concentration, with implications for possible received ^{99m}Tc dose to patients. Particle size distributions and electric charge states throughout the delivery system, including for the first time the incipient charge state of Technegas particles, along with further details of the clinical study, will be presented.

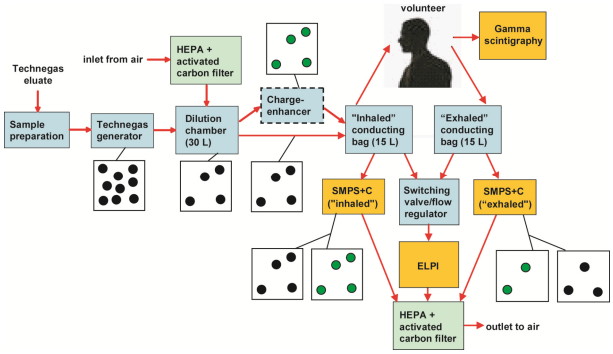

Figure 1. Schematic outlining the experimental setup for the human volunteer clinical study.

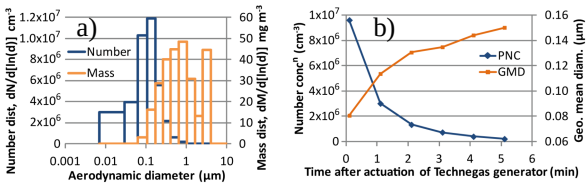

Figure 2. a) Number and mass distributions for Technegas particles, and b) number concentration and mean diameter evolution with holding time.

Theoretical and experimental investigation of aerosol deposition in realistic human airway model

A. Kerekes, A. Nagy, A. Czitrovszky

Wigner Research Centre for Physics of the H.A.S., Institute for Solid State Physics and Optics, Budapest, 1121 Hungary

Keywords: laser Doppler anemometry, aerosol deposition, human airway, breath simulator.

Presenting author email: kerekes.attila@wigner.mta.hu

In vivo measurement of the parameters related to transport and deposition of inhaled aerosols within the airways is quite problematic. Although some imaging techniques (MRI, CT, gamma camera, SPECT) can provide useful information regarding particle deposition there are both ethical issues and technical barriers (insufficient resolution, inappropriate size etc.) that hamper their systematic and efficient use. In contrast, in vitro experiments are more suitable, holding less risk and being more cost effective. Similarly, computational techniques are available to anybody. Imre Balásházy's research group has conducted computer simulations to study the fate of the particles after their inhalation. They have participated in the development of the Stochastic Lung Model, which is one of the best known whole respiratory deposition models in the world. They have applied the model to compute regional and generation number specific particle deposition fractions for different breathing parameters and particle characteristics [1-4].

In addition to the advances in the field of simulation of aerosol transport and deposition there is a constant improvement of measurement devices and techniques. Early attempts of aerosol measurements consisted in the measurement of airflow profiles and particle deposition in simplified airway geometries (pipes or simple smooth walled bifurcations). Idealized upper airway measurements have also been performed. For this purpose PIV (Particle Image Velocimetry) and LDV (Laser Doppler Velocimetry) methods can be applied. The development and spread of rapid prototyping techniques has opened new perspectives in this field. Nowadays it is possible to manufacture realistic replicas of the airways by digitally reconstructing them from CT images, then printing them with a 3D printer. A key element of the usage of such replicas for experimental purposes regards their optical transparency.

Numerical modeling of aerosol deposition in the stochastic lung model and the application of the CFD code for various respiratory tracts were performed. The results of the simulations were compared with the experimental results obtained from measurements with the realistic hollow airway model made by rapid prototyping.

Aim of the measurement

In case of aerosol drug administration it is important to deliver the right amount of medication to the right place [5]. In this way drug efficiency can be maximized and side effects minimized. Both computational and experimental efforts were spent to examine how drug deposition sites depend on breathing modes and parameters, especially breathing pattern. The measurements were performed with realistic aerosol drugs administrated by inhalers existing on the market.

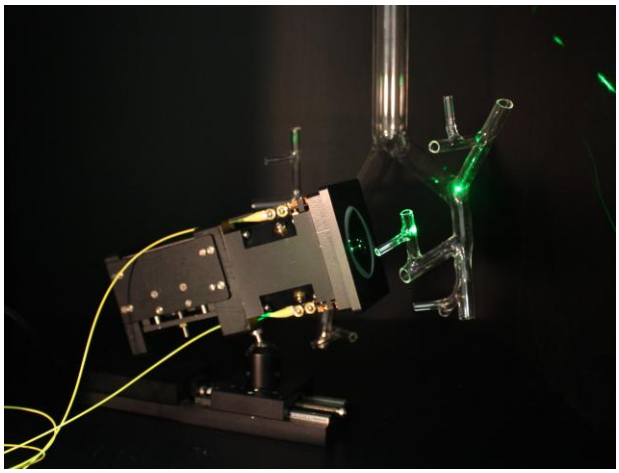

Figure 1. Laser Doppler Anemometer measurement in glass airway model.

In the last decade, medical aerosols have been employed for the treatment of lung cancer (Rao et al. 2003, Ally et al. 2005). In order to improve therapeutic efficiency and decrease side effects, magnetisable aerosol particles are guided to specific sites of the lung using an external magnetic field (Plank 2008).

In the present study, a preliminary computational study of the flow of magnetic aerosol particles in a physiologically realistic bifurcation (PRB) (Figure 1) under the influence of an external magnetic field generated by a cylindrical superconducting magnet is presented. The aerosol particles, in particular, are composites of magnetite nanoparticles dispersed in a polymer matrix (polysterene).

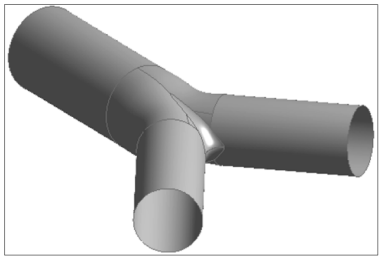

Figure 1. Physiologically realistic bifurcation of G3-G4 lung generations.

The PRB geometry is chosen, because it can be considered as a building block of the lung. The specific PRB in the present work is based on the geometrical characteristics of the bifurcation created by the third and fourth generation of the human lung. The in-house code developed by Makris et al. (2011) is used in order to obtain a high quality, multi-block, structured grid that describes the PRB. The airflow velocity and pressure fields in the PRB are, consequently, calculated through an in-house computational fluid dynamic (CFD) code (Neofytou & Tsangaris 2006).

The transport and deposition of aerosol particles under the influence of a magnetic field is described by the following steady-state population balance equation (neglecting aerosol internal processes):

$$\nabla \cdot \left[c \left(\vec{\upsilon} + \vec{v}_s + \vec{u}_m - \tau_p \, \vec{\upsilon} \cdot \nabla \vec{\upsilon} \right) \right] = \nabla \cdot \left(D \nabla c \right) \quad (1)$$

where c is the particles concentration, $\vec{\upsilon}$ the air velocity, $\vec{v}_s$ the particle settling velocity, τ_p particle relaxation time and $\vec{u}_m$ the velocity that a particle acquires due to the influence of the external magnetic field. Equation (1), thus, describes particle convective diffusion taking also into consideration the effects of particle inertia, gravity and magnetic force field in an Eulerian formulation. Total deposition fraction, particle concentration profiles and deposition sites are obtained under different conditions by solving Equation (1) numerically using a CFD-based code (Pilou et al. 2011). The parameters taken into account in the present study are the following:

- airflow Reynolds number,
- particles size,
- particles magnetic mass fraction,
- magnetic field flux density, and
- relative position of the PRB and the magnet.

Keywords: diesel exhaust particles, soy-biodiesel, macrophage, cytotoxicity.
Presenting author email: chensj@mail.npust.edu.tw

Diesel engines play an important role in industry, agriculture, and transportation because of their simple and strong mechanical structures, low fuel costs, and high thermal efficiencies. However, diesel engines are commonly responsible for the emission of large amounts of gaseous and particulate pollutants, which adversely affect health (Lin *et al.*, 2008; Tsai *et al.*, 2011). Many studies have shown that the use of biodiesel as an alternative fuel in diesel engines may improve combustion efficiency and reduce the emissions of carbon monoxide (CO), hydrocarbons (HC), particulate matter (PM) and polycyclic aromatic hydrocarbons (PAHs) (Lin *et al.*, 2006; Wu *et al.*, 2009; Tsai *et al.*, 2010). Although the use of biodiesel may significantly reduce PM emission from diesel engines, it is necessary to evaluate the potential cytotoxicity of diesel exhaust particles (DEPs) and their effects on health when using biodiesel.

In this study, the DEPs from a biodiesel-fuelled generator operated at stable energy output (110 V/60 Hz, 1800 rpm) loads (unload (0 kW) and 3 kW) were investigated. We tested two types of fuels: D100 (pure petroleum diesel) and S20 (v/v = 20% soy-biodiesel/80% D100). A micro-orifice uniform deposit impactor (MOUDI) and a Nano-MOUDI (with 0.01–18 μm aerodynamic diameters) were used to collect PM samples. Each sample was extracted in a *Soxhlet* extractor with a mixed solvent (n-hexane and dichloromethane 1:1 vol/vol) for 24 hr. Subsequently, human male macrophage/monocyte cell strains (U937) were exposed to various extract samples for 24 hours after various organic solvents had been replaced by DMSO (dimethyl sulfoxide). The MTT (3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay was adopted to analyze the cell viability rates of various DEP extracts.

Figure 1 shows the unit mass cytotoxicity (cell death rate per unit mass) of DEPs emitted from the diesel-engine generator fuelled with D100 and S20 under 0 kW and 3 kW loads. The DEPs with aerodynamic diameters of less than 0.1 μm (ultrafine particles and nanometer-particle) were found to have noticeably higher unit mass cytotoxicity than the DEPs with particles of other sizes (for D100, 4.92–5.60 times; for S20, 2.70–6.56 times). Additionally, under no load, the distribution pattern of unit mass cytotoxicity for particles of various DEPs obtained using S20 was similar to that obtained using D100. At 3 kW load, the unit mass cytotoxicity values of the extracts of nano/ultrafine DEPs (0.010–0.018, 0.018–0.032, 0.032–0.056, and 0.056–0.1 μm) were clearly lower when S20 was used than when D100 was used (by 47.7%, 46.5%, 63.3% and 52.8%, respectively), while those of larger DEPs (0.1–18 μm) were similar. The above results suggest that replacing D100 (petroleum diesel) with S20 (a mixture of 80% petroleum diesel with 20% soybean biodiesel) helped to reduce the bio-toxicity of DEPs that were emitted from the power generator.

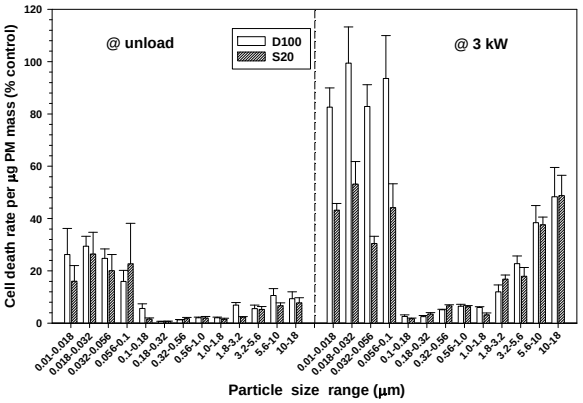

Figure 1. Unit mass cytotoxicity (cell death rate per unit mass) of DEPs emitted from the diesel-engine generator fuelled with D100 and S20 under unload and 3 kW loads.

Particulate matter (PM) present in suspension in the air we breathe has a complex composition which includes silicates, sulphates, nitrates, chlorides, carbonaceous particles and trace metals. The long-term exposure to elevated levels of this aerosol mixture has been linked epidemiologically to increased mortality from respiratory and cardiovascular diseases. Recent research has increasingly focused not only on the health impact of PM levels (legislated by the EU), but more especially on specific components within the aerosol chemical cocktail which may be causing much of the biological damage. In this context, metals, although generally low in mass, are prime suspects because of their known bioavailability. Although the source of many of these metals in the urban environment can be natural (such as volcanic eruptions or intrusions of air masses from desert areas), most are of anthropogenic origin and are mainly related to combustion-derived industrial and traffic emissions.

Air pollution due to vehicular traffic in ~~our~~ cities is a global problem. The exposure of sensitive individuals, such as children, to traffic-related PM is dependent on several factors, including the distance to the emission source (in this case the road), the number and type of vehicles, and subsequent processes during transportation that can transform PM characteristics. Therefore, different traffic densities within a given city will create zones with significant variations in the chemical composition of ambient inhalable PM.

The study of the risk that air pollution poses to the neuro-development and behavioural patterns of children is a challenge in the modern research environment. The BREATHE project funded by the European Union and led by the Research Centre of Environmental Epidemiology (CREAL, Spain) is currently measuring aerosols over both winter and summer of 2012 in primary schools located in the city of Barcelona. The schools are separated into high and low-traffic areas with the primary aims being to recognize if differences in ambient traffic emissions affect the neurological system of children and if there is a relationship between their behaviour at school and the levels of air pollution in their environment.

Within the BREATHE project the Complementary Action CECAT is considering the toxicological aspect of the problem by investigating the toxicity of PM by means of its ability to induce a systemic oxidative stress which damages cells and DNA molecules, and thus, create subsequent inflammation to produce a disease.

To achieve this, a total of 20 schools built in environments with highly contrasting variations in traffic conditions (10 with high density and 10 with low) have been selected and are being currently sampled. This sampling is being carried out inside the classrooms for 4 consecutive days at two different times a year (winter and summer of 2012) to take into account the effect of changes of air pollutants in different climatic conditions. For the determination of particle oxidative capacity, PM_{10} in the classrooms is being collected using an Airborne Sample Analysis Platform system (ASAP; Model 2800 Thermo, USA) on polyurethane foam substrates (PUF) with a high sample flow-rate of 200 l/min. The genotoxicity, inflammatory potential and cytotoxicity of the PM_{10} samples will be elucidated using three different but complementary biological assays::

- Plasmid Scission Assay (PSA) - genotoxicity
- DCFH ROS Assay - potential pro-inflammatory
- F-actin polymerisation Assay - cytotoxicity

These three assays are being performed routinely in the School of Biosciences, University of Cardiff and their application will allow the identification of PM component/s responsible for the toxicity of the sample. Determination of the toxic PM component/s will assist in identifying the related pollutant emitting source. The results that are currently being obtained and presented in this congress are helping us i) to reveal the effect of traffic emissions on air quality in school indoor environments, ii) to identify the inorganic components that may have an adverse effect on health, iii) to quantify the biological responses that subsequently cause health effects through measurements of both reactive species of oxygen and inorganic components (as well as their synergistic effects) and iv) to characterise and analyse the global response to different hierarchical levels (biochemical, and toxicological) of biological test systems, in order to reveal exposure dependent alterations.

This work is supported by the Spanish Ministry of Economy and Competitiveness with a Complementary Action (CECAT: CTM2011-14730-E) and by the BREATHE EU Advanced Grant ERC (Seventh Framework Programme).

Layered silicate nanofillers and their influence on the pulmonary surfactant

D. Kondej[1] and T.R. Sosnowski[2]

[1]Department of Chemical, Aerosol and Biological Hazards, Central Institute for Labour Protection – National Research Institute, Czerniakowska 16, 00-701 Warsaw, Poland

Keywords: lung/particle interaction, nanocomposites, industrial minerals, surfactant.
Presenting author email: dokon@ciop.pl

Polymer nanocomposites acquired special significance in recent years and they are of interest to researchers in nanotechnology. These are two-phase materials containing the polymer matrix and nanofillers (NF) added to improve the physical, thermal and resistance properties of nanocomposites. Layered silicates are an important group of NF due to their availability and relatively low price. Wide application of NF creates a potential hazard during manufacturing polymer nanocomposites as NF can be inhaled by workers involved in the production process.

The aim of this study was to evaluate the impact of selected layered silicate NF used in the production of polymer nanocomposites on the surface activity of the pulmonary surfactant (PS). Herewith, we present results regarding the layered silicates containing montmorillonite predominantly: a) PGV - bentonite, b) I.30E - nanoclay, surface modified contains 25-30 wt. % trimethyl stearyl ammonium, c) I.31PS - nanoclay, surface modified contains 15-35 wt. % octadecylamine and 0.5-5 wt. % aminopropyltriethoxysilane.

Observations of the NF morphology were conducted with the use of a scanning electron microscope - Fig. 1.

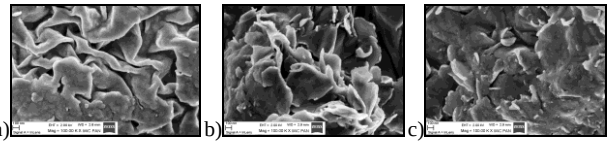

Figure 1. SEM picture of nanofiller particles: a) PGV, b) I.30E, c) I.31PS.

Specific surface area measurements were performed with the use of BET method - Table 1.

Table 1. Specific surface area of nanofillers.

Specific surface area (m^2/g)		
PGV	I.30E	I.31PS
67.3	14.0	13.5

The study of changes in the activity of PS after contact with NF particles was performed by using pulsating bubble tensiometer (PBS, Electronetics Corp., USA) with a dynamic tensiometric method (Kondej and Sosnowski, 2012). Pharmaceutical preparation Survanta (Abbott, France) was used as a model PS after dilution with sterile saline to obtain phospholipid concentration of 1.25 mg/ml.

Fig.2 and 3 show values of the relative surface tension hysteresis area, HA_R, and the relative minimum surface tension, σ_{Rmin}, found for different concentration of NF in the model PS: control (no NF), 0.5 mg/ml and 1 mg/ml. The decrease of HA_R and the increase of σ_{Rmin} for natural NF (PGV) were observed. The presence of surface-modified NF (I.30E and I.31PS) caused the increase of HA_R and the reduction of σ_{Rmin}. The results indicate altered surface activity of pulmonary surfactant caused by the presence of the particles of the layered silicate nanofillers.

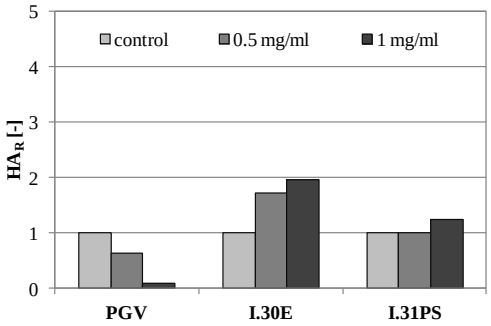

Figure 2. Comparison of the relative hysteresis area (HA_R) for PS/NF systems.

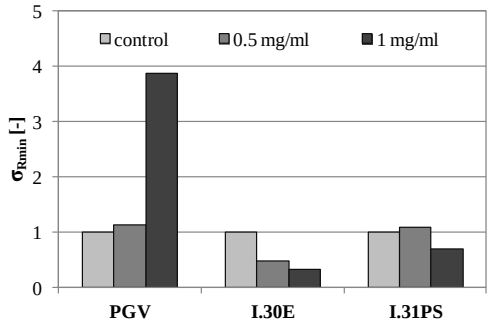

Figure 3. Comparison of the relative minimum surface tension (σ_{Rmin}) for PS/NF systems.

This paper has been prepared on the basis of the results of research project No. I.B.10 carried out within the National Programme "Improvement of safety and working conditions" partly supported in 2011-2013 within the scope of research and development by the Ministry of Science and Higher Education. CIOP-PIB has been the Programme main coordinator.

[4]Dept. of Environmental Sciences, University of Milan-Bicocca, Milan, 20126, Italy
Keywords: PM, perinatal susceptibility, spirometric values, FeNO
Presenting author email: felicegranato@yahoo.it

Aim of the study: to compare hospital admissions to a referral pediatric service of Milan with daily and seasonal variations in PM concentration, during 4 consecutive periods: winter/summer 2007, winter/summer 2008.

Methods: during 2007-2008, there were in total 440 pediatric admissions for respiratory diseases; 226 (132 M, 94 F) during the winter semester, and 214 (100 M, 114 F) during the summer semester. There were 12.7% asthma or asthma related admissions; 55.8% due to lower respiratory illness, and 31.5 % due to upper respiratory disease. The daily average of PM10 concentration during the 1st semester 2007 was 48.3+/- 17.9 mcg/m^3. There were 107 (59.1%) days with at least one hospital admission. The mean daily concentration of PM was higher in days with (n=107) than without (n=74) hospital admissions (p=0.032 or <0.05). Accordingly, children acute admissions were significantly affected by pollution data, with increased admission during winter, namely for upper air tract infections, whereas lower tract inflammation and acute admission for asthma were more frequent during spring-summer.

Between 2007-2008, 228 children, older than 7 y, were enrolled from 2 primary schools, in order to study pollution related respiratory symptoms and/or diseases in different places of Milan with a different traffic-related exposure. The former (S1) was located near a large park, the latter downtown (S2). Daily levels of PM10 and PM2.5 were measured both outdoor (garden) and indoor (corridors) for 7 consecutive days during 2 different campaigns (winter and spring-summer). Children underwent skin prick testing for inhaled allergens, analysis of exhaled nitric oxid (FeNO) and spirometry.

Results: the distribution of FeNO values was significantly different (p=0,02) between the two schools: the percentage of children with FeNO values <5ppb was almost double in S1; FeNO was 5- 20ppb in 73% of children from S2. The percentage of asthma exacerbations (previous 12 months) was higher in S2 (p=0.05). The prevalence of persistent allergic rhinitis in children allergic to grass pollen was higher in S1 (p=0.03). The latter children also had a greater activity limitation, due to rhinitis and concomitant conjunctivitis (p=0.03).

Discussion: air pollutants, at usual concentration in the atmosphere, are weak pollutants, with low intrinsic toxicity. Newborn exposure could be one the most relevant events determined by PM. Epidemiological studies evaluating concomitantly PM concentration and detectable diseases or hospital admissions usually miss this perinatal damage in foetuses and newborns. This damage is not immediately detectable, but is a delayed manifestation. Perinatal damage not only includes fetal malformations, birth defects or developmental alterations, but could also be responsible for the increased proportion of individuals who, because of the exposure to pollutants during the "perinatal susceptibility window", and because of epigenetic alterations, due to environmental factors, will turn from previously "unsusceptible" into "susceptible" individuals. The latter could also transfer this susceptibility to future generations, and develop not only asthma at age 4, but also respiratory, cardiovascular or systemic diseases, 20 or 40 y later.

Since peculiar pathophysiological mechanisms based on individual susceptibility play a major role in the occurrence of pollution related diseases, it is necessary to improve current epidemiological models, adding pathophysiological variables, which could account for tissutal damage, duration and type of exposure, or susceptibility markers.

Not only a better knowledge of the "particle side" of the interaction is required, but also a deeper insight into cause and effect relationships and pathophysiologic mechanisms or pathways, i.e. a deeper understanding of the "host side" of the host-particle interaction. A critical re-evaluation could open new avenues, including the design of new models, in which the increasing role of host reactivity will be properly considered. In particular, the possibility that autoimmune or inflammation related mechanisms, instead of purely toxic ones, could better explain clinical outcomes should be taken into account.

Traffic related air pollution is associated with a large variety of adverse health effects, including both cardiac and respiratory symptoms. Diesel engine emissions are considered to be probably carcinogenic in humans, as well as cause pulmonary and systemic inflammation. However, the old diesel emission particle studies are at low relevance in comparison to more modern engines. The effects of new fuels are largely unknown, and their effects need to be characterized in details, especially when new generation fuels are introduced to wider use.

In this study, a direct injected turbocharged Scania truck engine that fulfilled EURO4 emission class requirements was used. The conventional diesel fuel (EN590), and two biobased fuels; rapeseed methyl ester (RME) and hydrotreated vegetable oil (HVO) were used with different blends as well as combinations of particle oxidation catalyst, including also compressed natural gas powered bus. The mouse RAW 264.7 macrophages were exposed to several doses of emission particles from each situation for 24 hours. Thereafter, viability of cells was measured with MTT test and genotoxicity with comet assay method.

All the samples evoked dose dependent increase in the cell death (Figure 1A). With the emission samples of EN590, HVO cat and CNG bus, also the smaller doses were cytotoxic. The smallest emissions seemed to have the largest cytotoxic potential when the same mass dose was compared. However, the overall harmfulness of the emissions from catalyst and HVO combination or the CNG powered bus can be considered as the smallest since the very low emissions.

All the samples increased dose-dependently the DNA damage measured in the Comet assay (Figure 1B). There were substantial differences between the different samples in their ability to cause DNA-damage. Emission particles from the engine operated with EN590 and 30% HVO/EN590 blend were the most potent and those from CNG bus clearly the least harmful in this parameter. EN590 sample differed statistically significantly from all the samples. Moreover, all samples except 100% RME were more genotoxic than CNG bus derived sample. Catalyst reduced the genotoxic responses of particulate mass both with EN590 and HVO. From the plain liquid fuels, methyl ester biodiesel was the least potent in inducing genotoxic responses after the macrophages were exposed to the emission particles.

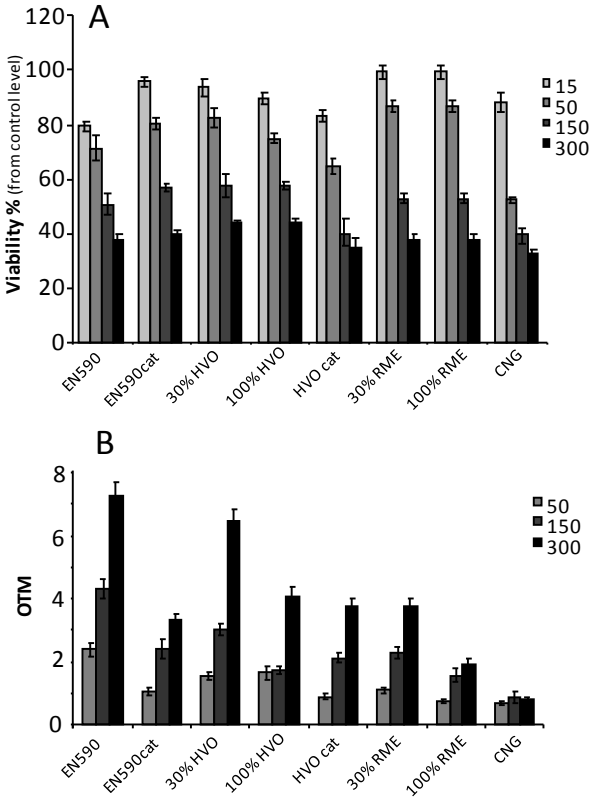

Figure 1. Cell viability assessed with MTT-test (A) and genotoxicity assessed with comet assay (B) after 24h exposure to PM_1 emission samples from EURO4 engine. Bars present control and four doses (15, 50, 150 and 300µg/ml) and whiskers the standard error of mean (SEM).

Experimental study of aerosol transport in semi-realistic human airway model

J. Jedelsky[1], F. Lizal[1], J. Elcner[1] and M. Jicha[1]

[1]Department of Thermodynamics and Environmental Engineering, Brno University of Technology, Brno, 616 69, Czech Republic

Keywords: Lung model, aerosol transport, phase Doppler anemometry.

Presenting author email: jedelsky@fme.vutbr.cz

In vitro studies of aerosol transport in human airway models give considerable information for advancement of targeted drug delivery and serve for validation of numerical simulations where more accurate turbulence models are needed. We applied a semi-realistic transparent model of human airways for a study of flow of micron-sized spherical particles dispersed in air using Phase Doppler Anemometry (PDA).

Geometry of the model is based on CT scans of human lungs. The model encompasses mouth cavity, realistic glottal geometry and three to four generations of bronchi with three-dimensional branching. To allow optical measurement with air, certain degree of simplification of the complex realistic geometry was needed. Cylindrical tubes were used to replace original rough and warped walls of airway channels. But all other original characteristic such as asymmetric and three-dimensional branching angles were preserved. Tube dimensions were set to keep original volume as well as mean perimeter of the tubes (Fig. 1 a). Physical semi-realistic model is composed of cylindrical glass tubes connected by Rapid prototyping made bifurcation segments (Fig. 1 b).

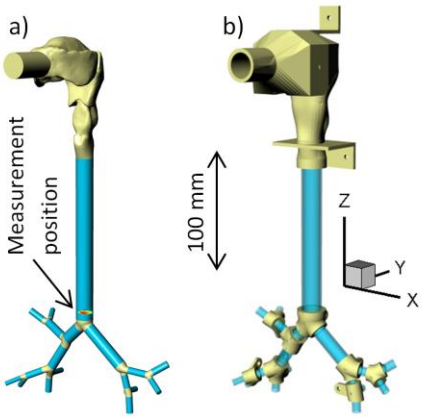

Figure 1. Airway geometry (a) and model (b) with system of coordinates.

1D PDA (Dantec Dynamics) with classical optics was used for measurement of time-resolved flow velocity and diameter of particle-laden air in multiple points of the optically transparent model for three steady breathing regimes. The PDA used focal length of both the transmitter and receiver of 310 mm, 1st order light refraction and scattering angle 45°. Aerosol particles of di-2-ethylhexyl Sebacate (DEHS) with 3 μm in diameter were produced by condensation monodisperse aerosol generator (CMAG TSI 3475), mixed in a static mixer with air and resulting dilute dispersed two-phase mixture was led to the lung model. We simulated three inspiration breathing regimes (Table 1).

Table 1. Breathing regimes

Activity	Flowrate (l/min)	*Re*	*Stk*
Resting cond.	15	1404	3.6E-03
Deep breathing	30	2809	7.1E-03
Light activity	60	5618	1.4E-02

Arbitrary results of the flow measurements are documented in Fig. 2. The particles flow in laminar or turbulent regime depending on Reynolds number (*Re*) with Stokes number *Stk* << 1, which suggests the particles follow the air flow closely (Table 1). The velocity profile is only very roughly parabolic. Maximum axial velocity is found near the centreline. Symmetry of the velocity profile along the X-axis is disturbed by the flow history, mainly by the complex structures of larynx. Symmetry along the Y-axis is harmed by the unlike distribution of the flow into main bronchi (past the bifurcation). Turbulence intensity (TI) reaches similar values in the centreline for all three regimes but spatial distribution varies significantly and also changes with regime. Particle deposition could increase in high TI regions as an effect of turbulent dispersion. Relation of the TI with deposition "hot spots" is a topic for our ongoing research.

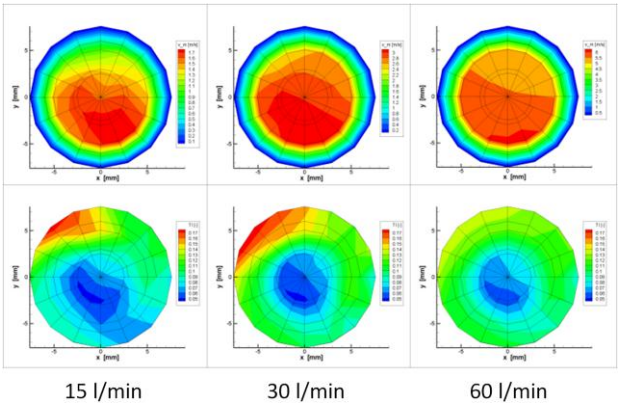

Figure 2. Mean axial velocity (top) and TI (bottom).

Hygroscopic particle deposition in the human lung – a model comparison

W. Hofmann[1], R. Winkler-Heil[1], G.A. Ferron[2] and B. Asgharian[3]

[1]Department of Materials Research and Physics, University of Salzburg, 5020 Salzburg, Austria
[2]Comprehensive Molecular Analytics, Helmholtz Center Munich, 8576 Neuherberg/Munich, Germany
[3]Health Effects and Medical Response, Applied Research Associates, Raleigh, NC 27615-2963, USA
Keywords: hygroscopic growth, inhalation, lung deposition, modelling
Presenting author email: werner.hofmann@sbg.ac.at

Most aerosol particles used in medicine and occurring in ambient air are hygroscopic. Hence these particles will absorb water vapour from the air at the high relative humidity present in the human respiratory tract during respiration. As a consequence, inhaled aerosol particles grow in size and thus change their deposition properties.

The primary objective of the present study is to compare total deposition patterns of hygroscopic particles computed with different hygroscopic growth and morphometric lung models. Such a comparison will allow us to investigate the specific roles of particle growth and lung morphology for particle deposition in the human lung.

First, the hygroscopic particle growth model proposed by Ferron *et al.* (1988a,b) was implemented into the stochastic lung deposition model IDEAL (Koblinger and Hofmann, 1990; Hofmann and Koblinger, 1990) (IDEAL&Ferron), which is based on a stochastic, asymmetric lung morphology. The theoretical results published by Ferron *et al.* (1988a,b) employed the same hygroscopic growth model, but applied to a symmetric, deterministic lung geometry (Weibel, 1963). On the other hand, Asgharian (2004) developed a different hygroscopic growth model, while applying an asymmetric though deterministic airway geometry similar to the stochastic lung model. The most significant difference between the two hygroscopic growth models is the time a particle needs to reach its equilibrium diameter. For an additional comparison, the hygroscopic growth model of Asgharian (2004) was also implemented into the stochastic IDEAL model (IDEAL&Asgharian).

The comparison of total deposition fractions for inhaled NaCl particles obtained by the different hygroscopic growth and deposition models is illustrated in Figure 1 for a wide range of particle sizes under defined breathing conditions (flow rate Q = 250 cm^3 s^{-1} and tidal volume V_T = 1000 cm^3, assuming symmetric breathing). While the general trends are the same among all models, differences for ultrafine and very large particles may be attributed to the use of different deposition equations for the extrathoracic region.

Since the stochastic deposition model uses the hygroscopic growth model of Ferron *et al.* (1988a,b), differences with their theoretical predictions may be attributed to differences in lung morphometry. Except for the smallest particle diameters, both models predict very similar deposition fractions, indicating that lung morphometry is not a major determinant of total deposition of hygroscopic particles.

The results reported by Asgharian (2004) are significantly lower than the IDEAL predictions for submicron and significantly higher for very large particles. The same tendency can be observed if the hygroscopic growth model of Asgharian (2004) is implemented into the IDEAL code. This systematic underprediction for submicron particles and overprediction for micrometer-sized particles is caused by a growth curve which starts rising earlier during the inhalation phase than that in the modified Ferron *et al.* model (1988a,b), thereby reducing deposition by diffusion and increasing deposition by impaction and sedimentation. This model comparison indicates that the starting point of the hygroscopic growth curve significantly affects the resulting deposition curves.

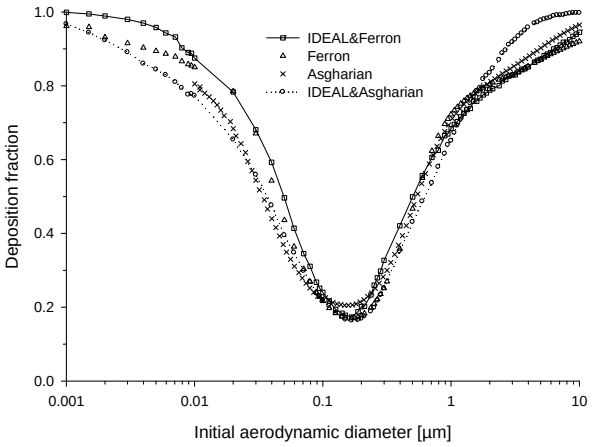

Figure 1. Comparison of total deposition fractions for orally inhaled NaCl aerosols predicted by the IDEAL&Ferron, modified Ferron (1988a,b), Asgharian (2004) and IDEAL&Asgharian models for defined breathing conditions (Q = 250 cm^3 s^{-1}, V_T = 1000 cm^3).

Current levels of ambient air fine particulate matter are associated with mortality and morbidity in urban populations. Since large proportion of $PM_{2.5}$ emissions are derived from small scale combustion, it is important to reveal the possible health effects of the particle emissions from the combustion appliances. Especially there is a lack of knowledge concerning modern wood combustion systems. In this study, toxicological properties of PM_1 emissions from biomass combustion reactor operated by three different ways were examined.

Three different combustion conditions, efficient, erratic and poor, were generated in combustion reactor using wood chips as fuel. The efficient conditions corresponded to optimal biomass combustion and the poor conditions approach to conventional batch combustion. Instead, the erratic conditions represented malfunctioning of combustion appliance. The demanded combustion conditions were achieved by adjusting fuel feeding, air flows and air staging. (Table 1).

PM samples for toxicological analysis were collected on PTFE-filters from diluted flue gas by using Dekati® gravimetric impactor. Samples were extracted from filters using methanol. Mouse macrophage cells (RAW264.7) were exposed for 24 h to four doses (15, 50, 150 and 300 mg ml^{-1}) of emission samples.

The studied emission samples by all doses induced a statistically significant dose-dependent decrease in cell viability (MTT assay) when compared to control (Fig.1). However, the efficient combustion caused clearly more cytotoxicity than the other samples.

When cells cell cycle phases were analyzed (dose 150 mg ml^{-1}) statistically significant apoptosis was detected with erratic and poor combustion (Fig.2). All samples caused statistically significant decrease of G_1-phase when compared to control. Interestingly, only efficient combustion caused statistically significant increase in S-G2/M-phase which is considered as sign of cell cycle arrest caused by DNA damage.

The results indicated that even modern wood combustion appliances and optimal burning conditions may have health impact. Efficient combustion was causing highest cytotoxicity and clear cell cycle arrest. However, emissions from efficient combustion were negligible compared to two other situations and that is even more important when the aim is to reduce human exposure to PM.

Table 1. Emission parameters in averaged values.

Parameter	Efficient	Erratic	Poor
Number Conc.(1/MJ)	1.4E+14	5.5E+13	2.7E+13
PM_1 Mass Conc. (DGI)(mg/MJ)	8 ± 3	61 ± 47	135 ± 22
CO(mg/MJ)	7 ± 37	303 ± 633	2300±3300
CH_4 (mg/MJ)	0.3 ± 0.3	4 ± 21	115 ± 190
OGC (mg/MJ)	3.6 ± 1.4	7.1 ± 25	180 ± 340

Aircraft Engine Soot Emissions and Smoke Number Uncertainties

M.E.J. Stettler[1] and A.M. Boies[1]

[1]Department of Engineering, University of Cambridge, Cambridge, UK, CB2 1PZ
Keywords: aerosol emissions, aerosol sampling, soot particles, generation of combustion aerosols
Presenting author email: ms828@cam.ac.uk

We describe how the current method to estimate aircraft particulate matter (PM), relying on measured engine smoke number (SN), shows significant discrepancies with recent published measurements. Flexibility within the SN measurement standard procedure is potentially a significant contributing factor. We describe results from a recent experimental study to examine the influence of changing filter diameter, sampling line temperature and sample line length within the prescribed ranges. These results are important to quantify the error associated with current estimation methods used in airport emissions inventories and motivate the development of alternative methods independent of SN.

Aircraft gas turbine engines emit particles with a geometric mean particle diameter less than 100nm (Kinsey et al., 2010) consisting of non-volatile and volatile particles. The non-volatile component is primarily black carbon soot (BC) (Timko et al., 2010). Emissions indices (EIs) of pollutants from aircraft engines are generally described in terms of mass of pollutant emitted per mass of fuel burned.

Currently, regulation is concerned with the visibility of aircraft exhaust, quantified via the SN. Each engine type in service has been measured for SN according to a standard procedure detailed in Aerospace Recommended Practice (ARP) 1179C (SAE, 1997). The SN is a dimensionless quantity related to the darkening of particle-loaded filters through the transmission of a given quantity of exhaust gas per unit of filter area.

Growing awareness of climate and air quality impacts of PM led to the development of an approximation method to estimate PM mass EIs. The non-volatile EI is estimated by relating the measured SN to a soot mass concentration in the exhaust sample via an empirical correlation. The latest version of this method is called the First Order Approximation v3.0 (FOA3) and is endorsed by ICAO and the US Federal Aviation Authority (ICAO, 2007; Wayson et al., 2009).

Current efforts by the SAE E-31 committee are directed towards specifying a new standard for aircraft exhaust non-volatile PM measurement (SAE, 2009), however in the absence of a campaign to enforce any new measurement standard on existing engines, PM emissions from engines currently in service will continue to be estimated.

Figure 1 shows that there is a factor of ten discrepancy in 40% of cases between FOA3 estimated and measured emissions index of black carbon EI(BC). For the real engine data (open symbols) two issues are clear: (a) a significant number of $EI(BC)_{FOA3}$ are zero even though $EI(BC)_{Measured}$ is non-zero, and (b) there is a significant underestimation of EI(BC), especially for the higher thrust setting of 85% rated thrust (F_{00}). Potential reasons for the discrepancy are discussed and the likely candidate of the observed discrepancy is identified as the correlation between SN and mass concentration and the potential for inconsistency in the SN measurement technique due to flexibility within ARP1179C.

We present results from an experimental study and quantify the error introduced to the SN as a result of the flexibility within ARP1179C with respect to flow velocity incident on the filter surface (a function of filter diameter), sampling line temperature and sampling line length. We discuss a potential alternative estimation method that is independent of SN and shows improved agreement with measured values.

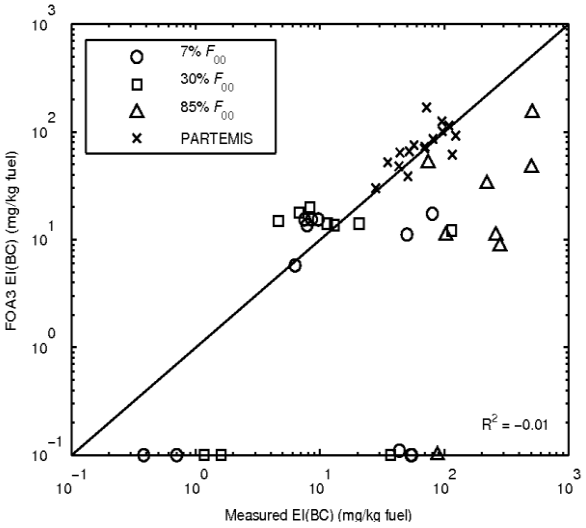

Figure 1: Comparison between FOA3 estimated and measured EI(BC) for real engines (open) and PARTEMIS combustor experiments (x). Calculated R^2 refers only to the engine data.

Estimation of uncertainty of elemental concentration in PM_1

G. Valotto[1], E. Pecorari[1], G. Rampazzo[1], F. Visin[1] and D. Zannoni[1]

[1]Department of Environmental Science Informatics and Statistics, University Ca' Foscari, Dorsoduro 2137, I-30123 Venezia, Italy

Keywords: measurement errors, chemical composition, PM1

Presenting author email: valotto@unive.it

In environmental studies, precision and accuracy of measurement are of considerable importance since they must be often compared to the existing legislation. Usually, laboratories minimize the data uncertainty by following measurement protocols that often need of a reference certificate standard. Unfortunately, there are not available standards for all matrix types, and existing ones are not certified for all their components (e.g., organic and inorganic). Furthermore, the error evaluation becomes difficult when the sample is handled several times before the analysis. This is the case of the elemental composition of atmospheric particulate, sampled on quartz filter, when it is characterized by ICP-OES (Inductively Coupled Plasma - Optical Emission Spectroscopy).

The aim of this research is at estimating the precision of elemental concentration of PM_1 sampled near the Venice airport and presenting a method simple and adaptable to other matrices for the evaluation of uncertainty associated to the data. It is worth noting that literature not always reports errors associated with environmental measures.

From November 2011 to June 2011, 200 samples of PM_1 were collected every 48 hours on a quartz filter (47 mm in diameter) at two site located at the start and the end of Venice airport airstrip (45°30'40''N, 12°20'38''E) by two Tecora Skypost PM HV at low volume (2.3 m^3 h^{-1}). PM_1 air concentration was determined gravimetrically: all filters were weighted before and after sampling with analytical balance after stabilization (48 hours at 20°C and 50% relative humidity). Filters were decomposed by microwave digestion with a mixture of HNO_3, HF and H_2O_2, and then diluted to 25 ml with high purity water. Before characterizing the elemental composition by ICP-OES, each sample was further diluted with calibrated micropipette by using high purity water (1:2). All these operations contribute to enhance the uncertainty associated to the determined concentration values. We used eq. 1 (quadratic formula of error propagation) to assess the error associated to the calculated concentration (PM_1 in air and elemental concentration of PM_1), and to identify the most critical sample processing steps, which we should focus to for improving the detection accuracy.

$$\delta F(x_1, x_2, \dots x_i, \dots x_n) = \sqrt{\sum_{i=1}^{n} \left(\frac{\partial F}{\partial x_i}\right)^2 \cdot (\delta x_i)^2} \quad (1)$$

where $\frac{\partial F}{\partial x_i}$ is the partial derivative of an F function over the x_i variable, and δx_i is the corresponding x_i uncertainty.

Field blank filter were used to correct the systematic errors and to evaluate measurement uncertainty of PM_1 air concentration and elemental concentration of PM_1.

This research shows that second dilution and ICP-OES analysis are the processing steps that most contribute to increase the error associated to PM_1 elemental concentration (as shown in figure 1).

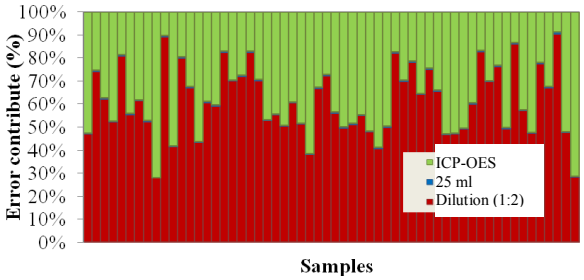

Figure 1. Error contribution of processing steps

Finally, for all detectable elements (Fe, Zn, Mn, K, S - whose concentrations are higher than the limit of detection of ICP-OES and are not highly concentrated in the quartz filter) was estimated the percentage error of element concentration as a function of PM_1 concentration and element concentration in PM_1. Table 1 shows the Fe example.

PM_1 concentration ($\mu g\ m^{-3}$)	Fe concentration in PM_1 ($\mu g\ \mu g^{-1}$)	Error (%)
0–10	$<2.5 \cdot 10^{-3}$	14
	$2.5 \cdot 10^{-3}$–$4.0 \cdot 10^{-3}$	10
	$>4.0 \cdot 10^{-3}$	7
10-50	$<2.5 \cdot 10^{-3}$	12
	$2.5 \cdot 10^{-3}$–$4.0 \cdot 10^{-3}$	5
	$>4.0 \cdot 10^{-3}$	4
>50	$<2.5 \cdot 10^{-3}$	7
	$2.5 \cdot 10^{-3}$–$4.0 \cdot 10^{-3}$	-

Collection efficiency and interstage nanoparticle loss in MOUDI

A. Awasthi, C. N. Liu, B. Gumgamsetty and C.J. Tsai

Institute of Environmental Engineering, National Chiao Tung University No. 1001, University Road, Hsinchu, 30010, Taiwan
Keywords: Collection efficiency, MOUDI, nanoparticle, particle loss
Presenting author email: awasthitiet@gmail.com

The performance of 13-stage MOUDI-II cascade impactor (MSP Model 122, 30 L/min) was studied for the collection efficiency and particle loss. Monodisperse test particles in the aerodynamic size range between 17 to 450 nm were used for experiments, which were generated by a constant output atomizer (TSI Model 3076) using solutions of Oleic Acid (OA) or Dioctyl Sebacate (DOS) of different concentrations. Particles generated by atomizer pass through the evaporation and condensation process before entering an electrostatic classifier (TSI 3080). Finally, a scanning mobility particle sizer (SMPS, TSI 3936); a combination of EC and Ultra-Fine Condensation Particle Counter (UCPC, TSI 3776) was used to scan the size distribution of classified particles and check their monodispersity.

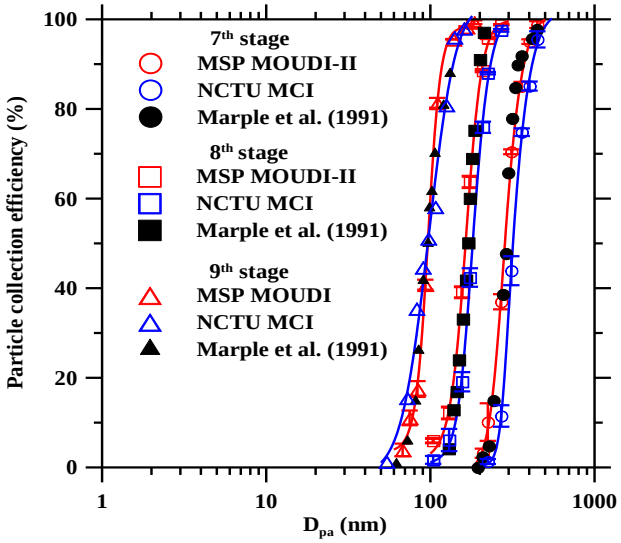

Figure 1: Particle collection efficiency curve of the 7, 8 and 9th stage of the MSP MOUDI-II and NCTU MCI.

From the particle collection efficiency curve (Figure 1) and experimental data, it was observed that the cutoff aerodynamic diameter (d_{pa50}) of 7, 8 and 9th stage of the MOUDI-II were 10, 8 and 3% lower than the nominal values given by Marple et al. (1991) and particle loss (Figure 2) increased from 13.85 to 31.96 % as the particle diameter was decreased from 83.5 to 17 nm for the inlet to the 8th stage (cutoff diameter is 180 nm). The loss is may be due to the high velocity jet from the nozzles, which creates a flow field recirculation region behind the impaction plate or near the rear end of the nozzles leading to diffusional deposition of nanoparticles. To increase the accuracy of the cutoff diameters, a NCTU MCI (micro-orifice cascade impactor) was designed using new micro-orifice nozzles with a smooth round nozzle shape for the 7th to 10th stages, which were fabricated using a semiconductor technique to reduce possible clogging inside the nozzles. The S/W values (S: jet to plate distance, W: nozzle diameter) of these lower stages were adjusted so that d_{pa50} values were close to the nominal values of the MOUDI-II. Results showed that S/W values, 3.5 (7th stage), 3.6 (8th stage) and 13.8 (9th stage) were different from those specified by Marple et al. (1991), which were 4.1 (7th stage), 6.4 (8th stage) and 10.6 (9th stage).

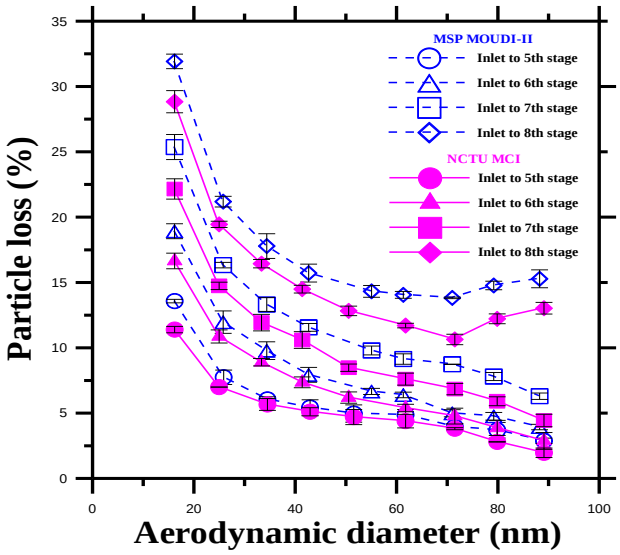

Figure 2: Particle loss for inlet to different stages of the MSP MOUDI-II and NCTU MCI.

Figure 2 shows that the particle loss of 31.96% was observed in the MSP MOUDI-II whereas the NCTU MCI with new nozzles shows maximum particle loss up to 28.87%. Newly designed smooth nozzles reduced the particle loss in MOUDI due to its smooth curved surface geometry. It is expected that the NCTU MCI with new micro-orifice plates are able to obtain more accurate mass distributions of ambient aerosols.

On the calibration of the Single Particle Soot Photometer (SP2)

M. Gysel, M. Laborde, P. Mertes, P. Zieger, J. Dommen, and U. Baltensperger

Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: black carbon, diesel soot particles, SP2, single particle analysis.
Presenting author email: martin.gysel@psi.ch

Atmospheric black carbon (BC) particles are known to contribute to global warming and to cause adverse health effects. Therefore BC emission reductions have been suggested for simultaneously mitigating near-term climate change and improving human health and food security, as BC particles have a very short atmospheric life-time (Shindell *et al.*, 2012).

An emerging method for quantitative measurements of BC mass concentration in atmospheric aerosols is the single particle soot photometer (SP2; Stephens *et al*, 2003), using laser-induced incandescence. The SP2 has many advantageous features, but also disadvantages, such as the need for empirical calibration for quantitative detection of BC mass. Furthermore, Moteki and Kondo (2010) have shown that the SP2's sensitivity to BC mass differs between different BC types, including SP2 calibration materials and ambient BC, and they identified the need for further investigations on ambient BC.

In this study we compare the SP2's sensitivity to Aquadag and fullerene soot, the most common SP2 calibration materials, with that to BC from diesel car exhaust, log wood stove exhaust and ambient air.

"Atmospheric" BC calibration aerosol was obtained by thermo-denuding the soot particles sampled from a diesel car, a wood stove or ambient air at 400 °C. Aquadag and two batches of fullerene soot were nebulised from aqueous dispersions and dried. An aerosol particle mass analyzer (APM) was then used to select the "pure" BC particles by their mass, prior to measurement of the corresponding SP2 incandescence signal amplitude.

The results of the SP2 calibration are shown in Fig. 1 for all BC samples, presented as absolute calibration curves (Panel A) and as relative sensitivity compared to that of diesel car BC (Panel B). Diesel car BC is chosen as a reference calibration for two reasons: first, diesel exhaust is the dominant source of atmospheric BC in many locations and, second, the non-BC components could readily be removed by thermo-denuding the fresh diesel soot particles. The ambient BC calibration is ~10% below the diesel car BC calibration. However, at least part of this difference is caused by incomplete removal of non-BC components from the ambient soot particles prior to mass selection. The SP2's sensitivity to wood burning BC is ~10-20% below that of diesel car BC, again somewhat biased due to incomplete removal of non-BC components. The two batches of fullerene soot agree within ±10% with the diesel car BC calibration, whereas Aquadag produces 20-40% higher incandescence signal at equal BC mass. In summary, fullerene soot can, in agreement with Moteki and Kondo (2010), be considered as a favourable SP2 calibration material resulting in ~10% uncertainty of measured ambient BC mass concentrations. In contrast Aquadag-based SP2 calibrations will result in substantial over-estimation of BC mass concentrations.

Above results will be presented in the context of general strength and limitations of the SP2 technique. Further insight will be given into the calibration of the scattering detector and the interpretation of these signals to derive particle mixing state information.

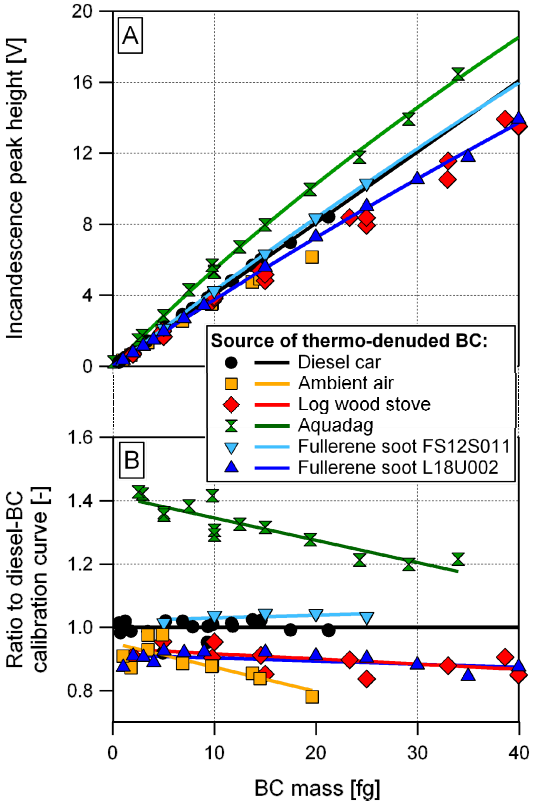

Figure 1. SP2 calibration: Absolute sensitivity to different types of BC (A) and relative sensitivity compared to BC from a diesel car (B).

Using a CPMA-Electrometer System as a Suspended Mass Standard

T.J. Johnson[1], J.P.R. Symonds[2], K.St.J Reavell[2], J.S. Olfert[1]

[1]Department of Mechanical Engineering, University of Alberta, Edmonton, Alberta, T6G 2G8, Canada

Keywords: Mass concentration, Particulate mass, Instrumentation, Measurement errors.
Presenting author email: tjjohnso@ualberta.ca

Many different methods have been developed to measure aerosol mass concentration and each system has measurement errors that are difficult to quantify. Gravimetric methods do not account for gas-phase material filter absorption or the evaporation of semi-volatile material. This method is also dependent on the relative humidity and temperature during measurement. Optical methods, such as Laser Induced Incandesce (LII) or MultiAngle Absorption Photometry (MAAP), are sensitive to particle morphology, composition or optical properties, such as refractive index.

The Centrifugal Particle Mass Analyzer (CPMA), which classifies particles by their mass-to-charge (Olfert *et al.*, 2005), can be used with an electrometer to calibrate these instruments. Since the CPMA classifies by mass-to-charge ratio, particles with multiple charges are also classified through the device (Symonds *et al.*, 2011). For example, a particle with one charge is classified the same as a particle with two charges and twice the mass as shown in Figure 1.

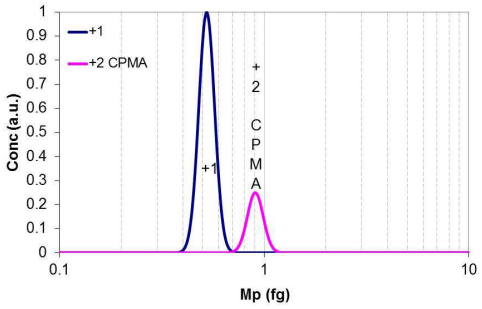

Figure 1. Effect of multiple charges on particle classification in the CPMA

Symonds *et al.* (2011) developed the theory of using a CPMA-electrometer system for a suspended mass standard. By using an electrometer to measure the charge of the particles, particles with *i* charges will be measured *i* times by the electrometer. The proposed setup is shown below in Figure 2.

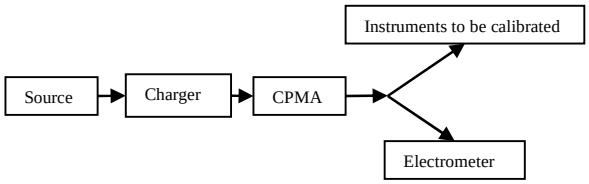

Figure 2. Experimental setup to account for multiply charged particles

The post-CPMA mass concentration (m_{total}) can be found by considering the total mass concentration of each particle charge level as shown in Equation 1.

$$m_{total} = m_{+0} + Mn_{+1} + 2Mn_{+2} + 3Mn_{+3} + \ldots \quad (1)$$
$$m_{total} = m_{+0} + M(n_{+1} + 2n_{+2} + 3n_{+3} + \ldots),$$

where m_{+0} is the mass concentration of neutrally charged particles, M is the mass set-point of the CPMA and n_i is the number concentration of particles with i charges.

Only the mass of positive particles is considered because the CPMA removes negatively charged particles. The current of the aerosol (I) is measured with the electrometer and is shown in Equation 2.

$$I = Qe(n_{+1} + 2n_{+2} + 3n_{+3} + \ldots), \quad (2)$$

where Q is the volumetric flow rate of the aerosol, e is the value of the elementary charge and n_i is the number concentration of particles with i charges.

Therefore by combining Equations 1 and 2, the post-CPMA mass concentration is given by,

$$m_{total} = m_{+0} + \frac{MI}{Qe}, \quad (3)$$

where the last term is simply the assumed singly charged number concentration displayed on the electrometer multiplied by the CPMA set-point. The zero-charge mass correction can be minimized or eliminated by: (1) minimizing small particles (of which many may be uncharged), (2) using a unipolar corona charger, and/or (3) using a DMA to remove zero-charged particles before the CPMA. A corona charger also increases system sensitivity as particles have more charges and the electrometer will measure a higher current.

The proposed system measures the mass concentration of an aerosol, while overcoming the uncertainties of other mass measurement methods.

Laser based mass spectrometric methods became a very important tool for the on-line analysis of single aerosol particles. There is a special focus on the detection of particle substances that may be responsible for adverse effects on human health. These organic molecules are often very difficult to detect due to the high degree of fragmentation. Therefore, an analytical tool that uses soft ionisation techniques is necessary.

The results of a first field application during a measurement campaign of a system affording these features will be presented. This setup consists of a differentially pumped inlet system to create a particle beam, a sizing unit for velocimetry and determination of the aerodynamic diameters of single particles (SP), an ion source for soft ionisation and a reflectron time-of-flight mass spectrometer (TOFMS) for ion analysis and detection. The ion source consists of a heating rod (T = 550 °C) for thermal desorption (TD) of particle bound molecules. A KrF-excimer laser (λ = 248 nm) is triggered according to the individual velocity of the detected particles for the selective ionisation of desorbed polycyclic aromatic hydrocarbons (PAH) via a resonance-enhanced multiphoton-ionisation (REMPI) process. By separating desorption and ionisation in two different steps, a soft ionisation with reduced fragmentation is provided (Bente, 2008).

This TD-REMPI-SP-TOFMS setup was tested for the first time in the field during a measurement campaign in Augsburg, Germany in winter 2010 with the scope to estimate the impact of particles deriving from wood combustion on ambient aerosol with an urban background (Oster, 2011).

About 360.000 particle events could be detected with the TD-REMPI-SP-TOFMS setup during the campaign. Analysis of the acquired mass spectra showed, that PAH could be found on 15.7 % of the analysed particles. On 13.5 % of the PAH-containing particles (2.1 % of all particle events), retene (m/z = 234) could be detected, a marker for the combustion of coniferous wood. 84.3 % of the particles showed no peaks that could be dedicated to PAH. It could be shown, that there are differences in the time series and diurnal variation of the occurrence of the separated particle classes (Fig 1). The differentiated particle classes also show differences in the size distributions of the measured aerodynamic diameters (Fig 2).

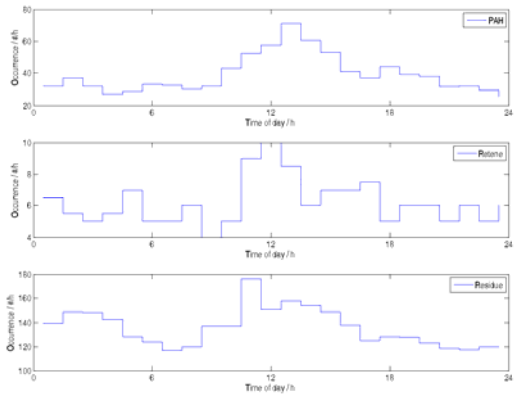

Figure 1: Diurnal variations of the PAH class (top), retene class (middle) and residue class (bottom)

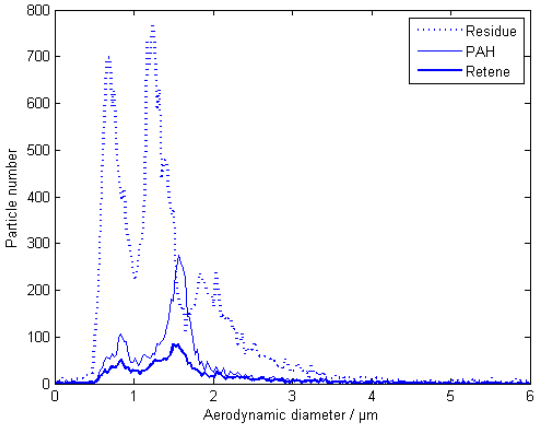

Figure 2: Size distributions of the PAH class particles (thin line), retene class particles (bold line) and residue class particles (dotted line)

The experimental setup for this work was enabled by the financial support of the Deutsche Forschungsgemeinschaft (DFG), grant ZI 764/1 and ZI 764/1-2.

In this study, experiments are described that are aimed to measure simultaneously the particle shape and fluorescence of secondary organic aerosol (SOA) produced from the reaction of α-pinene with ozone using an ASPECT aerosol size and shape analyser combined with an aerosol fluorescence sensor (AFS).

There is a considerable and growing interest in the detailed mechanism of the atmospheric oxidation of complex biogenic molecules, such as isoprene, terpenes and sesquiterpenes.[1-6] These volatile organic compounds (VOCs) are emitted from a wide range of vegetation[2] and their emission rate is estimated at around 1000 Tg yr^{-1}, *ca*. a factor of ten greater than the rate of release of anthropogenic VOCs.[3] There have been a large number of studies investigating the link between chemical mechanism and particle formation from the ozonolysis of terpenes, and how size and number of particles varies with reaction conditions. Such particles are likely to have severe health implications, since their size allows them to be easily inhaled. While the number density and size distribution are clearly important properties of SOA, the physical nature of the individual particle also has a major impact on SOA behaviour, affecting e.g. the interaction with radiation, its atmospheric lifetime and chemical processing. It is therefore important to employ techniques to investigate the physical properties of the aerosols.

The ASPECT aerosol size and shape analyser is the only commercial instrument which simultaneously measures the shape of an airborne particle in real time, as well as its size and total particle concentration. Many particle characterisation systems measure only particle size and base their measurements on the assumption that the particles are perfect spheres. [7] Both natural and man-made particles have a very wide variety of shapes and this non-sphericity may be an important parameter in classifying them. The ASPECT particle analyser uses Biral's Aerosol Size and Shape (ASAS) technology to simultaneously measure the size and shape of single particles at a high output rate.[7]

Samples were prepared in the following way at the University of Reading: A 100L inert Teflon bag is used as the sample chamber. A known pressure of the terpene is introduced into a 1L glass bulb attached to a vacuum line. The terpene is then diluted with synthetic air: the bulb is brought to atmospheric pressure and then evacuated slowly until the desired pressure is reached. The diluted sample is then blown into the bag using synthetic air. We can thus accurately determine the terpene concentration in the sampling bag.

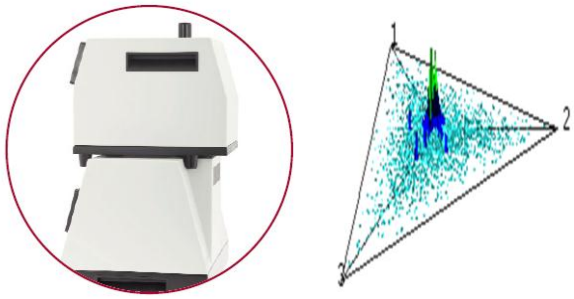

Figure 1: a) Image of AFS and ASPECT instruments for measuring particle size and shape in real time.[7] b) The triangular centroid plot illustrates the shape distribution of the SOA particles at 0% RH. The colour of each point denotes the number of particles at that location. Spherical particles can be seen close to the centre of the plot. Particles with flat surfaces such as cubic particles have a random orientation, therefore the display shows a three-point shaped distribution.[7]

Signal	UV Fluorescence	Visible Fluorescence
Minimum	187.00	768.00
Maximum	3219.00	4095.00
Average	1330.31	2309.18

Table 1. Summary of fluorescence data from the 100L sampling bag of SOA formed from the reaction of α-pinene (2 ppm) with ozone (1 ppm) at 0% RH recorded by two detection channels covering the UV and visible bands.

Conclusion: Our pump-priming study gives clear evidence for fluorescence in SOA formed in the reaction of α-pinene with ozone at 0% RH. The SOA generated in this study was predominantly of spherical shape.

Rupture event scanning: a novel procedure based on QCM to measure particle size within the nanometer range

F.N. Dultsev[1], S.N. Dubtsov[2]

[1]Institute of Semiconductor Physics, Novosibirsk, 630090, Russia
[2]Institute of Chemical Kinetics and Combustion, Novosibirsk, 630090, Russia
Keywords: Aerosol size distribution
Presenting author email: dubtsov@kinetics.nsc.ru

Determination of particle size is necessary in aerosol chemistry, in surveying health effects of particulate matter and in many other applications. The method based on QCM proposed by us previously (Dultsev, 2009) is a useful tool also in testing the reactivity of airborne particulate matter, because the chemical properties of the QCM surface affecting its affinity to the particles may be modified The necessary bonding of a particle with the surface may be achieved by coating the QCM surface with the appropriate agent. Provided that physical adsorption occurs (i.e. weak bonding), it is possible to analyze the particles several tens nanometers in size. We used particle generator described previously (Ankilov, 2002). It generates tungsten oxide nanoparticles 20–30 nm in size, depending on air flow rate at a given temperature of the tungsten filament.
The flow ratio through channels 1 and 2 was 1:30. Total flow rate into the reactor was kept constant in our experiments. The generator was calibrated with the diffusion spectrometer of aerosol (DSA). Particle size distribution obtained with the help of DSA is shown in Fig. 1.

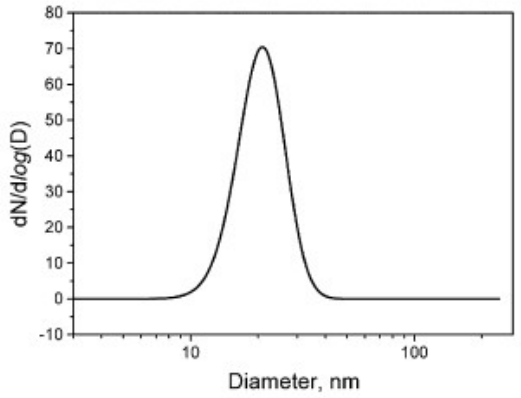

Fig. 1. Particle size distribution determined with the diffusion spectrometer of aerosol (DSA).

Filament temperature and flow rate were chosen so that the particles with the mean size of 20 nm were generated. The particles in air flow arrive from the generator to the chamber where the QCM is placed. The results of the measurements made with the help of QCM are presented in Fig. 2. One can see how the acoustic signal changes with an increase
in the voltage on QCM in the presence of nanoparticles in the gas phase, for different air flow rates through the particle generator.

The QCM (sensor) used in this experiment was a quartz strip with metal electrodes. The electrodes were coated with silicon dioxide. Thus prepared surfaces provide physical adsorption of nanoparticles (weak bonding). One can see that an increase in the flow rate causes a decrease in particle size. Such behaviour was previously observed with the help of DSA. With a decrease in tube length, an increase in particle concentration occurs due to the smaller particles. The signal from these smaller particles appears at a voltage of about 2V, while the major signal for particles 20nm in size appears at a voltage of 1.5 V..

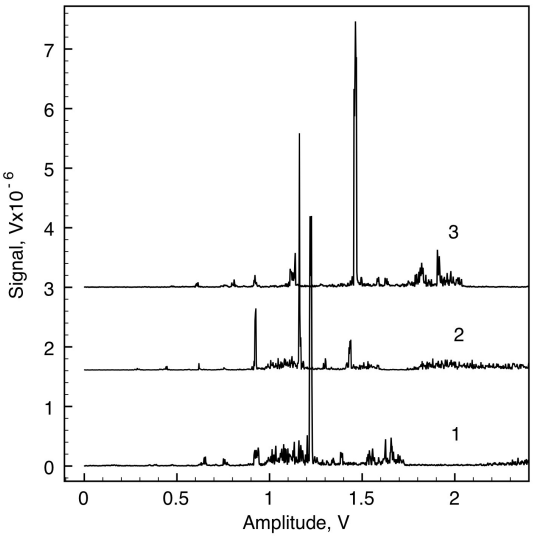

Fig. 2. Acoustic signal from rupture event scanning.

Thus, the application of a quartz resonator in the active mode allows us to obtain particle size distribution for the particles having similar interactions with the surface. This allows one to use this method in environmental monitoring and in aerosol measurements Frequency scanning simplified the adjusting procedure and allowed us to obtain amore complete picture of nanoparticle rupture from the surface. Integrated functioning of a single quartz strip both as an active resonator and a microphone registering the acoustic signal allows the development of simple and cheap procedures for detecting and identifying the particles with different bonding strengths.

We have developed a new optical method for the determination of different physical properties of aerosol particles suspended in the ambient air based on elastic light scattering on single particles (Szymanski et al. 2002). Comprehensive numerical analysis and laboratory tests were performed to study the reliability of the method (Nagy et al. 2007). A mobile prototype instrument were built so that we can study the method in field measurement campaigns and compared the results with other devices (TL-APC, Grimm-OPC, Magee Sc. Aethalometer, etc.).

In the frame of Jedlik Ányos project the Dual Wavelength Optical Particle Spectrometer (DWOPS) was utilized in 3 different longer measurement campaigns that aims to develop a new method/model for identification of different aerosol sources having different origin (anthropogenic - industrial, combustion/traffic, agricultural, etc.) (Fig. 1.). The main advantage of the new method is that with a short (several minutes) sampling time the contamination sources could be determined without further time consuming and expensive laboratory analyses. Fig. 2 shows the results obtained using DWOPS and Aethalometer instruments where the data from different instruments are presented. We have extracted and presented the number concentration and the absorbing fraction of particles (absorbing - imaginary refractive index are larger then 0.1) from the DWOPS data.

Figure 1. The measurement site at Gilice sqr, in Budapest.

The results of the measurement campaigns show that the counting efficiency of the instrument is similar to the counting efficiency of other commercially available instruments. The time series of the absorbing fraction of the particles behave differently in different size ranges.

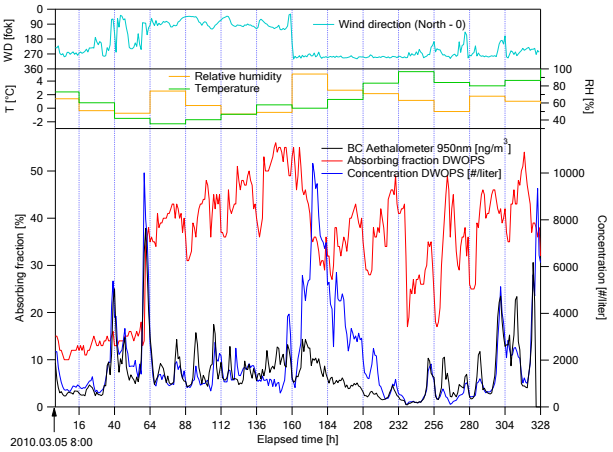

Figure 2. Some results of the measurement campaign

It is very important to measure atmospheric aerosols and analyze the characteristics of them since they have great effect on environment and human body. Satellite, aircraft, radio sonde have usually been used to measure vertical distribution of aerosols and its conditions such as temperature, humidity and atmospheric pressure (Daniel R. *et al*., 2008; Wenying H. *et al*., 2009). The common method of aircraft sampling takes that extracts collected particle on sampler filter and carries chemical analysis. Although, the method is favorable to measure the distribution of atmospheric aerosol, problems caused by fast flight speed; fragmentation of aerosol droplet and dispersion of collected particle (Hermann *et al*, 2001), legal limit; flight altitude, prohibited airspace and flight time, and economical limit; frequency of sampling, have been restricted the measurement. These restrictions can be resolved by our all-in-one balloon system applying custom-made polyurethane balloon controlled by electrical winch. The system is composed of developed mini-impactor of 56g weight, several sensors, pump and its data processing board. It can not only collect atmospheric aerosol depending on each altitudes and particle sizes at low cost, but also monitor the atmospheric conditions; temperature, humidity, wind velocity, atmospheric pressure, GPS data, during the measurement.

In this research, we performed the atmospheric aerosol measurement using all-in-one balloon particle sampler system at altitude of 300m and 900m. Figure 1. shows the atmospheric conditions profile depending on its altitude and Figure 2. shows the TEM images of collected particle. Figure 3. EDS analysis of Fig 3. samples

Keywords: impactor, particle concentration, collection trap
Presenting author email: chhuang@mail.ypu.edu.tw

The aerosol sampler using an impactor with collection trap was applied to determine particle concentration in the air stream. Due to the solid particle may bounce off from the surface of the impactor plate to change the particle size distribution; the porous substrate within the collection trap in the impactor has been used. The particle collection efficiencies of porous foam substrate within the collection trap in the impactor with larger porosity and thickness was found to be higher than those with smaller thickness and porosity (Huang & Lin 2010).

In this study, the collection characteristics of particles by separating the particles from the air stream that impacts on the porous substrate within the collection trap in the impactor were studied experimentally at different flow rates. Oleic acid particles were generated as liquid particles by utilizing an ultrasonic atomizing nozzle. An aerodynamic particle sizer was applied to determine the particle number concentrations at the inlet and outlet of a test sampler including a circular jet and collection substrate. Porous foams were used as the collection substrates with foam thicknesses of 3 mm and foam porosity of 100 ppi.

In the test, samples of particle concentration for single-nozzle impactor with collection trap were obtained from a titanium dioxide factory and a classroom. The sampling tests used a cyclone, a Multi-orifice Uniform Deposit Impactor, and an impactor with collection trap. In the sampling, two collocated IOSH cyclones used polytetrafluoroethylene and mixed cellulose ester filters to obtain samples for weight measuring and metal concentration measuring, respectively.

When particles went into the IOSH cyclone, those over the size of 4.0 μm were collected by cyclone, while those less than 4.0 μm were collected by the bottom filter of the device. The concentration of the particles collected by polytetrafluoroethylene is equal to the weight concentration of respirable particulate matter. The samples collected by the mixed cellulose ester filter were then processed according to standard digestion procedures; afterwards, they were analyzed for metal content using inductively coupled plasma - optical emission spectrometer.

Fig. 1 displays the penetration characteristics of particles for single-nozzle impactor with collection trap at the flow rates of 1.3 LPM and 1.9LPM. The figure shows that the particle collection efficiencies of the single-nozzle impactor with collection trap at the flow rates of 1.3 LPM are lower than those for 1.9 LPM. It indicates that the cutoff aerodynamic diameter of the penetration curve for the single-nozzle impactor with collection trap at flow rate of 1.9 LPM is found to be near 4.0 μm. This study will evaluate particle concentration based on the use of IOSH cyclone, Multi-orifice Uniform Deposit Impactor and the impactor with collection trap in different places.

Presenting author email: j.staelens@vmm.be

Ambient air pollution constitutes a risk to human health and can cause a significant reduction in life expectancy. Despite considerable improvements in air quality over the last decades, ambient aerosol concentrations remain high, particularly in areas where urban development is concentrated. A major part of the North-West European (NWE) region is considered as one of the two European hot spot zones for particulate matter. Research shows that pollutant metrics not often measured in air quality monitoring networks such as the number and characteristics of airborne ultrafine particles (UFP) constitute better links to human health effects than e.g. nitrogen dioxide and particulate matter (PM_{10}). However, there is little understanding of the spatial distribution of these metrics (Hoek *et al* 2011) and their relationship with health aspects. This hampers decision makers from taking effective measures.

Therefore, the primary aim of the Joint Air Quality Initiative (Joaquin) is to facilitate the development of health-relevant air quality policies in the NWE region. To achieve this, three work packages are carried out: (1) measuring health-relevant air pollutants such as UFP and elemental carbon, (2) evaluating measures to reduce human exposure to these pollutants and (3) raising awareness of policy makers, stakeholder groups and the general public on health effects of air pollution. The Joaquin project is a cooperation of nine partners and four sub-partners from four NWE countries (Belgium, the Netherlands, France and the United Kingdom), including research institutes and universities as well as regional and local public authorities.

Within the monitoring package of Joaquin (WP1), the most suitable air quality monitoring infrastructure for ultrafine particles will be selected based on a literature review and laboratory testing. This infrastructure will be set up in four of the partner cities (Amsterdam, Antwerp, Brighton and Leicester) to provide real-time information on the UFP number concentration and size distribution on a continuous and multi-annual basis, in combination with the monitoring of other air quality parameters such as PM_{10} and black carbon. The transnational character of the infrastructure and the use of equal devices and operational control will be a clear benefit for the data analysis. This fixed infrastructure will be complemented by a mobile station with identical equipment as the fixed stations, allowing validation and harmonization of the instrument operation. Furthermore, this mobile van will allow expanding the coverage of the fixed locations and testing the representativeness of these sites (Weijers *et al* 2004). Second, the composition and sources of PM_{10} will be studied during 1-2 years for all sites. Filter samples collected every 6th day (Vercauteren *et al* 2011) will be analyzed for elemental content, water-soluble ions, elemental and organic carbon, levoglucosan and reactive oxygen species. Third, to improve public availability of health-relevant air pollution information, all data of the Joaquin project will be gathered within a NWE air pollution observatory and information centre. In this way the data from the novel network and of the source characterisation studies will be collectively analyzed, assessed and distributed. Using data from other European networks and earth observing satellites, air quality data will be visualized within an open access on-line geographical information system.

In addition to the description of the monitoring work package of the Joaquin project, we will present results from a recent intercomparison study of UFP monitors. Eight different UFP monitors that measure size distribution were tested, differing in sample flow rate, differential mobility analyzer and type of aerosol charger (radioactive vs. corona discharge). After classification particles were counted using the condensation technique or an electrometer. The monitors were compared using generated aerosols consisting of several monodisperse polystyrene latex sizes (diameters ranging from 20 to 600 nm) and ammonium sulphate particles (~70 and ~150 nm). They were also challenged with ambient indoor and outdoor air, the latter with and without exhaust air. These results, together with the literature review, were used as a guidance to select the UFP monitor that is most appropriate for the fixed and mobile monitoring network of the Joaquin project.

The Joaquin project is supported by INTERREG IVB North-West Europe (http://www.nweurope.eu).

Keywords: light absorption, black carbon, in-situ measurements
Presenting author email: john.backman@helsinki.fi

Tropospheric aerosols are abundant and they both scatter and absorb solar irradiance. Therefore, they have the ability to affect the radiative budget of the atmosphere. Aerosols remain one of the uncertainties in atmospheric modelling (Jacobson 2001). Light scattering by aerosols is strongly size dependent while light absorption is dependent on the area of the light absorbing species, commonly referred to as light absorbing carbon (LAC) or black carbon (BC, Bond & Bergstrom 2006).

Airborne LAC can alter the temperature profile in the atmosphere by absorbing solar irradiance in the atmosphere and reducing it at the surface. An altered temperature profile can suppress convection and cloud formation.

Filter-based absorption measurements are a popular means of measuring light absorption coefficients or BC mass concentrations since they are cheap and suited for unattended use. The method relies on the deposition of aerosol particles onto a filter matrix in a known volume of air while light transmittance trough the filter is monitored.

There are a variety of issues associated with this method which have been addressed by the scientific community (Collaud Coen et al., 2010 and references therein) mainly focusing on the transmission correction function. The transmission correction function is intended to correct for the samples change in the radiative transfer of light in the aerosol-laden filter matrix.

Different correction algorithms have different approaches to deal with the issue as the filter gets loaded. These artefacts are due to the shadowing effect by pre-deposited particles, increased optical path by light scattering particles, the asymmetry of the particles using back scattering fractions, and the single-scattering albedo of the pre-deposited aerosols. Furthermore, it has been shown that the instrument response of filter-based absorption measurements is sensitive to the penetration depth of the sample particles (Moteki et al., 2010). Ideally, a correction algorithm would be able to compensate for all of these effects and the change from an aerosol-laden filter to a pristine one would go unnoticed. By comparing data before and after a filter-spot change we get an indication on how well the algorithms are able to compensate for these artefacts at different atmospheric conditions (Fig 1).

Seven Aethalometer correction algorithms were evaluated in comparison to reference absorption (MAAP) for two different data sets from Pallas in Finland (Fig. 1a) and Ispra, Italy (Fig. 1b). The data used is 9 and 18 months long respectively.

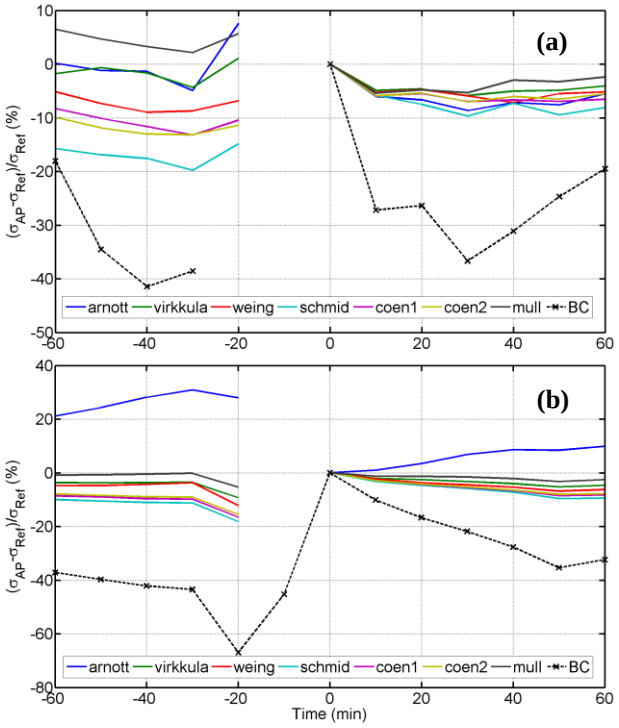

Figure 1. Aethalometer absorption coefficients calculated using seven different correction algorithms before and after filter change for Pallas, Finland **(a)** and Ispra, Italy **(b)**.

Water Soluble Organic Carbon (WSOC) Measurement: A Theoretical Analysis

M. Psichoudaki[1,2], S.N. Pandis[1,2,3]

[1]Department of Chemical Engineering, University of Patras, Patras, 26500, Greece

Keywords: organic aerosols, water soluble organic compounds, measurement characterization
Presenting author email: mpsichoudaki@chemeng.upatras.gr

Organic aerosol represents one of the least understood fractions of atmospheric aerosol, although it typically comprises a large fraction of ambient particulate matter. Due to the large number of sources each emitting hundreds of compounds and their subsequent atmospheric oxidation, thousands of semi-volatile organic species exist in the atmosphere, ranging from highly water-soluble to insoluble (Sullivan et al., 2006). The water soluble fraction of the organic particulate matter (usually referred to as WSOC) influences the interactions of aerosols with water and thus alters their hygroscopicity and their ability to act as cloud condensation nuclei. Additionally, WSOC is an indicator of the age of organic aerosol, since atmospheric oxidation of organic species generally leads to more water soluble species. However, WSOC is operationally defined and there is a variety of methods that are used for its measurement.

A typical off-line WSOC sampling technique includes sample collection on quartz fibber filters followed by extraction and total organic carbon analysis. The volume of water used for the extraction of the water soluble organic compounds per unit of area of the filter analyzed (V/A) ranges from 0.3 to 15 mL cm^{-2}. In this work we quantify theoretically the impact of the method used for the WSOC measurement on its results.

The fraction of an organic aerosol compound that will contribute to the WSOC depends not only on its solubility, but also on its concentration, the concentration of the aerosol components, and the method used for the WSOC measurement. We investigate two rather extreme cases: an organic aerosol phase that behaves like an ideal solution and in the other organics that act independently of each other. We also assume that the method used allows the organic aerosol-water system to equilibrate and that aqueous solution after the extraction is dilute.

In the ideal organic solution case the fraction of an organic compound that will be dissolved in the water after the extraction does not depend on its atmospheric concentration. On the other hand, it depends not only on the solubility of the compound, but also on the concentration of the other organic aerosol species (Figure 1). For higher organic aerosol concentrations the extracted WSOC fraction decreases.

If, on the other hand, an organic compound is assumed to be independent of the other organics (not dissolving in the organic aerosol phase) its fraction dissolved in the WSOC depends on its concentration in the particulate phase, its solubility and the water used for the WSOC extraction (Figure 2).

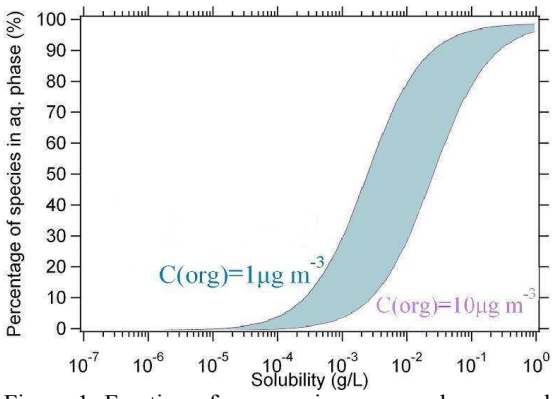

Figure 1: Fraction of an organic compound measured as WSOC for total organic aerosol concentrations 1 and 10 μg m^{-3} and V/A = 0.3 mL cm^{-2}.

In Figure 2 if the concentration and solubility of the compound are such that the corresponding point lies below the 100% line of a method, then 100% of the compound's mass will be measured as WSOC by this method. If a compound is in the upper triangle less than 10% of its concentration will be measured as WSOC.

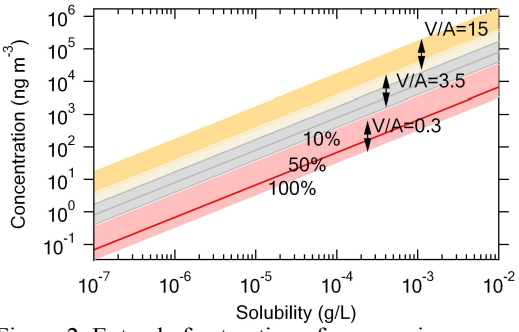

Figure 2: Extend of extraction of an organic compound as a function of its concentration, solubility and the extraction method.

The implications of these theoretical insights for the measurement of compounds as WSOC in different situations (ambient, laboratory, source characterization) will be discussed.

Many measurement methods have been developed for Black Carbon (BC) measurements based on light absorption and a lot of inter-comparisons among different methods have been conducted so far. Nevertheless, at the state of the art, a reference methodology and a clear definition of black carbon does not exist (Bond and Bergstrom, 2006).

In this presentation, we will show results obtained with a home-made polar photometer suitably set up to measure light-absorption by BC particles collected on quartz-fibre and Teflon filters. Parallel measurements by a Multi Angle Absorption Photometer (MAAP) were also performed. Thermal optical transmittance analysis was carried on quartz fibre filters to obtain $\sigma_{abs,BC}$ values by different thermal protocols.

Two field experiments were carried out in Milan in 2009/2010 and in 2011 performing sampling campaign during winter and summer periods in each experiment.

The first campaign was mainly devoted to the validation of our experimental set-up, which was demonstrated to give b_{abs} values (in Mm^{-1}) fully comparable to those obtained by a MAAP when using quartz fibre filters to collect atmospheric particles ($b_{abs,\ polar\ ph.} = 0.96\ b_{abs,\ MAAP}$ R^2=0.96). On the contrary, b_{abs} values (in Mm^{-1}) determined with the same set-up and radiative transfer scheme resulted significantly lower (about a factor 2) when collecting the aerosol on PTFE filters and – even if at a less extent – the same behaviour was detected on quartz fibre filters where the water soluble component was removed by washing the filter.

The second experiment was planned to investigate the potential role of volatile organic compounds on the differences observed on quartz fibre and PTFE filters. In this case, the sampler collecting on the quartz-fibre filter was equipped with an activated carbon monolith denuder to remove organic gases from the incoming air stream. Results obtained by our polar photometer showed a fairly good agreement between the absorption coefficients measured on quartz fibre and PTFE filters ($b_{abs,\ PTFE} = 0.90\ b_{abs,\ quartz\ denuded}$ R^2=0.97).

According to our results, the use of a denuder on optical systems collecting particle on quartz/glass fibre filters would give a more accurate b_{abs} value and, therefore, a better BC estimate.

In methods based on light-absorption measurements a crucial parameter is the BC mass absorption coefficient ($\sigma_{abs,BC}$ in $m^2\ g^{-1}$) defined as the ratio of aerosol absorption coefficient (m^{-1}) to the BC mass concentration ($\mu g\ m^{-3}$). Depending on the size distribution and refractive index, $\sigma_{abs,BC}$ can range between 2 and 25 $m^2\ g^{-1}$ (Bond and Bergstrom, 2006) and the absorption properties due to the internally mixed BC particles can be enhanced as compared to those in the externally mixed BC particles (Naoe et al. 2009). In particular, a problem arises when converting aerosol absorption properties to BC concentration as generally mass absorption coefficients are derived from the TOT/TOR analysis of EC, which is not standardised yet. During the field experiments carried out in Milan we determined the BC mass absorption coefficients using three different thermal protocols (NIOSH, EUSAAR_2, IMPROVE-like) on untreated quartz fibre filters and water washed fibre filters (first experiment) and the NIOSH protocol was used on denuded quartz fibre filters collected during the second experiment.

Results show that there is a very large variability in the $\sigma_{abs,BC}$ as reported in table 1.

Table 1. Comparison between BC mass absorption coefficients ($\sigma_{abs,BC}$ in $m^2\ g^{-1}$) obtained with the TOT method and different thermal protocols

	NIOSH	EUSAAR_2	IMPROVE-like
Untreated	16.0	10.7	10.1
Water washed	8.7	6.9	6.3
Denuded	9.6		

These results clearly show that the BC concentration given by optical systems using conversion coefficients based on EC values will always be affected by a certain degree of inaccuracy. Methods to overcome this problem are therefore mandatory as this practise is widely used by the scientific community using optical systems.

Black carbon (BC) is a by-product of anthropogenic (e.g. fossil fuel) and natural incomplete burning (wild fires). Being a strong absorber of solar radiation it is a key component in global warming, and due to its health effects, an important factor of air pollution. Diesel engines are one anthropogenic source of BC. E.g. the contribution of marine diesel engines on global BC emission and arctic ice retreat are being studied with theoretical models. However, there is a gap of knowledge between the parameters required by the models and the current measurement results of ship derived BC. A link between the climate model parameters and measurement methods commonly used in engine laboratories is needed.

Filter smoke number (FSN) is a common filter-based absorption method that detects the filter blackening caused by engine exhaust smoke. FSN requires substantial empirical corrections to derive BC mass (Northrop et al., 2011). Multi-angle absorption photometer (MAAP) is a filter-based instrument that measures the aerosol black carbon concentration at the wavelength of 670 nm. MAAP utilizes a combination of reflection and transmission measurements together with a radiative transfer model to yield the BC concentration (Petzold and Schönlinner 2004). The aim of this study was to compare the two filter-based methods in measuring black carbon concentration of diesel exhaust.

The measurements were performed in the emission laboratory of Wärtsilä Finland Oy in October 2011. The tested engine was a medium speed diesel engine and the used fuel was ultra-low sulphur diesel fuel. Eight engine load points were tested in two consecutive days. Each load point was tested for approximately 30 min. The data averaging time for the MAAP was 1 min and the flow rate was 10 lpm. A default absorption cross-section of 6.6 m^2 g^{-1} was used for the MAAP. The dilution ratio was in range 38–604. FSN was measured directly from the undiluted samples. In addition to BC, particle size distributions of diesel exhaust were measured with two scanning mobility particle sizers (SMPS), particle chemical composition with soot particle aerosol mass spectrometer (SP-AMS; http://www.aerodyne.com/products/soot-particle-aerosol-mass-spectrometer-sp-ams) and particle mass concentration with Tapered element oscillating microbalance (TEOM).

The measured BC concentration from the MAAP varied from 1 to 30 µg m^{-3} corresponding to the undiluted BC concentrations of 0.2–2.1 mg m^{-3}. BC from the MAAP and FSN correlated very well for the whole concentration range (Figure 1). On average the MAAP gave 27% lower values than the FSN. Black carbon constituted 43% of the particle mass measured by the TEOM on average, with the BC fraction ranging from 14 to 77% depending on the engine load. Organic compounds composed slightly lower fraction of the particle mass than BC; the mass percentage of organics was 33% on average. The rest of the particle mass either chemical components not measured by the AMS, or particles larger than ~1 µm in diameter that were included in the TEOM mass concentration but not in that of the AMS because of different cut-offs in AMS and TEOM sampling inlets.

The results obtained in this study indicated that the FSN method is comparable with the MAAP for measuring BC emission of medium speed diesel engine.

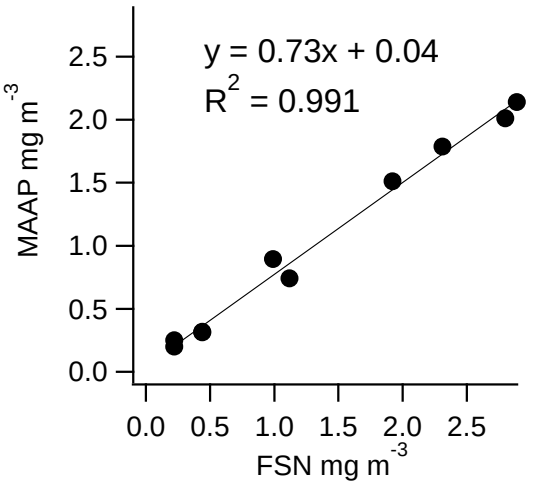

Figure 1. The comparison of black carbon concentrations measured by the MAAP and FSN.

Aerosol exposure is of great concern for medical and air-quality experts due to the particles' ability in crossing human respiratory system, depositing in its deepest and defenceless regions and carrying condensed toxic compounds. In particular, epidemiological, toxicological and environmental researchers are trying to understand what is the particle property mainly related to negative effect on human health. About the size the interest of such experts is moving from particle mass concentrations to particle number and surface area concentrations mainly characterized in terms of sub-micrometer and ultrafine particles (UFPs). Particle number concentrations are usually measured through condensation particle counters (CPCs) which are able to count particles down to few nanometers by optical methods after their growth by condensation of a working fluid onto the particles. Several CPC models were designed having different minimum detectable particle diameter (cut-off size) as function of the working fluid, the aerosol losses in the inlet of the CPC, the efficiency of the optical system, and the particle activation efficiency (Petaja *et al.* 2006). Due to their operation methods, such CPCs were mainly used for laboratory purposes. Anyway, in order to perform UFP exposure assessments on personal scale, hand-held, battery powered devices are needed. To this purpose a particle counter (NanoTracer, Philips) based on diffusion charging technique was developed. It does not require working fluid to growth the particles, and it is able to provide number concentration (in the range 10-300 nm), average particle diameter, and lung deposited surface area concentration measurements. Shortly, aerosol accurately charged is captured by fibrous filter in a Faraday cage producing a current signal proportional to the amount of charged particles, and their average diameter. Through a semi-empiric algorithm the device is also able to evaluate the different fractions of the lung deposited surface area (Marra *et al*. 2010).

In the present work a calibration method of two NanoTracers in terms of total number concentration, average diameter and total alveolar deposited surface area is proposed and applied. In order to perform such calibration an aerosol generation system (3940 TSI Inc.) was used. It is able to generate particles with a specific mode and total concentration. The first step was the calibration of a CPC 3775 (TSI Inc.) making a comparison with an Aerosol Electrometer 3068 (TSI Inc.) according the procedure reported in Hameri *et al.* (2002). In order to calibrate the NanoTracers a buffer volume (about 20 L) was used. Monodisperse and polidisperse aerosols accurately produced was flown in the volume where two NanoTracers were placed. Simultaneously, particles were sampled from the volume through a CPC3775, a Nanoparticle Surface Area Monitor (NSAM 3550, TSI Inc.) and a Scanning Mobility Particle Sizer spectrometer (SMPS 3936, TSI Inc.) in order to measure total particle number concentration, total alveolar deposited surface area concentration and particle number distribution, respectively. The following ranges are investigated: 10^4-10^5 part. cm^{-3} in terms of particle number concentrations and 30-200 nm for the mean diameter. Preliminary results obtained at a diameter of 50 nm and low concentrations ($8.4\times10^3 \pm 51$ part. cm^{-3}) are encouraging: maximum differences of 10% were found in terms of particle number and alveolar deposited surface area concentrations, as well as of 4% in terms of mean diameter (Figure 1).

Carbonaceous material in atmospheric particulate matter can be classified as elemental carbon (EC), organic carbon (OC) and carbonate carbon (CC) (Birch and Cary, 1996). OC is associated with organic compounds either directly emitted from the sources or formed by the condensation of products formed via the atmospheric photooxidation of organic species. Emissions of EC are dominated by primary emissions from combustion sources.

Traditionally, organic and elemental carbon measurements have been made by collecting particulate matter on quartz fibre filters that are subsequently analyzed by offline thermal evolution and combustion techniques. For OC end EC speciation a thermal – optical method is used. In this method He-Ne laser light passed through the filter allows continuous monitoring of filter transmittance. A flame ionization detector is used for quantification of evolved carbon. (Birch and Cary, 1996).

In recent years, a semi-continuous OC/EC analyzer has become available (Sunset Laboratory - Forest Grove, OR). In a first stage it provides the sampling of atmospheric particles on quartz fibre filter and in the second stage the thermal analysis and the detection are carried out. An infrared detector is used for quantification of evolved carbon.

This work presents the results of the intercomparison among the offline instrumentation (Sunset Laboratory) of the Department of Chemistry, University of Bari (offline 1) and the offline (offline 2) and the semi-continuous analyzers (online) (Sunset Laboratory) of ENEL - Research Technical Area of Brindisi.

PM_{10} samples were collected at different times (2, 4, 8, 12 and 24 hours) in order to assess the analytical agreement over a wide range of OC, EC and total carbon (TC) concentration.

Five replicates of the same filters were analyzed by the offline instruments and three replicates were analyzed by the semi-continuous analyzer. Student's *t*-test showed that 64% of the OC, EC and TC average data were not significantly different ($\alpha = 0.05$) when analyzed by different instruments and 22% of the significantly different data were referred to EC.

Good linear correlations were found between the OC, EC and TC data obtained by the offline analyzers. As example, in Figure 1 the linear correlation between the OC data sets from the offline 1 and offline 2 instruments is reported.

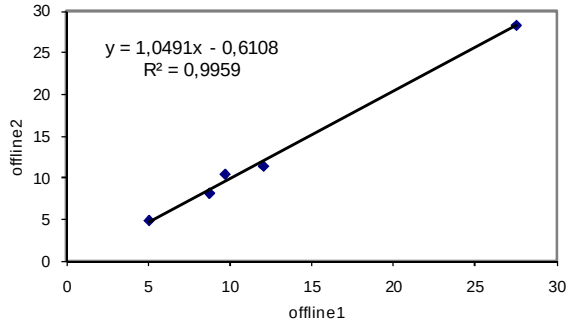

Figure 1. Comparison between OC data from offline instruments

However, a worse agreement was found from comparison among the offline analyzers and the online instrument data, in fact in these cases slopes deviate from the unit value. Such results showed a different response when samples at the lowest and highest concentration were analyzed by offline and online analyzers. This bias does not occur at the intermediate OC, EC and TC concentrations.

In Figure 2 the linear correlation between the OC data sets from the offline 1 and online analyzers is reported.

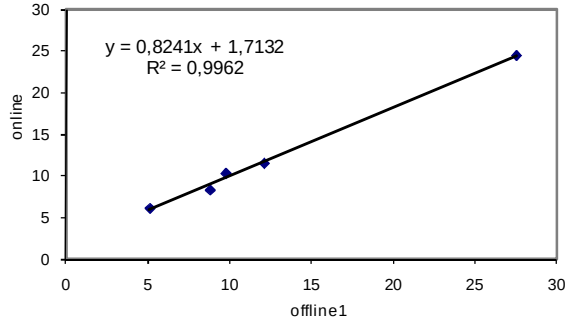

Figure 2. Comparison between OC data from offline 1 and online instruments

Global estimates of secondary organic aerosol (SOA) formation flux show that current descriptions miss a large fraction of the sources (Goldstein and Galbally, 2007). This gaping underestimation has been linked to a poor understanding of aerosol functionalization in the atmosphere (Volkamer *et al*., 2006) and lead to the formation of a new conceptual framework for the description of the aerosol, based on volatility versus polarity plots (Jimenez *et al*., 2009). This new framework is almost exclusively based on High Resolution Time of Flight Aerosol Mass Spectrometer (HR-Tof-AMS) data, as this instrument gives access to average H:C, N:C and O:C ratios for the bulk aerosol.

Electrospray ionization coupled with high-resolution linear ion trap Orbitrap™ (Thermo Corp.) mass spectrometry (ESI-HRMS) provides an alternative for retrieving such elemental information on the aerosol organic fraction.

The highest resolving power of HR-ToF-AMS reaches Δm/m=4300 at m/z 200, with mass range ranging from 10 to 500 amu. The AMS estimates for O:C and H:C ratios are thus based on heavy fragmentation of organics followed by stoichiometry attribution on those fragments. Given the resolution of the HR-ToF-AMS, such an attribution is not feasible above a certain mass, making fragmentation a necessary aspect of the measurement. On the other hand, Orbitrap-HRMS provide a resolution of 100,000 at m/z 400, with a mass range 50 – 2000 amu, enabling stoichiometry retrieval up to higher masses than the AMS. Coupled to a "soft" electrospray ionization method, Orbitrap-HRMS gives O:C and H:C ratios on entire molecules in the analysed mixture. In order to cross-validate the measured O:C and H:C ratios, we applied both methods on different types of atmospherically relevant samples: two surrogates of secondary organic aerosol, obtained from controlled aqueous phase photochemistry experiments, and samples from two different field experiments.

The first photochemistry experiment investigated the aqueous phase photooxidation of methacrolein (MACR) and methylvinyl-ketone (MVK), the two main oxidation products of isoprene, the volatile organic compound (VOC) that is mostly emitted on the global scale. Photolysis of H_2O_2 provided OH radicals whose reaction with MACR and MVK initiated the production of oligomers that extended up to 1400 amu (Liu *et al.,* 2012). Taking advantage of the regularities observed in the oligomer systems, the ESI-HRMS data were used to propose stoichiometries for more than 75% of the observed signal. The observed stoichiometries and their evolution during the reaction are compared with HR-ToF-AMS data obtained from the nebulized content of the aqueous phase photoreactor.

The second photochemistry experiment investigated the photosentitized reaction of selected VOCs in an aerosol flow tube, where the resulted AOS was analyzed online by HR-Tof-AMS, and collected for off-line Orbitrap analysis.

Finally, we used samples from two contrasted field campaigns: the first at an urban kerbside site (Grenoble, France) and the second at an urban site impacted by harbor activities and regional photochemistry (Marseille, France).

The French Région Rhône-Alpes is acknowledged for GSM PhD grant. The MOCOPO and APICE programs kindly provided the field samples. The photochemistry experiments were conducted analysis were conducted under the CUMULUS and Atm-Orbitrap projects.

Determination of site specific correction parameters for Aethalometer using multi-wavelength photoacoustic data.

Á. Filep, T. Ajtai, N. Utry, Z. Bozóki, G. Szabó
Department of Optics and Quantum Electronics, University of Szeged, Hungary

Keywords: photoacoustic spectroscopy, optical absorption, Ångström exponent.
afilep@titan.physx.u-szeged.hu

Light absorption by aerosols strongly influences the global radiation balance and visibility. Additionally, absorption feature of aerosol is characteristic to its constituent, therefore on-line investigation of absorption provides unique possibility for identification of its chemical composition or its changes. The most frequently used instrument for on-line measurement of light absorption by atmospheric aerosols in the visible and the upper UV region is the 7λ-Aethalometer (Magee Scientific), which obtains aerosol absorption coefficient from the real time measurement of light transmission on filter accumulated aerosol at seven wavelengths. The absorption coefficient deduced from changes in light transmission is suffering from serious measurement artefacts. When the filter is relatively unloaded with aerosol, multiple scattering, when the filter gets more polluted, shadowing effect influences the deduced absorption. To increase the reliability of deduced absorption the additional correction of measured data is necessary. Although numerous efforts have been made to correct these artefacts, no generally valid correction procedure is available, due to the fact that the complex interaction between filter and aerosol depends not only on relative abundance of the sampled analyte, but also on its microphysical (size distribution, single scattering albedo, shape irregularity) properties (Collaud Coen et al. 2010). Although the only method that can measure the light absorption by aerosol in-situ, without sampling artefact is the photoacoustic spectroscopy, it is not as widespread in its application as the filter-based technique yet. In the last decades several promising technical realization of the photoacoustic method for measurement of light absorption by aerosol has been published, but most of them is operating only at one wavelength in the visible, limiting their selectivity. We have introduced recently a novel multi wavelength photoacoustic instrument for the measurement of absorption behaviour of the ambient aerosol in the UV, VIS, and near-IR spectral region. The instrument operates at four discrete wavelengths (266 nm, 355 nm, 532 nm, 1064 nm) and applies wavelength independent calibration procedure providing a unique possibility on sensitive and selective measurement of the absorbing fraction of the ambient (Ajtai et al. 2011).

We present the results of optical absorption measurements on atmospheric aerosols carried out in different meteorological conditions at different seasons and sites using a conventional 7λ-Aethalometer and the 4λ-PAS. Optical absorption determined by the two instruments was thoroughly inter-compared in the overlapped wavelength region and out of the common wavelength range, especially focusing on UV region, where measured (4λ-PAS) and extrapolated (7λ-Aethalometer) results were compared. We also present a possibility on determining site-specific, wavelength dependent correction parameters using concurrently measured absorption by photoacoustic spectroscopy.

We demonstrate that by using site specific correction parameters optical absorption deduced from measurement data of the Aethalometer are reliable in its operational wavelength range; but extrapolated absorption coefficients towards the shorter wavelengths need further correction. We also demonstrate that the correction towards the shorter wavelengths strongly depends on the absorption Ångström exponent (Fig. 1).

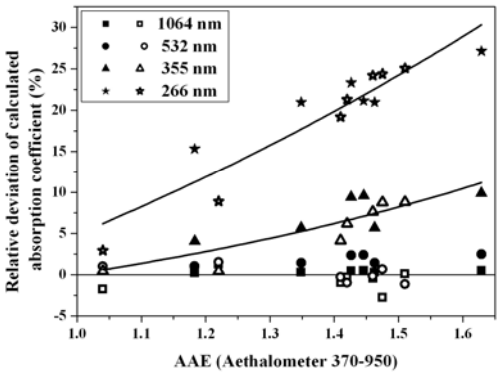

Figure 1: Average relative deviations of the 4λ-PAS and the 7λ-Aethalometer as a function of the average absorption Ångström exponent of the 7λ-Aethalometer.

Presenting author email: elefther@ipta.demokritos.gr

Recent toxicological studies have demonstrated that ultrafine particles (UFPs), that is particles less than 100 nm in diameter, may have a greater impact on human health than larger particles. These findings highlight the need to complement monitoring of traditional parameters (such as PM_{10} and $PM_{2.5}$) with UFPs measurements, when studying associations with health effects and developing mitigation measures. Ultrafine particles contribute very little to particle mass concentration but account for the bulk of the number concentration. In this framework it has become apparent that there is a need for reliable particle counters and sizers that may be used for long-term monitoring and require less maintenance and experienced personnel than traditional instrumentation. The aim of this work was to assess the performance of a new UFP monitor designed by TSI Inc. for long-term, air quality monitoring networks, against a reference system such as a Scanning Mobility Particle Sizer (SMPS).

Measurements were conducted in Athens, Greece, during June and July of 2010 and covered in total a period of one month. Two sites were selected: the N.C.S.R. "Demokritos" urban background monitoring station (DEM) and a heavy-trafficked site located in a central residential urban area (CRU). Particle number size distributions were monitored by an SMPS (DMA, Model 3081 and CPC, Model 3776, TSI, Inc.) and an Ultrafine Particle Monitor (UFP, Model 3031, TSI, Inc.). The logging intervals were 5 and 15 min for the SMPS and UFP, respectively. SMPS measured in the size range 5.9 – 224.7 nm. In order to compare results with the UFP, the SMPS data were grouped in the UFP's size bins. In addition to particle counters, a DustTrak DRX (Model 8533, TSI, Inc.) was employed in CRU, in order to monitor short-term variation of PM_1, $PM_{2.5}$ and PM_{10} concentration.

Temporal variation of the number concentrations obtained by the two instruments showed in general good agreement for all size bins. The 15-min time-series of the number concentration in the size range 20 – 200 nm, measured by UFP and SMPS during the whole measurement period is shown in Fig. 1. SMPS was more effective in capturing short-term peak concentrations which may be attributed to the longer time needed by the UFP to scan the measured size range (15 versus 5 min). Mass and number concentrations variation patterns were dissimilar most of the times, indicating that different sources contributed to the levels measured by each metric parameter.

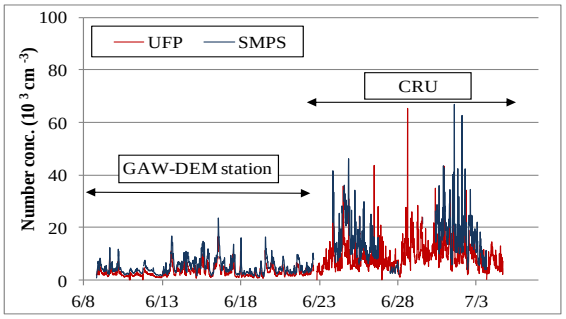

Figure 1. 15-min variation of number concentration in the size range 20 – 200 nm.

Mean 1-hr concentrations at each size bin obtained by the two instruments were linearly correlated for both sites (Table 1). The data were highly correlated but UFP showed a constant underestimation of the concentration by a factor of two approximately, in relation to SMPS. Similar results have been reported by Bae et al .(2009) and Wehner et al. (2007). This underestimation was more pronounced in lower size bins and higher concentrations. Based on these initial results, TSI, Inc. has proceeded to re-calibration of the UFP, using polydisperse, ambient aerosol and SMPS systems as reference.

Table 1. Linear correlation of UFP versus SMPS mean 1-hr data: Coefficient of correlation (r), slope (a) and intercept (b) [10^3 cm^{-3}].

A dry high altitude astronomical observatory in continental Europe

A. Gardini[1], E. Pérez[1] and J.A. Quesada

[1]Instituto de Astrofísica de Andalucía (CSIC), Glorieta de la Astronomía s/n, Granada 18008, Spain
Keywords: columnar water vapour, modelling (regional).
Presenting author email: gardini@iaa.es

Summary. A study of the precipitable water vapour (PWV) above the observatories in Sierra Nevada, the southernmost high altitude location in continental Europe with a dry climate, indicates that Sierra Nevada is a very competitive location for MIR-submm, with PWV<0.2mmH2O, and a 25% quartile of PWV=2.3 mm(H2O) as compared with 2.1 for Mauna Kea.

Method. We use four independent methods to measure PWV: (i) radiometer opacity at 225 GHz located at the 30m IRAM observatory; (ii) on- off- narrow band photometry at 940 nm; (iii) spectroscopic monitoring in the band 800-1000 nm; and (iv) bi-daily balloon-borne atmospheric soundings (retrieved from the University of Wyoming database, fig.1). We use the radiative transfer code SCIATRAN to model the local atmosphere and calibrate the on-site spectroscopic data which measure with high precision the very dry epochs.

Results. **Balloon-borne atmospheric soundings.** The statistical calibration of the results between the IRAM taumeter, the narrow band photometry and the balloon soundings for Gibraltar all agree extremely well, which indicates that the Gibraltar soundings are a reliable proxy. The outcome is shown in figure 2. Sierra Nevada compares very favourably with Hawaii, even though its altitude is 1260m less. The dotted probability line gives the values for an altitude of 3400m, the highest available in Sierra Nevada, where the statistics is similar to or better than Hawaii at 4160m.

We are now able to characterize the statistics of very low PWV epochs.

Results. **Radiative transfer model atmosphere and spectroscopic data.** We obtain direct solar irradiance spectra with an array spectrometer (BWspec) operating in the 700-1020 nm range (0.25 nm spectral resolution). The Wyoming radiosounding data is used to provide profiles of Temperature (T), Pressure (P) and H_2O mixing ratio (mr) as a function of the geopotential height. The Radiative Transfer Model (RTM) incorporated in the SCIATRAN 2.2 package developed at the Institute of Remote Sensing/Institute of Environmental Physics of Bremen University (Germany), allows to simulate radiance/irradiance spectra in the 240-2400 nm range. The RTM was used to simulate the direct solar irradiance spectra at OSN and to compare them with those measured with the spectrometer. After testing the RTM we fixed the parameters: aerosols, spectral albedo, profiles of line-absorbers and continuum-absorbers gases.

Background:

QNano is a European Union-funded infrastructure for nanomaterial safety testing. This four year project which has begun in February 2011 comprises 27 top European analytical and experimental facilities in nanotechnology, medicine and natural sciences. It aims to create an integrated hub to support Europe's nanosafety research community. It also covers research themes about nanoparticle production and characterization. In WP 5 one aspect is to define the sources for batch-to-batch-variability of nanoparticles within one production route.

Material and Methods:

Particle production:

The only variable is the amount of aqueous ammonia present in the system which was used to determine resultant particle size. To a defined amount of aqueous ammonia (28%) in a polypropylene container was added EtOH (99.9%) to a volume of 50 ml and stirred at 25^{0}C (for SilNP007 and SilNP009) or 55^{0}C (for SilNP008 and SilNP010) and 600 r.p.m on a plate stirrer. To this rapidly stirring solution was then added Tetraethylorthosilicate (TEOS) (1670 µl) in one aliquot. The solution was then sealed under N_2 and stirred for a further 20 hours at 25^{0}C. The resulting nanoparticle suspension was divided in fractions and centrifuged down at 14,000 rpm for 20 minutes with the pellet then resuspended in fresh ethanol aided by bath sonication. This washing procedure was repeated twice more with ethanol followed by 3 pure water washes and a final resuspension in pure water to a concentration of 10 mg/ml.

Size Measurements

The silica nanoparticles were size characterized by different methods: in suspension by dynamic light scattering with a Malvern Zetasizer Nano ZS and for comparison it was aerosolized by electrospray (Model 3480, TSI, USA) and measured with SMPS (Model 3934, TSI, USA) in the range of 7 – 350 nm.

Results:

The analysis shows a very similar behaviour but depending on method and suspension medium there is a difference in number mean size of about 10 nm. The batches SilNP007 and SilNP009 show a modal value at about 43 nm by DLS (Table 1) but 50 and 53 nm in the SMPS measurements in aerosol phase (Figure 1). The batches SilNP008 and SilNP010 were determined to be 20 nm in liquid suspension and 33 nm in the gas phase.

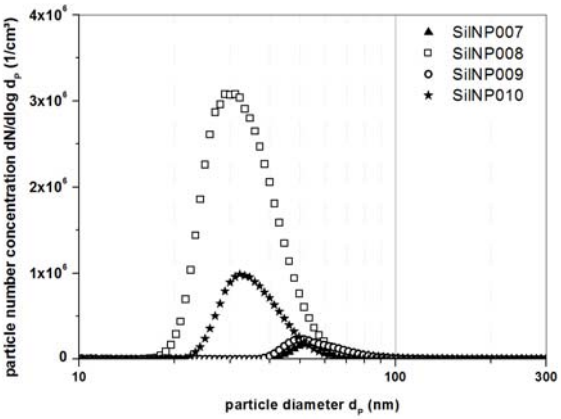

Figure 1. SMPS measurements of the 4 batches SilNP007 – SilNP010 of Stöber synthesized silica suspended in air by electrospray.

Table 1. Comparison between different methods of size measurements. DLS: number mean in nm. SMPS: Modal diameter of number size distribution in nm.

	DLS	SMPS
SilNP007	43	53
SilNP008	20	33

Field experiment with ozone scrubber for monitoring of PAHs

L. Hejkrlík, I. Nikolova, H. Plachá

Czech Hydrometeorological Institute, Branch office in Ústí nad Labem, Czech Republic
Keywords: PAH(s), ozone, denuder
Presenting author email: hejkrlik@chmi.cz

It has been demonstrated that determination of benzo(a)pyrene (BaP) in ambient air may be influenced by the presence of oxidants such as ozone. The losses can be reduced by adding an ozone removing device (denuder) into the sampling line.

Here we present preliminary results of testing the ozone MnO_2-coated ceramic ozone denuder by Digitel in the process of monitoring 15 select PAHs at the measuring station Ústí nad Labem – Kočkov of the Czech Hydrometeorological Institute in period from February to June 2011.

Samples were collected every third day on a quartz filter and a polyurethane foam cartridge using two parallel low volume (2.3 m^3/h) samplers, one of them was equipped with the ozone scrubber (D+), the other was without it (D-).

The laboratory tests of denuder with synthetic air with known concentration of ozone at flow rate 10 l/h (Table 1) confirmed high efficiency of the scrubber even after both 4 and 7 months of use.

Table 1. Efficiency of the ozone denuder

	O_3 (µg.m^{-3}) D-	O_3 (µg.m^{-3}) D+	Efficiency
12/5/2011	60	2	96.7 %
	200	6	97.0 %
	858	36	95.8 %
31/8/2011	58	0	100.0 %
	259	0	100.0 %
	856	2	96.7 %

The fine dust losses were investigated by weighing D+ and D- filters, the mean values were about 10%, maximal weight losses reached as much as 41%.

Regarding the relation between the concentrations measured with/without the denuder, the PAHs were separated into three groups. The concentration of BaP, and similarly of all particle associated PAHs, were underestimated when denuder was not present (Group 1, Figure 1). Second group was formed by PAHs with 4 rings, which were mostly in gas phase in the samples. It is evident from Figure 2 that their concentrations decreased in the case of denuder, probably due to adsorption at the active centres of the catalyst. The third group (Figure 3) was represented by the PAHs that demonstrate unpredictable behaviour related in 75 % of events to Group 1 and in the rest to Group 2.

We have found that the denuder effectively decomposes the ozone and minimizes the decay of PAHs bound to the particles. The application for lighter PAHs in the gas phase is questionable because of possible oxidation.

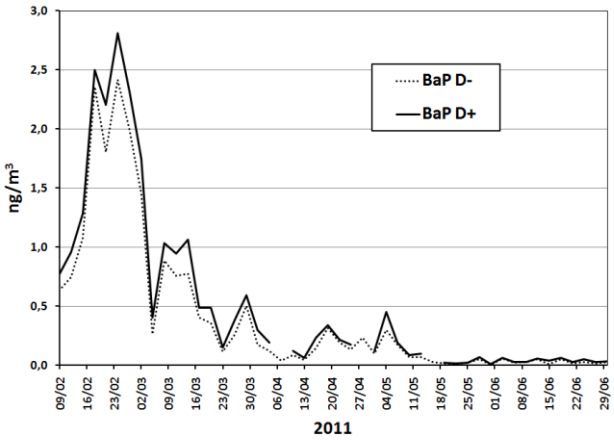

Figure 1. Concentrations of BaP (Group 1, similar behaviour exhibit particle associated PAHs)

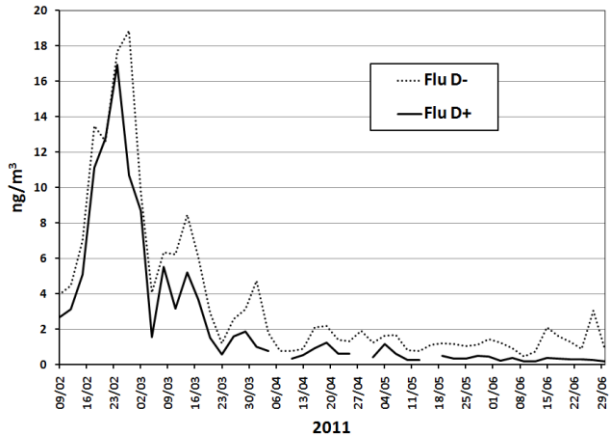

Figure 2. Concentrations of fluoranthene (Group 2, similar behaviour was found for pyren)

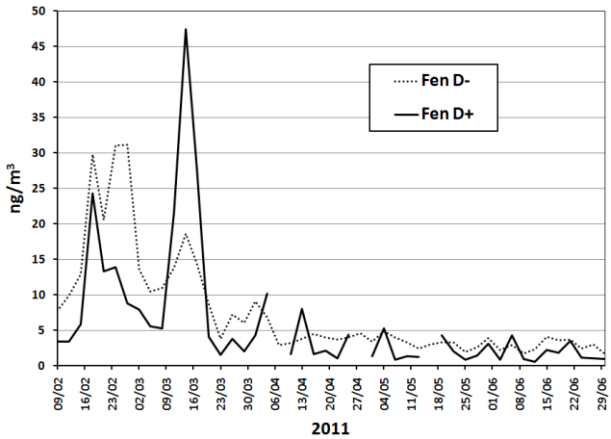

Figure 3. Concentrations of phenanthrene (Group 3, similar random behaviour exhibit anthracene and fluorene)

Retrieval of sky radiance at three wavelengths using a sky camera

Presenting author email: robertor@fa1.uva.es

Several columnar aerosol properties can be retrieved from sky radiance measurements using inversion codes. Dubovik *et al* (2006) and Olmo *et al* (2008) derived the columnar aerosol size distribution, the single scattering albedo, the phase function and the asymmetry parameter from sky radiance measurements (using a CIMEL sunphotometer) in the almucantar and in the principal plane configurations, respectively.

The principal aim of this work is to develop a method to retrieve radiance measurements using images from a sky camera. For this goal we use a radiative transfer model combined with aerosol properties retrieved from sun/sky photometer. There are some advantages in the proposed method. Thus sky cameras are less expensive than sky photometers. Furthermore, a sky camera can take a measurement of the full sky (including almucantar and principal plane) in a few milliseconds, while the sun/sky radiometer requires a few minutes.

The measurements used in this work were taken on the rooftop of the Andalusian Center for Environmental Studies (CEAMA, 37.17º N, 3.61º W, 680 m a.s.l). The All-Sky Imager consisting of a digital color CCD camera with a fish eye lens encapsulated in an environmental housing that is temperature regulated with a peltier cell. The system is installed in a sun tracker which blocks the direct solar radiation by a shadow ball. Images are taken every 5 minutes and are composed of three images at three channels: red, green and blue. All information about All-Sky Imager is detailed in Cazorla (2010). A sunphotometer CE-318 (CIMEL Electronic, France) was installed next to the sky imager in the same rooftop. This instrument (included in the AERONET network) provides sky radiance measurements and optical properties of aerosol like aerosol optical depth at different wavelengths.

The UVSPEC model, included in the LibRadtran library developed by Mayer and Kylling (2005), was used to estimate sky radiance under cloud-free conditions. First, the UVSPEC simulations were tested with almucantar radiance measurements (CIMEL): finding a great agreement when all aerosol properties were included as inputs in the model. The model showed the worst results for the estimations near to the sun. The effective wavelengths of each channel of the camera (464, 534 and 626 nm) were calculated using the UVSPEC radiative transfer model and the spectral response of the camera.

Then, a set of cloudless images were chosen, and the radiances at the effective wavelengths were simulated for these images. The signal of each pixel was linearly correlated with its corresponding radiance. Therefore, for each spectral channel a matrix, which ij-element converts the signal of the ij-pixel in the radiance viewed by the ij-pixel, was developed. An image is transformed in three radiance images when the matrices are applied.

The calibration procedure was tested using an independent set of images. The radiances in the principal plane and almucantar were compared with the radiances measured side by side by the CIMEL radiometer,. After considering the spectral differences we obtain average bias smaller than 15% for scattering angles larger than 10º for the three wavelengths.

In conclusion, a method to obtain sky radiance measurements at three wavelengths (which can be used to obtain columnar aerosol properties using inversion codes) is developed. The proposed method provides a tool with higher temporal and spatial resolution than sun/sky photometers. The differences between the estimated (camera) and measured (CIMEL) radiance are lower than 15% for all channels.

Correlating the extinction-based dustiness to the morphology of particles

S. Bach, E. Schmidt

Department of Safety Engineering / Environmental Protection, University of Wuppertal, Germany
Keywords: Dust, Air quality, Optical instrumentation, Respirable aerosols, Shape factors
Presenting author email: sbach@uni-wuppertal.de

It is still widely unknown which material-specific properties lead to special dustiness behaviours of powders and/or bulk solids. The topic is especially complex, because it is not only due to the nature of the material but also to the energy induced to the powder by the test apparatus used to measure the dustiness.

The present research project employed an approach with a single-drop apparatus, the "DustView" from the Palas GmbH in Karlsruhe, Germany (see fig. 1). This dustiness testing method measures the laser beam attenuation (opacity) caused by a dust cloud. The material falls down a tunnel into a dust chamber (total drop height: 70 cm) and is then dispersed inside the chamber through the impact forces. The relatively low mechanical stress the material is exposed to usually leads to lower measured dustiness indices then with other testing principles (Lyons and Mark, 1992). On the other hand, the material does not alter significantly during the process (Burdett et al., 2000).

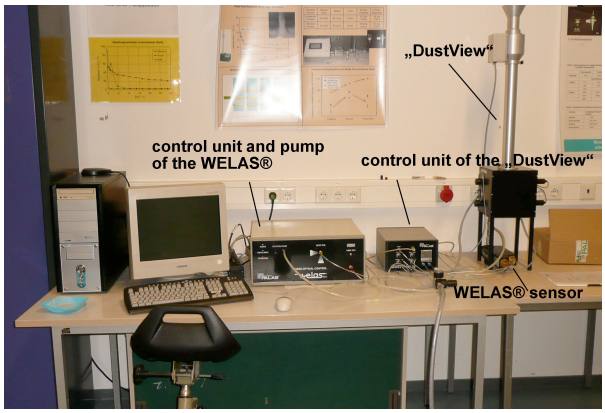

Figure 1. Modified version of the Palas DustView, including single-drop apparatus and OPC "WELAS®"

With the new laboratory set-up, it is possible to measure the opacity every 10 ms as well as the particle number concentration and size distribution with an Optical Particle Counter (OPC) simultaneously. The main question of the project is, do these variables, opacity and number concentration resp. size distribution, correlate in a way that enables the user to gain information about health- and safety-related dustiness – for example about the contingent of the inhalable or respirable aerosol fraction in the dispersed particles – from the opacity values.

Additionally, other material-specific properties have been eaxmined, to ensure the best possible knowledge of the examined powders. Bulk density, relative humidity and particle density have been analysed as well as the particle size distribution of the original material (with laser diffraction spectrometry) and particle morphology (with scanning electron microscopy).

This presentation will focus on the coherence between the dustiness behaviour (i.e. caused opacity, particle number concentration and size distribution of the dispersed powder) and the obtained shape factors.

A total of 15 materials has been examined with the "DustView" and analysed for their particle morphologies. Nine of those were calcium carbonates (limestones) of different particle size distributions. Figure 2 shows an example for a calculated correlation coefficient according to Pearson (r_{xy}), only considering the limestones. Here, the circularity is displayed over the opacity-value after 30 seconds.

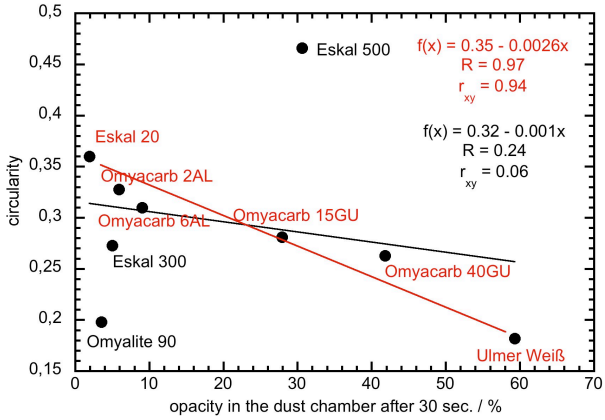

Figure 2. Circularity over 30-sec.-value of the opacity for nine calcium carbonates. Black line and curve fit parameters: all limestones, red line and parameters: six out of nine

The three materials displayed in black characters have two things in common; they only consist of relatively small particles (< 5 µm), whereas the other materials all contain one or more bigger size modes. And secondly, they show comparatively narrow mass- and number-based density distributions.

The present work will try to connect more similarities and peculiarities of powders to the dustiness behaviour of a material, leading to a better understanding.

This work was supported by the German Federation of Industrial Research Associations (AiF).

Workplace atmosphere is an important distribution of various pollutants, resulting from the handled products and concerned processes. The fate of these pollutants in the air (transport, deposition, degradation), is determined by their distribution between atmospheric particles and gas phase (Lohmann et al. 1998). Harmfulness of particles in workplace atmosphere and the disease hazards that they present are related to their chemical nature and size. The production of one kilogramme rigid polyurethane foam releases nearly 7362 milligrams of solid particles in air.

In this work, we used the personal aerosol sampler CIP10-R (Courbon et al. 1988) and filters for evaluation of alveolar (Gorner et al. 1996) and inhalable fractions of particles during clean of casts after injection of the polyurethane foam (PU) (fig 1). HPLC was used for detection of MDI in different post (fig 2).

Obtained Results reveal that MDI in alveolar fraction prevail the total collected particles, this can be allotted to the process used for cleaning and to the quality of formulated foam.

Chemical composition of commonly used CPC calibration ions in the sub 2nm range

J. Kangasluoma[1], J. Mikkilä[2], K. Lehtipalo[1,2], J. Vanhanen[2], H. Junninen[1], M. Sipilä[1], M. Kulmala[1], T. Petäjä[1]

[1]Department of Physics, University of Helsinki, 00560 Helsinki, Finland
[2]Airmodus Oy, 00560 Helsinki, Finland
Keywords: CPC, mass spectrometry, nanoparticles, characterization
Presenting author email: juha.kangasluoma@helsinki.fi

Recent development of condensation particle counters (eg. Vanhanen et al. 2011) has led to a need of generating monodisperse ion samples that are smaller than 2 nm in mobility diameter in order to calibrate the counters. Apart from electrospray experiments there are no reports on the ion composition in the sub 2 nm range and no reports related to the problems that might arise for example due to impurities, charger ions and relative humidity in the calibration experiments. We present here the first step towards reliable CPC calibrations, which is the analysis of mass spectra of the commonly used calibration ions, ammonium sulphate, sodium chloride, silver and tungsten oxides.

Airmodus A09 PSM is a turbulent mixing type CPC that is able to detect particles down to 1 nm in mobility diameter by condensing diethylene glycol on to the particles. It is possible to choose the cut-off diameter between approximately 1 and 2 nm by changing the flow in the saturator. APi-TOF (Junninen et al. 2010) is a time of flight mass spectrometer with a mass resolution of 5000, which therefore allows measuring the mass defect of a molecule which increases the possibility to solve the chemical composition.

Excluding tungsten oxides, which were generated with a hot wire generator, the sample ions were evaporated to a nitrogen flow with a tube furnace, cooled down in a water bath, charged with a bipolar Am241 neutralizer and finally classified with a high resolution, closed loop Herrmann DMA (Herrmann 2000) with resolution of 20. After the DMA the sample was then led to the mass spectrometer and after its inlet to the PSM and the electrometer without any dilution or disturbances from the room air. Before the experiments all sample lines were chemically cleaned, and the tube in the oven and tungsten wire were heated for several hours to minimize the impurities.

Ammonium sulphate consisted mainly of series $(HSO_4)_x(NH_3)_y$(mass 112)$_z SO_4$-, where mass 112 is an unknown organic impurity most probably coming from the sample, as it was not present in all ammonium sulphate experiments. In the sodium chloride spectrum there were two series: $(NaCl)_xCl$- and $(NaCl)_x$mass- 141, where again mass 141 is some unknown impurity. In the tungsten oxide spectrum the peaks were of series $H_xW_yO_z$(mass 88)$_i$-, where the ratio y/z was about 1/3. In addition to the pure tungsten oxide peaks in some of them was also impurity molecule of mass 88 present. The silver spectrum was full of unidentified peaks without any regular series, although some silver peaks were found, for example Ag_x, where x=3, 5, 7, 9, 13, 17 or 19. However at the moment silver is not in good enough level to be used in calibrations due to high amount of impurities. In spite of some impurities in the mass spectra, the first three can be considered rather clean and usable for calibration experiments.

Methodology for mapping air pollution in an urban environment: the background issue

M. Van Poppel, J. Peters, N. Bleux.

VITO - Flemish Institute for Technological Research, 2400 Mol, Belgium

Presenting author email: martine.vanpoppel@vito.be

Traffic related air pollution is one of the major concerns in urban environments. Fixed air quality monitoring stations have limitations when used to assess spatial patterns of traffic related pollutants (UFP, $PM_{2.5}$, BC) in urban environments.

Mobile platforms are increasingly used to acquire high level temporal and spatial resolution measurement in a complex urban environment. As such, mobile measurements provide a solution to assess spatial variation of pollutants with a limited number of instruments and in a confined timeframe. In this way, mobile measurements can be used for air quality mapping, hot spot identification and exposure assessment. However, issues related to representativeness of repeated runs and variation in background concentrations are not yet solved.

At VITO, a measuring bike – called Aeroflex – was developed for mobile measurements and mapping of UFP (P-trak, TSI), PM (Grimm Dust monitor) and BC (µ-Aethalometer, AethLabs). A method to take into account differences in background concentrations and to compare repeated runs is discussed in this paper. In addition, a method to compare street-by-street variation based on repeated runs is presented. The developed method was applied on a case study.

A case study was performed in Mol, Belgium (a city with 34,000 inhabitants). The 10 km long sampling route was repeated 20 times on 10 different days and includes roads characterized by different amounts of traffic. The sampling route comprises 6 different zones characterised as: (1) access road outside the city centre, (2-3) major road in the city, (4) road with restricted traffic, (5) green space, (6) road in the city centre. The different zones are also characterised by differences in the surroundings: more 'open' zones (1, 5) and 'street canyon'-like (2, 3 and 6).

Significant differences between different zones for UFP and BC, however not for $PM_{2.5}$ were found (Kruskal-Wallis test, $p<0.05$). Urban concentrations contain a background component in addition to the street level contribution. When trying to assess spatial variation in an urban environment by repeated mobile measurements, we are confronted with differences in background that hamper the averaging over different runs.

Therefore a background correction should be applied. A common practice is to subtract a background concentration from the mobile measurements, resulting in the local component of the pollutant concentration. To determine a background concentration based on the mobile measurements, different percentile concentrations were calculated for the entire run and for the green zone (5) only. The green zone is considered to give a good estimate of the variable background concentration and represents 10% of the entire data volume in this study.

As an example, average UFP concentrations of one run for the different zones are compared to different percentile concentrations for the green zone . The results show that the local contribution of UFP was 2 to 3 times higher than the background concentrations. In contrast, for $PM_{2.5}$ 80% or more could be attributed to background.

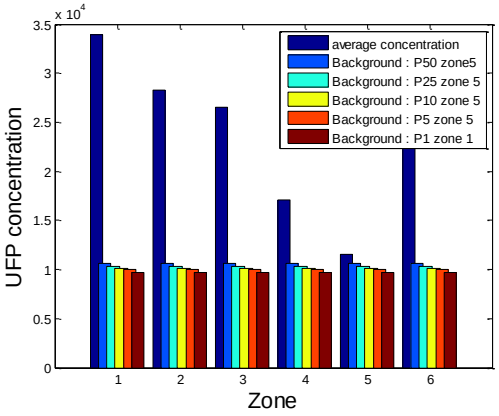

Figure 1: Average concentrations of UFP compared to different percentile concentrations (P1, P5, P10, P25 and P50) for the green zone.

A background correction, by subtracting the 1st quartile concentration of the green zone resulted in a higher similarity of pollutant concentrations over the different runs. The P25 for the green zone corresponds to the P5 over the entire run in this study. The advantage of using a percentile concentration of a green zone as background value is that the number of measurements made in the green zone is not important and will not influence the result. Whereas, if a lower percentile concentration of the entire run is chosen, more care must be taken in selecting the route.

This analysis showed the potential of mobile measurements to assess spatial variation of traffic related pollutants in an urban environment. However data-processing accounting for background concentrations is important for interpretation and comparison. The background correction presented in this paper can be easily integrated in the mobile mapping methodology, without the need for data from fixed AQ monitors.

On the use of Direct Analysis in Real Time/Quad-Time of Flight (DART/Q-TOF) for the analysis of Organic Aerosol

A. Sylvestre[1], S. Ravier[1] and N. Marchand [1]

[1]Aix-Marseille Univ., CNRS, Laboratoire Chimie Environnement, 13331, Marseille, France.
Keywords: DART, organic aerosol, organic markers.
Presenting author email: alexandre.sylvestre@etu.univ-provence.fr

In the last ten years, ambient mass spectrometry creates a lively interest for sample analysis. Many ambient ion sources have been designed such as Extractive Electrospray Ionization (EESI) (Chen et al., 2005), Desorption Electospray Ionization (DESI) (Cooks et al., 2004) or Direct Analysis in Real Time (DART) (Cody et al., 2005) which allow direct analysis from surfaces. Thus the sample preparation step is simplified as much as possible avoiding analyte losses and reducing the length of the analytical procedures.

DART source can be used to analyse gases, liquids, solids and materials on surfaces. A gas (helium or nitrogen), cross a chamber (figure 1) where an electrical discharge produces ions, electrons, metastable atoms and molecules. Perforated lenses remove charge particles, and only metastable species and neutral gas molecules remain. Then, those species can be heated and the grid electrode focuses them through the insulator cap to the sample surface, containing an analyte M. In positive mode, when helium is used, $[MH]^+$ ions are formed by proton transfer reaction :

$$He(2^3S) + H_2O \rightarrow H_20^{+\cdot} + He(1S) + e^-$$
$$H_20^{+\cdot} + H_2O \rightarrow H_3O^+ + OH^\cdot$$
$$H_3O^+ + n\,H_2O \rightarrow [(H_2O)nH]^+$$
$$[(H_2O)nH]^+ + M \rightarrow MH^+ + nH_2O$$

In negative ionisation mode, $[MH]^-$, $M^{-\cdot}$ and $[MO_2]^{-\cdot}$ ions formation occur according to the following reactions:

$$\text{Excited gas} + \text{surface} \rightarrow \text{Gas} + \text{surface} + e^-_{fasr}$$
$$e^-_{fast} + \text{atmospheric pressure gas} \rightarrow e^-_{slow}$$
$$e^-_{slow} + O_2 \rightarrow O_2^-$$
$$O_2^- + M \rightarrow MH^- + OH^\cdot$$
$$O_2^- + M \rightarrow M^{-\cdot} + O_2$$
$$O_2^- + M \rightarrow MO_2^{-\cdot}$$

DART source enables soft ionization and produces simple mass spectra in a few seconds. What it can be suitable for complex matrix like biological matrix (Jagerdeo et al., 2009), food matrix (Vaclavik et al., 2010) or warfare agent (Nilles et al., 2009).

DART source has been used in many fields, and while this technique offers great perspectives in field of organic aerosol analysis, DART source has not been applied on aerosol filter samples, for now. Thus, this study aims to test the ability the DART source to analyse organic aerosol deposited onto filters. The DART source is coupled to Q-ToF mass spectrometer (Synapt G2 HDMS, Waters) with a mass resolution up to 40 000. Our first objective was to test the ability of this analytical setup to quantify organic markers such as levoglucosan, PAHs, hopanes and fatty acids. To do so, different parameters like gas temperature, gas flow, sample position, etc., have been tested on standard solutions. Matrix effects have also been studied by the addition of ammonium nitrate and ammonium sulfate. In a second step, various ambient and smog chamber samples have been analysed (urban samples collected during the APICE field campaign, cooking samples and Kerbside samples). Results obtained have then been compared with traditional GC/MS technique, if any.

The Single Particle Soot Photometer (SP2) was originally designed to measure (refractory) black carbon, but also absorbing materials different from black carbon can be detected. This presentation shows results from experiments with volcanic ash and hematite, performed during two laboratory studies, and introduces a method to distinguish these materials from black carbon.

The SOOT11 campaign at the KIT AIDA (Aerosol Interaction and Dynamics in the Atmosphere) chamber in November and December 2010 was dedicated to compare the performance and efficiency of six different SP2s (Laborde *et al*. 2012). During one experiment of the SOOT11 campaign, a ground sample of ash from the Eyjafjallajökull volcano was brought into the AIDA chamber to test the SP2's sensitivity to absorbing materials different from black carbon. The volcanic ash aerosol remained in the AIDA chamber for several hours and was mixed externally with black carbon later in the experiment. Experiments with pure hematite and an external mixture of hematite and black carbon were performed as part of the Boulder light absorption intercomparison study (BLAC09) in January and February 2009.

The SP2 uses laser-induced incandescence to measure the mass of individual absorbing particles which are heated in a continuous laser beam with Gaussian intensity distribution such that they emit thermal radiation and evaporate. This radiation is detected at two different visible wavelength bands. The ratio of the signals from the two incandescence channels, the color ratio, provides a relative measurement of the incandescence temperature of the particle (Moteki & Kondo 2010). While a particle passes the laser beam, also the scattered laser light is recorded. Initially, this scattering signal allows to derive the optical size of the whole particle before evaporation started. In contrast, the scattering signal at the point of maximum incandescence corresponds to the optical size of the incandescing particle core.

Both volcanic ash and hematite were found to be detectable in the SP2 incandescence channels with low efficiency only, as they absorb light less efficiently than black carbon. About 5-10% of all measured particles were detected in the incandescence channels, with the percentage rising with size.

Comparisons between the different materials show that the color ratio is larger for black carbon than for both volcanic ash and hematite, because the incandescence temperatures of those materials are lower. For both mixtures, the color ratio shows two peaks: one at the level of black carbon, and one at a lower level corresponding to the less absorbing material. This method is difficult to apply for single particles, because the color ratio may be noisy, especially for small particles.

A more precise distinction between the materials can be made by using the differences in both optical and physical properties. Volcanic ash and hematite particles with similar incandescence signals will have scattering signals different to those of black carbon particles at the point of incandescence, as they have different incandescence temperatures and refractive indices. Therefore, the ratio between the signals in the scattering and incandescence channels at the point of incandescence shows a strong dependence on material. Figure 1 shows this ratio for the volcanic ash experiment of the SOOT11 campaign. The data points separate into two clusters: the lower one represents the black carbon particles, while volcanic ash particles have higher values with a distinct gap between the two materials. This makes it possible to distinguish materials on a particle-by-particle basis.

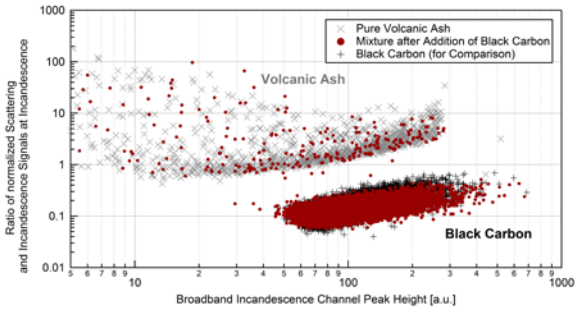

Figure 1: Signal ratio at incandescence for volcanic ash before and after the addition of black carbon (SOOT11 experiment). Pure black carbon data from another experiment are added for comparison

Detection efficiency of a TSI Environmental Particle Counter 3783 particle counter: experimental and simulated results

J. Hakala, H.E. Manninen, T. Petäjä and M. Sipilä

Department of Physics, University of Helsinki, PL 64, 00014 University of Helsinki, Finland
Keywords: CPC, Aerosol instrumentation
Presenting author email: jani.hakala@helsinki.fi

Monitoring the number concentration of aerosol particles is one of the basic measures to characterize the air quality for health and climatological purposes. The Condensation Particle Counters (CPCs), which include the new water based TSI Environmental Particle Counter (EPC) 3783 under the study, are widely used for this purpose. In this study we present the experimental and simulated results of the performance of the EPC 3783 for hygroscopic and hydrophobic materials.

The detection efficiency and cut-off diameter D_{50} for a TSI model 3783 were determined by particles produced by evaporating silver (Ag), ammonium sulphate ($(NH_4)_2SO_4$) and sodium chloride (NaCl) to passing nitrogen flow in a tube furnace. As the flow cooled down after exiting the furnace, the vaporized material nucleated forming polydisperse aerosol particles. A monodisperse fraction of a certain diameter was selected with a Differential Mobility Analyzer, and the detection efficiency of the EPC was determined by comparing the number concentration measured by EPC 3783 to the number concentration measured by an electrometer. The cut-off diameters for different materials with default saturator and growth tube temperatures (20°C and 60°C respectively) are presented in table 1.

Table 1. The EPC 3783 cut-off diameters for particles of different chemical composition.

Particle material	D_{50} [nm]
Ag	6.4
$(NH_4)_2SO_4$	4.8
NaCl	4.3

The supersaturation inside the growth tube is the key element affecting the detection efficiency of the laminar flow water based CPCs (Hering and Stolzenburg, 2005). It was calculated using Comsol Multiphysics 3.5a simulation software. Knowing the supersaturation, it was possible to calculate the contact angle best suited to replicate the detection efficiency curve for non-soluble particles using the heterogeneous nucleation theory (Fletcher, 1958). The contact angle for silver particles retrieved from the simulation was 36°, which is in good agreement with experimental results from Porstendörfer et al., 1985. In figure 1 are presented the simulated and experimental results for the detection efficiency of the EPC 3783 for silver particles. It can be seen from the figure that the contact angle alone can not be the only parameter for predicting the detection efficiency.

The Kohler-theory was used to simulate the detection efficiency for hygroscopic and water soluble salts. It turned out that the simulations overestimated the detection efficiency for NaCl and $(NH_4)_2SO_4$ particles. It seems that there are no experiments published that study the hygroscopic growth and activation of NaCl and $(NH_4)_2SO_4$ particles below the diameter of 8 nm to compare our results with.

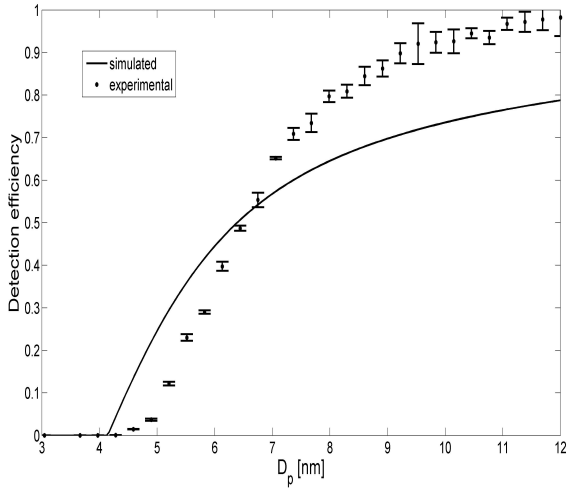

Figure 1. The simulated and experimental detection efficiency of the TSI EPC 3783 for silver particles.

Presenting author email: marek.maasikmets@klab.ee

Atmospheric aerosols play important roles in human health, visibility, acid deposition, and global climate. The Aerodyne Aerosol Chemical Speciation Monitor (ACSM) provides robust, low-maintenance measurements of non-refractory submicron particulate matter in real-time, making it well-suited for long-term monitoring applications. The ACSM is based on the widely used Aerodyne Aerosol Mass Spectrometer (AMS) and combines an aerodynamic lens for particle focusing with high-vacuum particle thermal vaporization, electron impact ionization, and mass spectrometry (Ng, et al. 2011). A critical parameter for quantitative ACSM (and AMS) measurements is the "bounce collection efficiency" (E_b), defined as the probability that a particle impacting the ACSM/AMS vaporizer does in fact vaporize, rather than bouncing off the vaporizer surface and remaining undetected.

E_b depends strongly on particle phase, with solid particles more likely to bounce than liquid ones. An E_b of ~0.5 has been found to be appropriate for many ambient measurements, and this value is assumed to be correct in many published AMS datasets. However, E_b > 0.5 has been observed in previous laboratory and field studies with increasing particle acidity, nitrate content, relative humidity (at the instrument inlet) and coatings of pure liquid organic material (Matthew et al., 2008; Middlebrook et al., 2012).

Here we investigated the effect of different parameters (meteorological data, gas-phase pollutants e.g., CO, NO_x, O_3, NMVOC, O_x and aerosol species) on E_b. E_b was estimated as the volume ratio between ACSM and SMPS. It was assumed that ACSM and SMPS have same transmission efficiency. For the volume calculation it was assumed that Org, SO_4, NO_3, NH_4 and Chl have density of 1.27, 1.78, 1.72, 1.75, 1.4 g/cc respectively. For the SMPS volume calculation the particle density was assumed 1.5 g/cc. The measurements were conducted from February 2011 to January 2012 in Zürich Kaserne (urban background) station. This long-term dataset provides a more statistically robust sampling of E_b-influencing parameters than is possible with short-term intensive campaigns. The ACSM measured non-refractory PM1 chemical composition with a time resolution of 15 to 30 min. The SMPS measured submicron particle number size distributions between 13 and 615 nm mobility diameter with a time resolution of 5 min. For the ACSM and SMPS the same inlet (4m above ground) with Nafion dryer (Perma-Pure, length 100 cm) was used.

The CE analysis showed that the mean E_b results are with 0.62 somewhat higher compared to default E_b. Three main periods according to daily mean temperature were identified – warm (mean +16.9±6.35°C), cold (mean +7.2±4.32°C) and mixed period (mean +15.85±5.02). CE rose during the summer when f43, f55, temperature and O_x were high. This can be explained by the fact that freshly emitted organic aerosols (cooking, BVOC) are detected by the ACSM with minor losses or/and there are evaporative losses of semi-volatile species in the SMPS. During the colder period the f44, f57 and BC were high, which indicates that more primary aerosols were available during those periods. Rather low E_b (< 0.5) were found for periods with intermediate temperatures but higher f44 than in the warm summer periods.

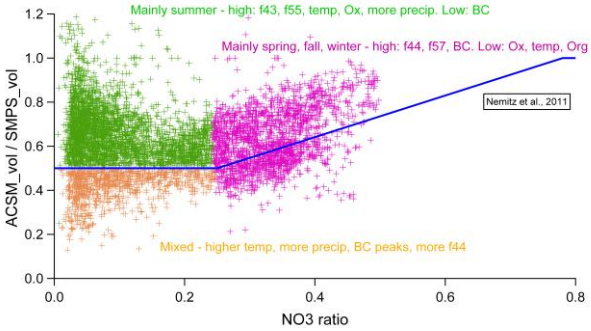

Figure 1. CE analysis based on ACSM and SMPS ratio

An innovative and efficient method for the analysis of levoglucosan in ambient air particulate matter by thermal desorption coupled with GS/MS.

E. Grandesso, P. Pérez Ballesta, K. Valler, K. Kowalewski

European Commission. Joint Research Centre, Ispra (VA), 21027, Italy

Keywords: Levoglucosan, thermal desorption, air monitoring.
P. Pérez Ballesta: pascual.ballesta@jrc.ec.europa.eu

Levoglucosan (1,6-anydro-β-D-glucopyranose) is an important constituent of particulate matter emitted in large quantities during biomass burning (Simoneit, 1999). Due to its atmospheric stability and high concentrations, it has been used as a tracer for the long-range transport of biomass aerosol (Nolte *et al*. 2002; Fraser and Lakshmanan, 2000; Lee *et al*. 2008; Caseiro *et al*. 2009). For these reasons determination of levoglucosan is becoming an important issue, in particular, for source apportionment modelling that requires concentration values on daily bases.

In this work, a quick and sensitive method for analysis of levoglucosan in PM filters using thermal desorption (TDU/CIS4, Gerstel, GmbH) coupled with GC/MS (Agilent Technologies) is presented. Analysis results by this new method are compared with previously reported data from certified reference material (CRM) 1649a. The method consists on the derivatisation of levoglucosan directly on the liner used for thermal desorption.

The optimisation of the method was done by means of standard solutions (STD) prepared with known amount of levoglucosan and Levoglucosan-d7 (98%). The STD were spiked on a quartz filter placed inside the liner on top of a glass wool plug. 5 µL of derivatising agent (N,O-bis(trimethylsilyl) trifluoroacetamide with 1% of trimethylchlorosilane, BSTFA+TMCS) was then added. Reaction conditions of 5, 15, 30 and 45 min at 60°C and of 5 min at ambient temperature (22°C) were tested. The reaction was complete in all cases, with no significant difference in the total yields and peaks abundances. Therefore, the derivatisation occurred almost instantaneously even at ambient temperature.

Thermal desorption parameters were critical for levoglucosan determinations. For primary thermo desorption (TDU) temperatures of 120, 150, 170, 200 and 300°C were tested with holding times of 10 minutes. The transfer line temperature was kept equal to the primary desorption temperature. The cryogenic trap (CIS) was hold at -15°C during the primary desorption step and subsequently ramped to a final temperature of 50°C over the primary desorption temperature for injection into the column. Flow parameters were set as previously reported (Van Drooge, 2009). These parameters were tested not only on STD, but also on CRM.

CRM analysis was performed by different techniques: a) by liquid extraction, as refereed in bibliography (Simoneit, 1999; Larsen, 2006.) and b) by suspension and deposition on the TDU liner filter to simulate sample filter analyses. While no difference in response was found on varying desorption temperature when analyzing STD or liquid extracts, significant differences were observed for the CRM suspension.
Liquid extraction technique resulted in an average concentration of 85 ± 11 mg/kg. Such a value was in accordance to the concentration reported for CRM 1649a and to those reported by Larsen, (2006). On the other hand, the analysis of the CRM suspension resulted in 90 mg/kg at a TDU desorption temperature (T) of 120°C, 86 ± 2 mg/kg (n=2) at T = 150°C, 95 ± 2 mg/kg (n=2) at T = 170°C, 143 ± 15 mg/kg (n=4) at T = 200°C and 1265 ± 179 (n=2) at T = 300°C.

The high amounts of levoglucosan detected at 300°C could be due to artefacts produced during sample heating in the TDU under nitrogen stream. Since at TDU temperature lower than 170°C levoglucosan determinations were not varying significantly and were comparable to the concentration reported by the CRM certificate of analysis the recommended desorption temperature was fixed at 150° C.

This method has been applied for analysis of PM10 samples on quartz filters at the JRC Ispra site during winter 2010. The low volume sample filters were cut at an optimal section of 2.5 mm, placed in the liner on top of the quartz filter and spiked with 3 µL of internal standard. The addition of 5 µL of BSTFA+TCMS was sufficient to cover completely the filter with the reagent. The method provided good reproducibility results (generally better than 15 %). Moreover, this new method presents the advantages of providing quick analyses, by eliminating the use of solvent and tedious extraction steps, improving in this way the limit of detection (Van Drooge, 2009).

The use of quartz filters as reference material for analysis of PAHs in particulate matter ambient air samples

P. Pérez Ballesta, E. Grandesso, K. Kowalewski

European Commission, Joint Research Centre, Ispra (VA), 21027, Italy

Keywords: PAH, standard reference material, particulate matter, intercomparison exercise.
P. Pérez Ballesta: pascual.ballesta@jrc.ec.europa.eu

The use of an appropriate reference material for PAH analyses in air particulate matter (PM) is a very relevant issue for the data quality and control. Although desirable, a PAHs reference material from real ambient air sampled on filter is currently not available. The objective of this work is to demonstrate the feasibility of producing certified reference concentrations for PAHs on real PM ambient air filters by using a methodology that allows: i) A rapid and accurate analysis on tiny pieces of filter; ii) testing homogeneity and stability of the filter composition; iii) the selection of filters based on custom laboratory requests. The feasibility of the proposed methodology is supported from the results obtained in an inter-laboratory comparison (Grandesso *et al*., 2012).

PM10 was sampled in background areas of Madrid (Spain) and Prague (Czech Republic) on quartz filters (QM-A, 20.3 mm x 25.4 mm, Whatman International Ltd., England) using a Anderson high volume sampler (HVS). Those filters were cut in twenty circles of 39 mm diameter, corresponding to low volume filter samples. The circles were systematically cut by means of a pattern specifically designed for this purpose. The low volume dimension filters were than accurately packed for distribution and storage.

The filters were analyzed using a thermal desorption unit coupled with a cryogenic trap (TDU/CIS4, Gerstel GmbH) according to previously reported method (Van Drooge, 2009). This system allows for the direct introduction in the TDU of glass liners in which small filter sections were deposited and pre spiked with an internal standard mixture containing deuterated PAHs. After desorption the compounds were analyzed by means of a GC/MS.

To verify the homogeneity of the PAHs distribution in the filter, a minimum of four small filter sections were randomly taken from each filter for analysis. Figure 1 reports for two different HVS filters, the analytical repeatability standard deviation (RSD) obtained from liquid standard injections and the homogeneity RSD derived from the real sample analysis. The sum of both RSD was lower than 10% except for some compounds with concentrations close to the detection limit or with co-elution problems. It was noted that instrumental variability had a high contribution to the overall analytical uncertainty especially for filters with low PAH concentration levels. The calculated "RSD homogeneity" values were in any case low enough to guarantee the use of these filters in an intercomparison exercise.

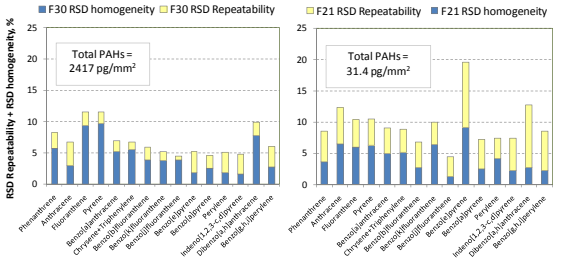

Figure 1 – Repeatability and homogeneity standard deviation for PAHs determination in HVS PM10 filters.

Stability of filters over more than a year of storage time was tested at temperatures of 20°C (ambient temperature) and -18°C. At -18°C all the filters showed insignificant variations with respect to the initial concentration values. A significant decrease in concentration of the more volatile PAHs (i.e., Phenanthrene, Fluoranthene, Pyrene) was observed for filters kept sealed at ambient temperature for long periods, i.e., one year. Nevertheless, this was not when the storage time was shorter than one month.

PAH concentrations determined by thermal desorption were in agreement with the intercomparison reference value, with overall expanded uncertainties better than ± 20%.

Therefore, by means of this methodology it is possible to select, characterise and certify PAH concentration levels in PM filters in accordance with laboratory or sampling needs, *i.e.* concentration levels, matrix characteristics or PM origin with a minimum use of filter surface.

Safe application of the promising and quickly growing nanotechnology requires a comprehensive clarification of the effects on person and environment. Inhalation of engineered nanoparticles (ENP) in industrial processes and in consumer products poses a potential and largely unknown risk. Individuals with chronic lung diseases, as well as children and the elderly are expected to be more vulnerable than healthy adult subjects. Safety testing needs to include studies in the susceptible population. Furthermore, for efficient, economical, and ethically sound evaluation of health hazards by inhaled nanomaterials, as well as for regulatory toxicity testing, animal-free in vitro test systems that mimic real situations are needed.

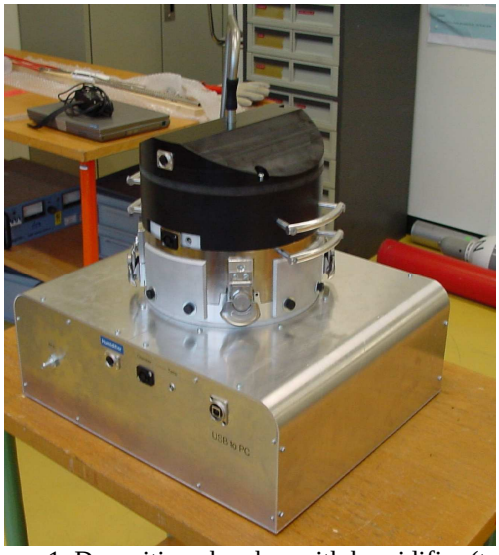

Figure 1. Deposition chamber with humidifier (top), insert holder and control box

Based on previous work (Savi et al. 2008), an aerosol deposition chamber for efficient and quantitative deposition of nanoparticles out of a continuous air-stream on cell cultures has been developed. It allows the parallel deposition of particles on 24 cell cultures in standard inserts. The particles are first charged by a unipolar diffusion charger. Then the particle containing gas is first humidified to an adjustable RH (typically 90%). The whole chamber is temperature controlled. Particles are precipitated on the cells by electrostatic deposition.

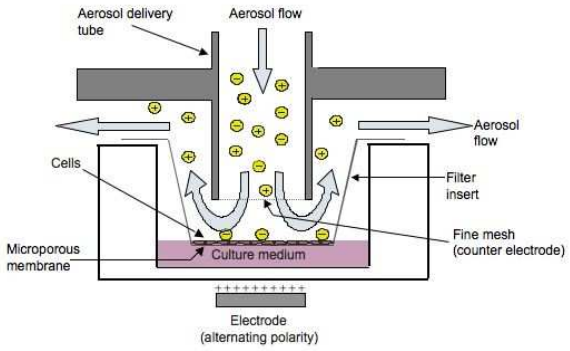

Figure 2. Electrostatic particle deposition on cell culture

To determine the amount of particles deposited, the flow is split after the charger and a part is passed through an electrostatic precipitator, having the same deposition characteristics as the inserts. The current produced by the particles precipitated there is measured and integrated.

First tests show that the deposition efficiency on all 24 inserts is very.

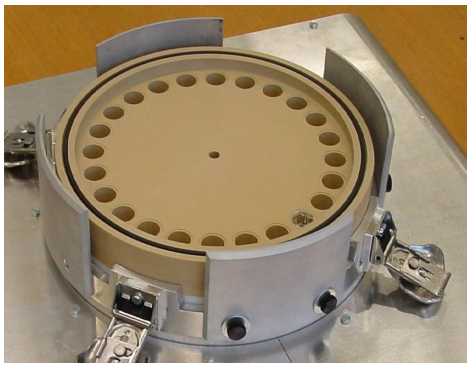

Figure 3. Disc with 24 holes for the inserts

Developments towards an NO_2 denuder for elevated temperatures

J. C. Wolf and R. Niessner

Chair for Analytical Chemistry, Technische Universität München, Marchioninistr. 17, 81377, Munich, Germany

Keywords: NO_2, Diesel exhaust, coatings, diffusion denuder, ionic liquids.
Presenting author email: jan.wolf@mytum.de

The occurrence of artefacts during aerosol measurement and sampling is a known problem in analytical chemistry. Especially reactive gases like ozone, SO_2 and NO_2 can cause degradation of several analytes of interest. Ozone and NO_2 for instance are known to cause negative sampling artefacts for polycyclic aromatic hydrocarbons (PAH). In contrary several authors (e.g. Samy et al.; Carrara et al.) reported positive sampling artefacts for nitrated polycyclic aromatic hydrocarbons (NPAH) due to NPAH formation out of PAH and NO_2 during filtration.

Usually diffusion based denuding techniques are used to remove such interfering reactive gases prior to sampling or measurement. There have been several approaches to optimize the geometry and the coatings for each individual target gas at room temperature. Since 1984, several coatings for selective stripping of NO_2 have been proposed (e.g. MnO_2, alkaline guiacol, potassium iodide, cobalt oxide).

However, PAH and NPAH are formed during incomplete combustion and are therefore monitored in various combustion processes. For example, in the case of automotive exhaust, PAH and especially NPAH might be formed due to the incomplete combustion and the high NO_2 levels present in the aftertreatment system. Here the question arises, whether these newly formed NPAH are in the gaseous state or adsorbed on particles. To give an answer on such questions a NO_2 denuding system is required that can withstand the temperatures of automotive exhaust and thus avoid condensation of water or analytes.

For this reason, we investigated and improved common coatings for NO_2 stripping, with focus on heat stability. Besides of that, we developed a new coating based on an ionic liquid. We used the ionic liquid Butyl-methyl-imidazolium iodide $[BMIm]^+[I]^-$ as coating in a newly designed heatable 13 channel annular denuder. The denuder was then passed by 50 ppm of NO_2 in nitrogen at a flow of 5 l/min. The breakthrough curves were recorded by a chemiluminescence analyzer (*CLD 700-Al, Eco Physics*). In comparison with the polyethylenglycole/ potassium iodide (PEG + KI) coating we found a three fold higher capacity for $[BMIm]^+[I]^-$ (see figure 1) at room temperature.

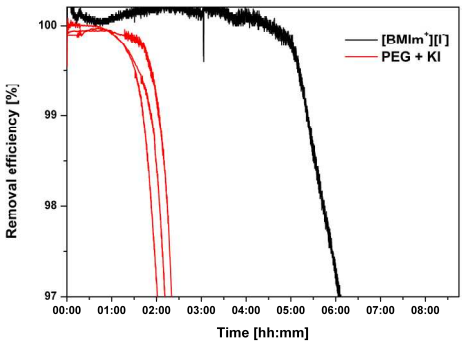

Figure 1.: Breakthrough curves of polyethylenglycole/potassium iodide (PEG+KI) and $[BMIm]^+[I]^-$ coating (25°C; 5 l/min; 0% RH; 50 ppm NO_2 in N_2)

With increasing temperature the NO_2 binding capacity of both coatings decreases rapidly. For potassium iodide, we additionally found a PEG aerosol formation at temperatures above 423K. This was not the case for $[BMIm]^+[I]^-$ due to the low vapour pressure. Nevertheless, the potassium iodide coating was more efficient at elevated temperatures.

Table 1. Comparison of NO_2 denuding capacity of potassium iodide and $[BMIm]^+[I]^-$ at different operation temperatures.

Capacity	KI (ppmh)	$[BMIm]^+[I]^-$ (ppmh)
298 K	112	300
373 K	38	17
423 K	13	11

Our investigations revealed two coatings suitable for denuding NO_2 at temperatures up to 423K. In addition, the ionic liquid coating $[BMIm]^+[I]^-$ showed extraordinary NO_2 removal and binding efficiency at room temperature, indicating its use in other fields e.g. ambient sampling.

Development of a portable instrument to determine the fractal dimension from angular light scattering meaurements

Zs. Jurányi, A. Keller and H. Burtscher

Institute of Aerosol and Sensor Technology, University of Applied Sciences Northwestern Switzerland, Windisch, 5210, Switzerland
Keywords: soot agglomerates, light scattering, fractals, optical instrumentation.
Presenting author email: zsofia.juranyi@fhnw.ch

Introduction

Black carbon is a major constituent of the atmospheric aerosols and has most of the time anthropogenic origin. It is produced during incomplete combustion processes, and forms usually fractal-like particles through aggregation. Fractal aggregates are scale invariant, which means that within limits they appear the same when viewed over a range of scales. An important property of aggregates is the fractal dimension which connects the number of primary particles (N, proportional to the mass) in the aggregate to the radius of gyration (R_g, measure of the overall radius):

$$N = k_0 \cdot \left(\frac{R_g}{a} \right)^D$$

Where k_0 is a constant in the order of unity, a is the radius of the primary particle and D is the fractal dimension.

The angular light scattering of fractal aggregates depends on the wavelength of the incident light, the complex refractive index, the shape of the particle and the scattering angle. According to the scaling approach of angular light scattering by fractals from Sorensen and Oh (1998) the measured scattered light intensity as function of the magnitude of the scattering vector (q, proportional to the sinus of the half of the scattering angle) contains the information on D: the logarithm of the intensity versus the logarithm of q has a slope of D in a specific q range. This q regime is called the power law regime.

Results

At the University of Applied Sciences Northwestern Switzerland a portable instrument is being developed in order to measure the angular scattering of aerosols. The goal is to be able to measure the scattering signal simultaneously at several angles and to derive the fractal dimension of fractal-like particles. The aerosol is brought into a closed chamber where a laser diode illuminates the particles that can be found in the sampling volume. The scattered light is then detected by avalanche photodiodes at different angles.

Now, the chamber is built, and ready for the first tests. These tests aim for the better understanding of the instrument's performance and therefore are performed using almost spherical salt particles. The nebulized salt particles were size selected by a differential mobility analyser (DMA) before entering the chamber. The number size distribution of the nebulized aerosol was also measured. Figure 1 shows the measured results along with theoretical calculations at two different (35 and 150 degrees) scattering angles. The calculations were done using Mie theory (Bohren and Huffmann, 2004) and the refractive index of 1.54+0i. The effect of the different concentrations at the different diameters was taken into account by weighing the theoretical differential cross section with the normalized size distribution. The DMA transfer function and the effect of the multiple charged particles were also considered.

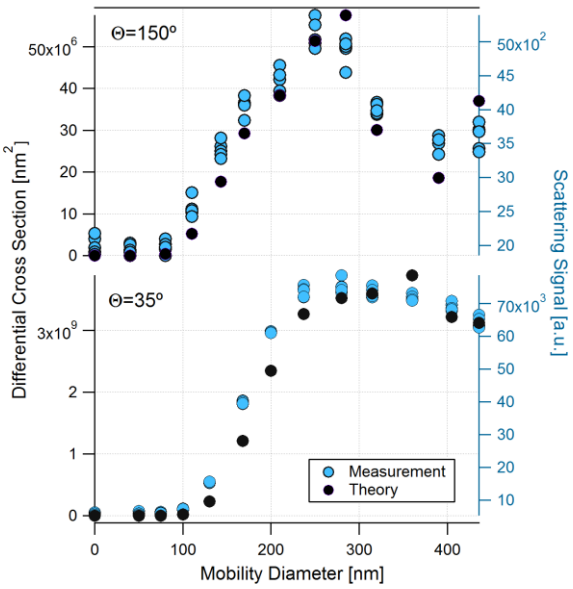

Figure 1. Theoretical and measured scattering signal of 660 nm laser light as function of the nominal mobility diameter from the DMA, see the text for more details

The curves of the measured and the calculated values show a very good agreement. The small differences can be associated with measurement errors and with the fact that the number size distribution was not measured simultaneously with the scattering. We can state that the instrument is ready for further tests and measurements.

An increasing number of people carry a smartphone with internet connection, a camera and considerable computing power in their pocket almost all the time, wherever they go. iSPEX, a spectropolarimetric add-on with complementary App makes use of this opportunity, and instantly turns a smartphone into a scientific instrument to measure dust and other aerosols in our atmosphere (Figure 1). A measurement involves scanning the blue sky, which yields the angular behavior of the degree of linear polarization as a function of wavelength, which can unambiguously be interpreted in terms of size, shape and chemical composition of the aerosols in the sky. The measurements are automatically tagged with location and pointing information, and submitted to a central database where they will be interpreted. Together with observations from other users at random locations, the data is compiled into an aerosol map. Through crowd sourcing, the general public will thus be able to contribute to a better assessment of the presence of different types of aerosols in the atmosphere. It may also improve the understanding of the relationship between atmospheric aerosols and health issues or climate change.

iSPEX is based on our new ground-based SPEX instrument which will also be presented at the conference [see contribution of J. de Boer et al.]. With SPEX (Spectropolarimeter for Planetary Exploration) we perform multi-angle, multi-wavelength measurements of the intensity and polarization of sunlight scattered by aerosols in the atmosphere (Snik et al. 2009). It will be deployed at CESAR, the Cabauw Experimental Site for Atmospheric Research, which is also host to complementary aerosol measurement equipment, including PM_{10} and $PM_{2.5}$ monitors, sunphotometers and lidar instruments. Both for the ground-based SPEX and iSPEX, we interpret the data using a modified version of the POLDER algorithm (Hasekamp, 2010). The data from the SPEX instrument add significantly to the current suite of aerosol measurement equipment, but they are restricted to the Cabauw site. By distributing many iSPEX units, an air quality measurement network can be created that has both large coverage and the potential for detecting localized effects. Such a smartphone spectropolarimeter is less accurate than its official counterpart at a meteorological site, but we show how many measurements allow for suppression of errors through averaging.

We will give a live demonstration of the first iSPEX prototype. We hope to convince you that iSPEX is not only a great outreach tool to engage the public in issues pertaining to atmospheric aerosols, but that it may also contribute to the solution of several urgent social and scientific problems.

Near-ground hyperspectral imaging for urban scale remote sensing of aerosols, during nighttime –laboratory and upscaling study

Y. Etzion[1], D.M. Broday[1]

[1] Department of Environmental and Water Resources Engineering, Technion - Israel Institute of Technology, Haifa 32000, Israel

Keywords: remote sensing, urban pollution, fine PM, aerosol measurement, hyperspectral imaging

Spatiotemporal variations of fine ambient aerosols near the ground are important indicators for air pollution events and public health risk assessment, especially the diurnal variations of aerosol size resolved concentrations and composition at urban-scale resolution.

Aerosol remote sensing is an accepted methodology to retrieve aerosol size distributions in vertical atmospheric columns, based on PM interactions with radiation in the visible-NIR range that are measured at multiple wavelengths or multiple angles. Both satellite and ground remote sensing (RS) platforms mostly rely on solar radiation, and therefore they are limited by sun elevation angle and the cloud cover, and also by the revisit periods and variability of surface albedo for satellite-borne sensors.

Current RS procedures can provide estimates of bi-modal size distributions in vertical atmospheric columns (Wang *et al.*, 1996; Dubovik *et al.*, 2002). However, the correlation between the vertical aerosol profiles and ground-level particulate matter (PM) distribution at the urban-scale resolution is highly influenced by the geo-site specific seasonality and the corresponding mixing layer height (Schäfer *et al.*, 2008).

The aim of this study was to apply ground hyperspectral imaging in order to extract the size attributes of fine PM along horizontal open paths of 1-4km. A camera that acquires high resolution spectral signatures in the visible-NIR range (VDS Vosskühler Cool-1300Q, λ=400-1100nm, 160-180 wavelengths) was used for that purpose. A dedicated procedure was developed by exploiting nocturnal illumination sources as a novel concept for urban scale horizontal RS, as well as an innovative solution for nighttime when solar radiation cannot be used.

Validation of the hyperspectral response to fine PM was obtained as a first step in a controlled laboratory chamber, for bimodal mixtures of PSL standards, using halogen illumination. Analysis of the hyperspectral sensor response showed highest sensitivity to AOT in 550-900nm wavelength range, which encompasses signatures of fine modes above ~0.2 μm, based on Mie calculations. The retrieval of modal concentrations was demonstrated by applying random search. The HS imaging procedure was next applied during time series release of tri-ethylene glycol aerosol (urban-like) in ambient conditions, and demonstrated correlated spectral signatures to the measured size distributions of that aerosol.

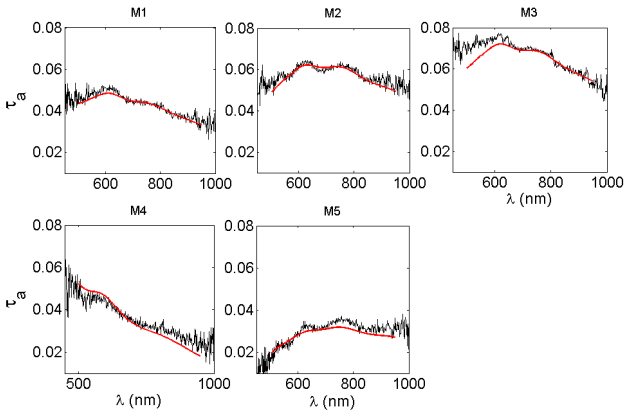

Figure 1. Experimental (black) vs. computational (red) hyperspectral signatures of bimodal PSL aerosols in a laboratory chamber. The computed attenuated spectral signature is based on simultaneously measured aerosol size distributions.

New instrument to investigate size-resolved chemical composition of nano-particles

A. Kürten, J. Hoker, C. Fuchs and J. Curtius

Institute for Atmospheric and Environmental Sciences, University of Frankfurt, Frankfurt, 60438, Germany
Keywords: nucleation, nano aerosol, mass spectrometry, CIMS.
Presenting author email: kuerten@iau.uni-frankfurt.de

Determining the speciated chemical composition of sub-20 nm particles remains a major challenge in atmospheric chemistry. There are only very few instruments available which can perform such an analysis in real-time for atmospherically relevant concentrations of aerosol particles. The TD-CIMS (Thermal Desorption-Chemical Ionisation Mass Spectrometer) is a unique instrument (see Voisin *et al* (2003) and Smith *et al* (2004)) which has given valuable information about the composition of particles in that size range. However, additional experimental studies are required to further elucidate the mechanisms how freshly nucleated particles can overcome the gap between their initial size of ~2 nm and ~20 nm. This step is crucial for the fate of the particles. It decides whether they are scavenged out by larger particles or if they eventually reach sizes where they can act as cloud condensation nuclei and thereby exert a substantial effect on the Earth's climate.

In this study, a new instrument is introduced which allows collecting aerosol particles on a small substrate. The particles are electrically charged before they enter a DMA-like geometry where they are separated from their carrier gas and classified according to their electrical mobility diameter. After the classification they are electrostatically precipitated inside the DMA on a short stainless steel wire. Following appropriate collection times, the wire can be translated into the sampling line of a Chemical Ionisation Mass Spectrometer (CIMS) by means of a linear motor. This CIMS (THS Instruments, LLC) is used to measure gaseous sulphuric acid through the reaction of H_2SO_4 with NO_3^- primary ions. However, the instrument can in principle also be used with other primary ions, e.g. when it is intended to analyse organic compounds. Before their chemical analysis, the collected aerosol particles are evaporated by applying a heating current to the wire. During these periods ultrapure nitrogen is introduced further upstream into the CIMS sampling line in order to measure only the particulate constituents of the sample (Figure 1). The distance between the wire and the CIMS ion source is minimized which prevents substantial wall loss of the evaporated material.

The main advantages of this method are the following: (1) The same instrument (CIMS) can be used to study gas phase compounds as well as aerosol particles in the sample gas. No measurement time is lost despite the rather long collection times for the aerosol particles. (2) A size-resolved analysis is possible. The accessible size range is roughly between 5 and 50 nm. The size range of the classified aerosol particles which are subsequently chemically analyzed is adjustable. (3) The particle collector is compact and modular. In principle it can be combined with any other analytical instrument, e.g. with a PTR-MS or even with GC-MS systems.

The set-up of the new instrument will be introduced in detail. First results on its performance for test measurements in the laboratory will be presented. For these, aerosol particles of known chemical composition and size are generated and collected over specified time intervals. From the collected mass detection limits for various compounds can be derived. Other studies which will be presented include the characterisation of the size accuracy of the classifier and its collection efficiency with respect to different particle sizes.

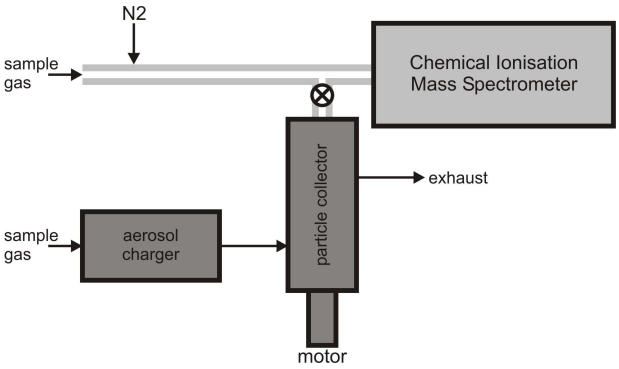

Figure 1. Schematic set-up of the new particle collector combined with a chemical ionisation mass spectrometer (CIMS) for chemical analysis of nano-aerosol particles.

Development of New Particle Size Magnifier Using Cooling Nucleation Tube

T. Yamamoto and M. Adachi

Department of Chemical Engineering, Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, 599-8531 , Japan
Keywords: Nanoparticles, Heterogeneous nucleation, Condensation
tyamamoto@chemeng.osakafu-u.ac.jp

Introduction

The 1 nm-range particles have been one of hottest topics in the atmospheric aerosol research field[1]. A particle size magnifier (PSM) is one of strong candidate for the measurement of the 1 nm-range particles. Vanhanen et al. have developed a new PSM using low temperature nucleation tube[2]. We have also investigated the same concept PSM; called the cooling type PSM, for 5 years.

New PSM using cooling nucleation tube

In the PSM, the mixing of nanoparticle aerosol and condensed vapour is very important for the performance. Therefore, we have proposed and developed the novel mixing unit which has a critical orifice. Figures 1 (a) and (b) show our PSM and vertical cross-section view of the developed mixing unit, respectively. The mixing unit consists of upper disk wall and under disk wall. The center of under disk wall has a critical orifice with a hole of 0.3 μm in the diameter. DBP vapor is expanded at exit of the orifice and makes lower pressure space in the mixing unit. Therefore, the nanoparticle flow is sucked in the mixing unit by the pressure lower than the atmosphere. As the results, particle losses are prevented.

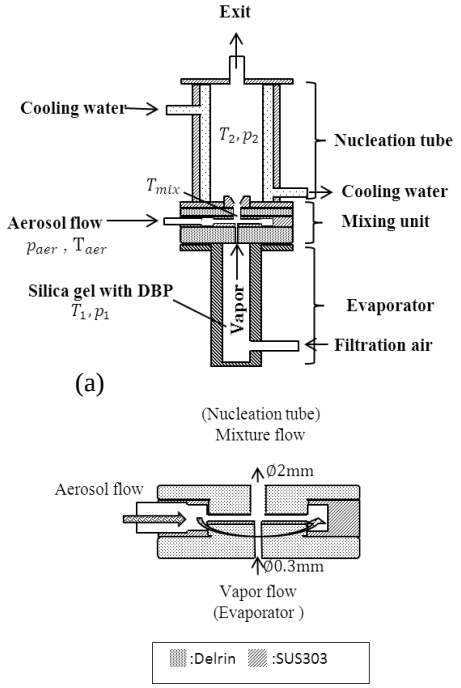

Fig.1 (a) cooling type PSM (b) vertical cross-section view of mixing unit.

Results

Monodisperse 5nm Ag particles were used as the test aerosol. Number concentrations at inlet and exit of PSM were measured by condensation particle counter (TSI Model 3025A). Figure 2 shows the result at various nucleation tube temperatures. The penetration ratio becomes equal to 1.0 at the nucleation tube temperature of 288K and the evaporator temperature of 353K.

Particle size distributions after the growth of the test aerosol were measured by the optical particle counter (Rion Model, KC-01E). The PSM was operated at the evaporator temperature of 353K, nucleation tube temperature: of 288K and ratio of DBP vapor flow rate to total flow rate of 0.3. Figure 3 shows the particle sizes distribution in size range larger than 0.3μm. The 68 % of 5 nm Ag particles was magnified to size lager than 0.3 μm by the DBP vapor of 353 K.

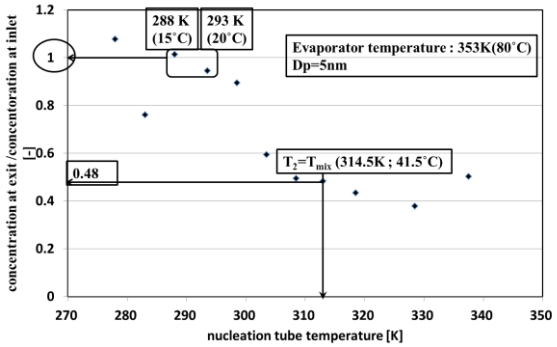

Fig.2 Penetration ratios of 5 nm Ag particles

High Temperature Condensation Particle Counter

K. Rongchai and N. Collings

Department of Engineering, University of Cambridge, Cambridge, CB5 1QH, UK
Keywords: Particle Concentration, CPC, Aerosol Instrumentation, Instrument development, High Temperature
Presenting author email: kanchit.rongchai@gmail.com

Condensation Particle Counters (CPCs) are commonly used to measure the number concentration of airborne nanoparticles in various applications. A typical CPC consists of three major stages. They are: a saturation stage where an aerosol sample is saturated with vapour of a fluid e.g. butanol; a supersaturation stage where the nanoparticles grow to optically detectable sizes by condensation of the vapour on particle surfaces; and an optical particle counter (OPC). The working temperature of a typical CPC is around ambient or slightly higher.

This work is connected with the development of a CPC that operates at such a high temperature that volatile material is not measured, due to it being evaporated or prevented from condensing. The obvious application is measurement from internal combustion engines, where the European legislated particle number method (PMP) requires a complex system for the removal of volatile material, prior to measurement by a conventional CPC.

The study involves theoretical modelling, design, construction and testing of a high temperature CPC. Di-Ethyl-Hexyl-Sebacat (DEHS) has initially been chosen as the working fluid because it is non-toxic, is a liquid at room temperature and has a high boiling point. The supersaturated region in the condenser where particles are grown, is modelled by numerically solving the heat and mass transfer equations based on the finite difference method. The model was found to be in good agreement with an alternative model due to Stolzenburg and McMurry (1991).

The simulations suggest that the high-temperature CPC will be able to grow and detect fine particles. The saturator and condenser would be held at approximately 210˚C and 190˚C respectively. For a likely embodiment, the saturation ratio in the condenser is shown in Figure 1. Particle growth was modelled by the mass and heat balance at the droplet surface, following the approach of Ahn and Liu (1990). The growth profile of a 23 nm particle is shown in Figure 2.

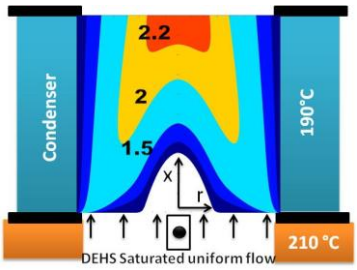

Figure 1. Supersaturation contour in the condenser.

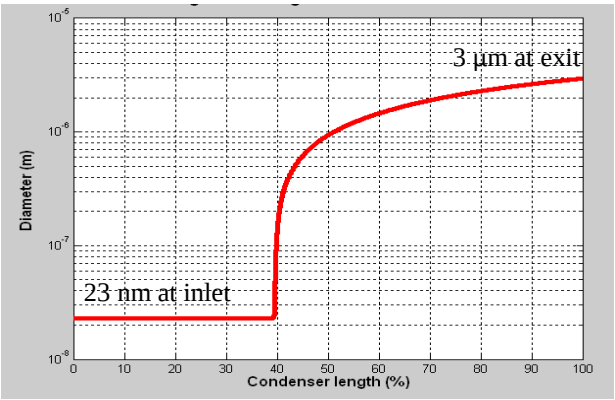

Figure 2. Particle growth along the condenser.

Experimental Study

A step decrease in particle concentration was introduced at the aerosol inlet. Particle pulses in the optical signal were counted over periods of 20 ms. The particle number vs. time is shown in Figure 3.

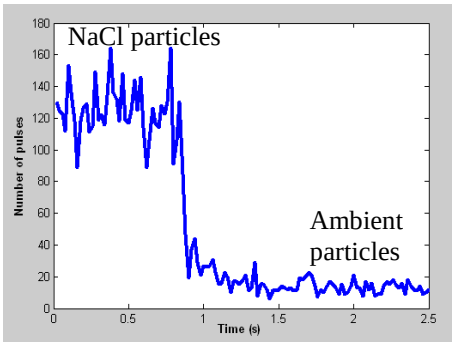

Figure 3. Testing of the high-temperature CPC Particle counts vs. time

The high-temperature CPC has been shown to successfully grow and detect NaCl particles and ambient particles.

Presenting author email: giamarel@env.aegean.gr

By simultaneously selecting aerosol particles having different sizes, Differential Mobility Analyzers (DMAs) with multiple monodisperse-particle outlets can have a number of advantages in aerosol metrology. When used in electrical mobility spectrometers, for instance, they can significantly reduce the time required to measure the particle size distributions. Depending on the relative location of the first and the last outlet from the inlet, one can also increase the dynamic mobility range of the measured particles in a single measurement.

Based on the approach proposed by Stolzenburg (1988), we have recently developed the theoretical framework for determining the transfer function and the resolution of DMAs with multiple monodisperse-particle outlets (cf. Giamarelou et al., 2011; 2012). To describe the spreading of the transfer function due to the Brownian motion of the particles, we divide the classifier into segments defined by successive monodisperse-particle outlets. The total diffusional broadening along the whole path of the particle that leads to the i^{th} sample exit can be approximated by

$$\sigma^2_{\Gamma_{i,total}} = \sum_{j=n}^{i} \sigma^2_{\Gamma_{i,j}} . \qquad (1)$$

Here $\sigma_{\Gamma_{i,j}}$ denotes the diffusional broadening of the particles classified through the i^{th} monodisperse-particle outlet during the time they travel through the j^{th} segment of the MMO-DMA.

Fig. 1a shows the comparison of the model to the measurements with the 3-monodisperse-particle-outlet DMA tested by Chen et al. (2007). The loss-corrected theoretical transfer functions for both sample outlets, at 2.54 cm and 15.24 cm, are in perfect agreement with the experimental values. The predicted resolution for each of the three outlets agrees well with the reported measurements (Fig. 1b), indicating that the theory captures well the broadening of the transfer function for particles having diameter smaller than 20 nm.

Using the validated transfer function model we provide design considerations for building a DMA with two monodisperse-particle outlets, and predict its performance under different operating conditions. A critical parameter when designing multiple-exit DMAs is the minimum distance between the entrance and the nearest sample exit as well as between the successive sample exits so that the flow profile remains laminar.

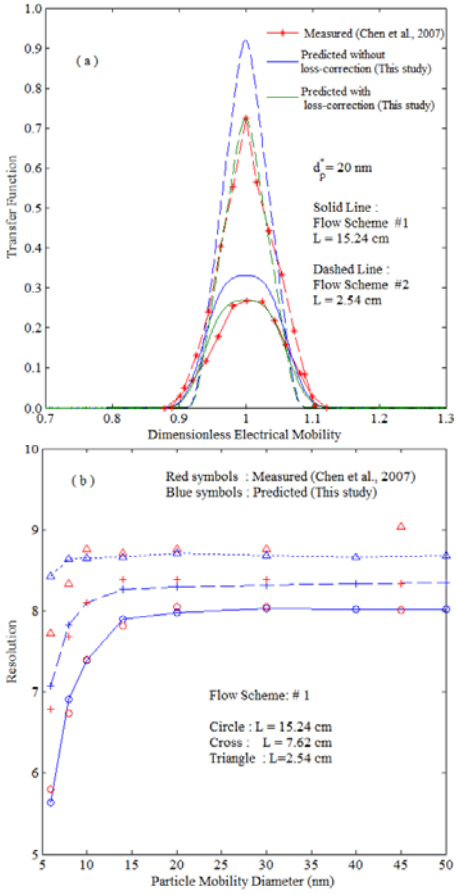

Figure 1 (a) Comparison between predicted and measured transfer function of the DMA with 3 monodisperse-particle outlets (measurements from Chen et al., 2007). The monodisperse-particle outlets are located 2.54, 7.62 and 15.24 cm downstream of the polydisperse aerosol inlet. Flow scheme #1 corresponds to 20 lpm sheath flow, 2.4 lpm polydisperse aerosol inlet flow, and 0.8 lpm for each monodisperse outlet flow. The respective values for flow scheme #2 are 20, 1.5 and 1.5 lpm. (b) Comparison between predicted and measured resolution of the DMA with 3 monodisperse-particle outlets.

Influence of Turbulent Diffusion in an Electrical Mobility Spectrometer

J. Salm[1], P. Intra[2], A. Yawootti[2], N. Tippayawong[3] and U. Hõrrak[1]

[1]Institute of Physics, University of Tartu, Tartu 50090, Estonia

[3]Department of Mechanical Engineering, Faculty of Engineering, Chiang Mai University, Chiang Mai 50300, Thailand
Keywords: aerosol, particles, electrical mobility, diffusion, turbulence.
Presenting author email: jaan.salm@ut.ee

The spectrometer had one long column of coaxial, cylindrical electrodes (Intra and Tippayawong, 2009; 2011). The inner electrode of the spectrometer was maintained at a high DC voltage while the outer chassis of the spectrometer was grounded. The charged particles were collected on a series of electrically isolated electrometer rings positioned at the inner surface of the outer chassis of the spectrometer column. The inputs of highly sensitive electrometers were connected to these electrometer rings. In this spectrometer, the 22 electrometer rings used resulted in the classification of aerosols into 22 mobility ranges. The entire size range of particles collected on the electrometer rings could be varied by adjusting the aerosol and sheath airflow rates and the voltage applied to the inner electrode.

For approximate estimations, consider a model of the differential mobility classifier of second order with parallel plain electrodes and a uniform gas flow. Such a simplified classifier model has a characteristic (limiting) mobility (Tammet, 1970; Salm, 2000):

$$Z_C = \frac{ud^2}{VL}, \qquad (1)$$

where u is the gas flow velocity, d is the gap width between the electrodes, V is the central rod voltage, and L is the distance from aerosol inflow section to the corresponding electrometer ring (collector). Charged aerosol particles with a mobility of Z reach the electrometer ring with a characteristic or central mobility of Z_c, if $Z = Z_c$. The distance L determines a particular electrometer ring.

According to the theory proposed by Salm (2000), the mobility resolution can be expressed as:

$$R_d = \frac{Z_C}{\Delta Z_{\min}} = \frac{\sqrt{ud/D}}{2\sqrt{2}\sqrt{L/d + d/L}}, \qquad (2)$$

where ΔZ_{min} is the least distinguishable interval of the mobility spectrum and D is the diffusion coefficient of charged particles.

Molecular diffusion and turbulent diffusion share attributes. However, turbulent diffusion has two essential peculiarities. First, the coefficient of turbulent diffusion does not depend on the mobility of a particle. Secondly, in general the correlation between successive random displacements of a particle cannot be neglected.

In the case of small-scale turbulence ($\lambda << d$, where λ is the Eulerian length scale of turbulence), the coefficient of turbulent diffusion may be defined in its first approximation as:

$$D_T = u' \lambda, \qquad (3)$$

where u' is the root-mean-square pulsation velocity of gas flow.

Neglecting the evolution and the decay of turbulence in the classifier, the resolution R_d may be approximately estimated from Eq.2 when substituting D_T for D. The root-mean-square pulsation velocity u' inside the classifier depends on the intensity of turbulence of the inflowing gas and on the flow conditions in the classifier. Usually the pulsation velocity is roughly proportional to the average velocity u and considerably less than u. The turbulence intensity is calculated as u'/u. A turbulence intensity of 1% or less is generally considered low and turbulence intensities greater than 10% are considered high. If the spectrometer is operated in a still environment, low turbulence intensity is expected. The length scale of turbulence, λ, is a physical quantity related to the size of the large eddies that contain the energy in turbulent flow. In ducts or channels, λ is restricted by the size of the duct, since the turbulent eddies cannot be larger than the duct. In the classifier, it is rational to assume that usually $\lambda << d$.

An example with low and small-scale turbulence: the velocity $u = 0.25$ ms^{-1}, the gap width $d = 1.5$ cm, the turbulence intensity 1% and the length scale $\lambda = d/15$, i.e. $u' = 0.0025$ ms^{-1} and $\lambda = 0.001$ m. For the electrometer ring No. 22, $L_{22} = 0.45$ m. These numbers when substituted into Eq.3 yielded $D_T = 2.5\times10^{-6}$ m^{2}s^{-1} for turbulent diffusion, and the resolution for the electrometer ring No. 22 was $R_{d,22} = 2.5$. As Eq.2 showed, a relatively short, $L \approx d$, classifier is advisable for increasing the resolution.

The authors wish to express their gratitude to the National Electronic and Computer Technology Center, Thailand for their support (contract no. NT-B-22-SS-11-50-18). A Micro-Orifice Volatilization Impactor (MOVI) coupled to an ion trap mass spectrometer with a soft ionization source (APCI-IT/MS) for the analysis of secondary organic aerosols

M. Brueggemann, A. Vogel and T. Hoffmann

Institute of Inorganic and Analytical Chemistry, Johannes Gutenberg-University, Mainz, Germany

Keywords: Instrumentation/chemical char., SOA (Second. Organic Aerosols), Inertial impactor, Mass spectrometry.
Presenting author email: brueggemann@uni-mainz.de

We describe the development and characterization of a Micro-Orifice Volatilization Impactor (MOVI) which is coupled to an ion trap mass spectrometer with atmospheric pressure chemical ionization (APCI-IT/MS), and its application in laboratory and field measurements. The MOVI-APCI-IT/MS allows the quantification of organic acids and other oxidation products of volatile organic compounds (VOCs) in secondary organic aerosols (SOA) on a semi-continuous basis. Furthermore, the vapour pressure and saturation concentration of the particle components can be estimated.

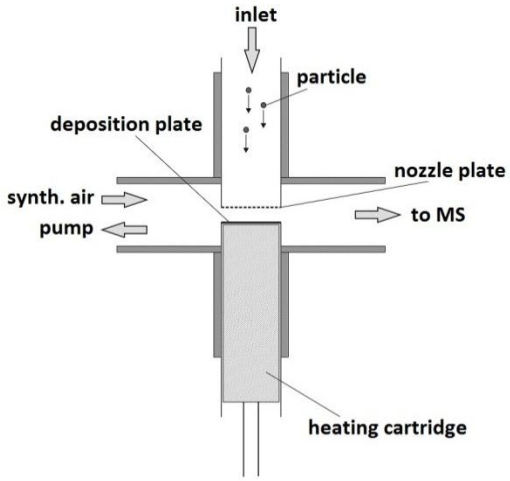

Figure 1: Cross section through the Micro-Orifice Volatilization Impactor (MOVI).

The MOVI was first described in 2010 by Yatavelli and Thornton. It is a single stage, multi-nozzle impactor with 100 nozzles, each having a diameter of 150 µm. At a flow-rate of 10 L•min^{-1} air is drawn through the MOVI and particles are collected on a deposition plate. The cut-point diameter (d_{50}, diameter of 50% collection efficiency) is at 130 nm. A low pressure-drop of only 5.3% of atmospheric pressure behind the nozzles allows collecting not only low-volatile but even semi-volatile compounds, which are an important part of SOA. After collecting particles hydrocarbon-free synthetic air is led over the collection surface into the APCI-IT/MS and the collection surface is heated up to 120 °C in less than 200 s, volatilizing the sampled SOA. The vaporized compounds are transferred into the ion source and subsequently analysed by mass spectrometry. Due to the soft ionization at atmospheric pressure the obtained mass spectra show only low fragmentations and can easily be interpreted.

In laboratory experiments the MOVI-APCI-IT/MS was used for the chemical analysis of SOA generated from α-pinene-ozonolysis in a smog chamber. The limit of detection was found at 7.3 ng for pinic acid. The vapour pressure $\log p^0$ and the saturation concentration C_{25}^* for pinic acid were calculated from the desorption temperature using the method presented by Faulhaber *et al* (2009). Furthermore, in summer 2011 the MOVI-APCI-IT/MS was successfully tested in field measurements during the „Bio-hydro-atmosphere interactions of Energy, Aerosols, Carbon, H_2O, Organics and Nitrogen – Rocky Mountain Biogenic Aerosol Study" (BEACHON-RoMBAS) in a ponderosa pine woodland in the southern Rocky Mountains of North America. The study was focused on understanding the formation, growth and properties of biogenic organic aerosol. We measured the composition of the aerosol particles and determined the concentration of pinic acid and isobaric substances. By means of intercomparison studies with other instruments like an aerosol mass spectrometer (AMS) and a MOVI coupled to a chemical ionization mass spectrometer (CIMS) we could validate our measurements.

The Aerodyne Aerosol Mass Spectrometer (AMS) (Jayne, 2000) provides quantitative, highly time-resolved mass spectra of non-refractory, submicron particles. These data have been widely used to quantify inorganic species and organic material, segregate primary and secondary aerosol, and identify certain primary sources. The Aerosol Chemical Speciation Monitor (ACSM) (Ng, 2011) is a low-cost version of the AMS designed for long-term operation and stability, and thus requires minimal user maintenance. Its small size also makes it well-suited for integration into existing monitoring stations, or other locations where space is limited. However, the quadrupole-based ACSM (hereafter denoted "Q-ACSM") is much less sensitive than the standard AMS, constraining both detection limits and achievable measurement time resolution. Here we present the testing and initial deployment of a new Time-of-Flight ACSM (ToF-ACSM).

In the ToF-ACSM the quadrupole mass spectrometer in the conventional Q-ACSM is replaced with the new Tofwerk E-ToF mass spectrometer. This modification yields a higher mass spectrometer duty cycle and hence improved sensitivity. Preliminary results indicate a hardware dependent improvement of the detection limits compared to the Q-ACSM of a factor of 4 - 18 (organics), although the instrument was not yet fully optimized. This means that the detection limits lie between the ones of the W-mode and the V-mode HR-ToF-AMS. In Fig. 1, a subset of the raw ToF-ACSM spectrum of aerosols in ambient laboratory air averaged over 1 min is shown, while Fig. 2 depicts a background subtracted mass spectrum of NH_4NO_3 particles. The air peaks and the instrument background were subtracted using a filtered measurement, and the peak signals were integrated, converted to ions / s and illustrated as UMR sticks. With a resolving power of 300 - 500 Th / Th, isobaric mass peaks are easily resolved, and even the mass excess of ions is discernible.

We will report instrument performance, including detection limits, short- and long-term stability and amount of maintenance required. An intercomparison of the ToF-ACSM with Q-ACSM and a high resolution (HR-) ToF-AMS will be presented. Furthermore we will present first ToF-ACSM field data from deployment at the high-altitude Jungfraujoch station, which resides in the free troposphere for most of the year (Baltensperger, 1997). The low aerosol concentrations at this site provide an ideal test case for the ACSM. Finally we will demonstrate the application of the positive matrix factorization (PMF) (Ulbrich, 2009) source appointment method to the ToF-ACSM data.

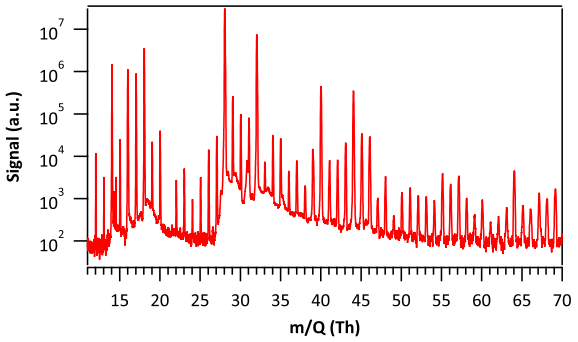

Figure 1: Excerpt from a mass spectrum of ambient laboratory air with 1 min averaging time, recorded with the ToF-ACSM.

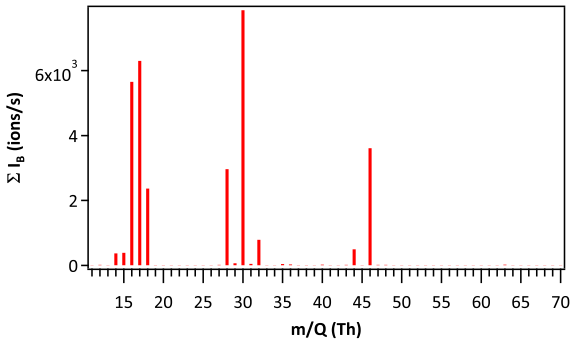

Figure 2: Excerpt from a background subtracted stick difference spectrum of NH_4NO_3 particles ($d = 300$ nm, $N = 7.5 \cdot 10^3$ cm^{-3}, $Q = 1.52$ cm^3/s), recorded with the ToF-ACSM.

Novel Polar Nephelometer for the Measurement of the Particle Asymmetry Parameter

Paul L. Kebabian, Timothy B. Onasch, Joda C. Wormhoudt and Andrew Freedman

Aerodyne Research, Inc., 45 Manning Road, Billerica, MA 01821, U.S.A.
Keywords: polar nephelometer, particle asymmetry parameter
Presenting author email: af@aerodyne.com

Radiative transfer models use the particle asymmetry parameter, *g*, as a measure of scattering angle because it is far more computationally efficient than including the entire scattering phase function. A number of other parameters, such as backscatter fraction and hemispheric backscatter fraction, are also used because comparatively simple instruments exist which can provide estimates of these parameters.[Ogren, et al, 2006] However, linking these measured parameters with *g* requires various assumptions and/or use of supporting data, especially the aerosol size distribution of particles below 1 micron diameter and their refractive indices. While using these approximations appears to produce values of *g* which agree with one another to a reasonable degree, it raises the question of how accurate these values really are. Calculations indicate that a 10% change in the assumed value of *g* (which is typically in the range of 0.5-0.7) can have a 20% effect on radiative forcing at the top of the atmosphere and only a somewhat lesser effect at the earth's surface. [Andrews, et al, 2006]

We present a proof-of-principle demonstration of an apparatus capable of directly measuring the aerosol scattering phase function and aerosol asymmetry parameter without the need for calibration or adjustment of data. The measurement technique utilizes a technique which allows for the collection of scattered light at all angles simultaneously and thus offers the potential for more rapid acquisition of scattering data from ambient polydisperse aerosols compared to polar nephelometers which measure scattered light from one angle at a time.

Figure 1 shows the measured asymmetry parameter of polystyrene latex particles of known diameter and a comparison to Mie theory. The illumination wavlength is 532 nm. Figure 2 presents the measured scattering phase function of a polydisperse distribution of ammonium sulfate particles. The Mie scattering calculation is based on the measured size distribution of the generated particles. The agreement between experiment and theory in both cases is excellent.

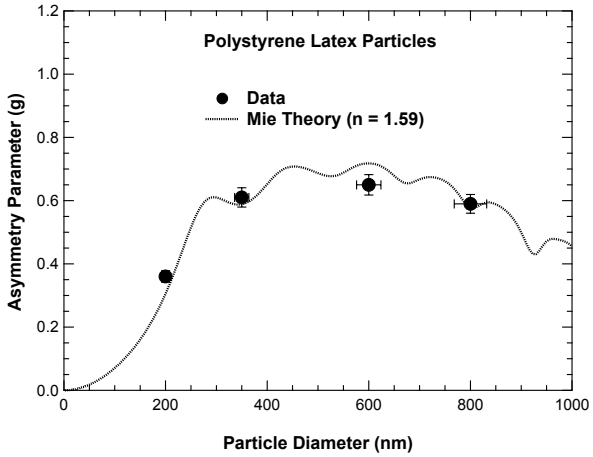

Fig. 1 Plot of asymmetry parameter obtained for four sizes of polystyrene latex particles at 532 nm.

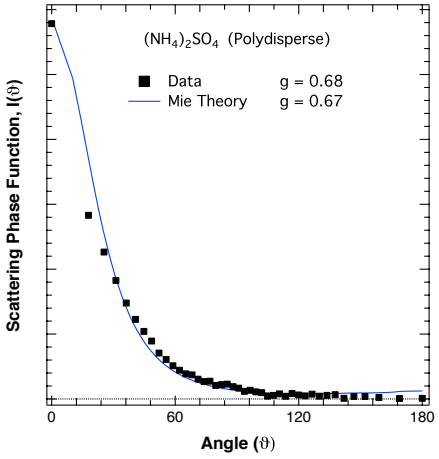

Fig. 2 Scattering phase function obtained from a polydisperse distribution of ammonium sulfate particles at 532 nm.

Since decades integrating nephelometers are in widespread use for measuring the particle scattering coefficient. Integrating nephelometers are easy to operate, calibrate and long-term stable what makes this instrument favourable device for monitoring and laboratory purposes.

Drawbacks of the nephelometer design are the *truncation error* and the *non-Lambertian* illumination by the light source. Truncation error means that light scattered by particles in small angular ranges in forward and backward directions are not detected by the instrument because of limitations of the design. Truncation angles of the nephelometer of type Aurora4000 (Ecotech Pty Ltd.) are from 0° to 10° and 170° to 180°. Ideally, the light source should have a Lambertian light emission pattern proportional to sin(θ). For the Aurora4000, the light source characteristics was determined to be proportional to $\sin(\theta)^{1.109}$. A correction of measured scattering intensities because of the truncation error and the non-Lambertian illumination is given in Anderson and Ogren (1998) for multi-wavelength nephelometers. This correction is a function of the spectral run of the scattering coefficient, which is described by the scattering Ångström exponent. However, corrections using the Ångström exponent are sensitive to the particles refractive index (c.f. Figure 2).

The new polar nephelometer of type Aurora4000 (Ecotech Pty Ltd.) measures the scattered light for several illumination sectors by blocking a part of the emitted light in forward direction with a controllable shutter. The shutter allows to block light from 0° to a user controlled angle α in the range 0°<α<90. Measured illumination functions are shown in Figure 1.

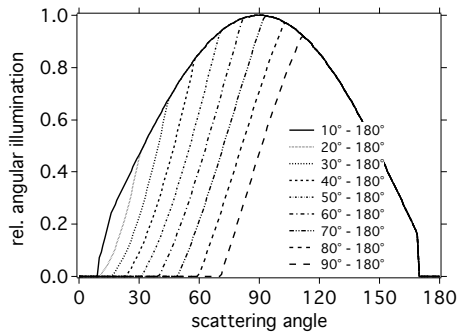

Figure 1: Angular illumination functions of the Aurora4000 for different illumination sectors by changing the shutter position in steps of 10°.

Correction for truncation errors, defined by the ratio of the scattering measured with nephelometer and the true scattering coefficients, were calculated using Mie theory. Also the relative scattered intensity I(α) for different angles of the shutter position were calculated. A quasi-phase function was determined from differences of scattering intensities calculated for pairs of shutter positions, e.g. I(0°)-I(10°), I(10°)-I(20°), etc. Mie-calculations were done for a range of particle size distributions with mode diameters from 0.1 to 1.0 µm and a standard deviation of 1.5. The real and imaginary parts of the complex refractive index ranged from 1.5 to 1.6, and 0.0 to 0.1, respectively. The Mie-simulated nephelometer signals were used as a test data set to develop methods for correction of the truncation error and for retrieval of the particle asymmetry parameter.

Henyey-Greenstein phase functions were fitted to the simulated quasi-phase functions and permit to derive an asymmetry parameter g_{HG}. A good correlation between the nephelometer truncation error and g_{HG} was found and a correction function for the truncation error was derived. Figure 2 shows values of the corrected nephelometer scattering coefficient $\sigma_{neph,cor.}$, calculated using the new correction based on the polar measurements and the correction from Anderson and Ogren (1998).

Values of the Henyey Greenstein asymmetry parameter g_{HG} differ from values of the asymmetry parameters calculated with Mie theory g_{Mie}. However a good correlation between g_{HG} and g_{Mie} was found.

Use of polar scattering measurements can significantly reduce the uncertainties for correction of the truncation error of nephelometers and allows to determine the asymmetry parameter.

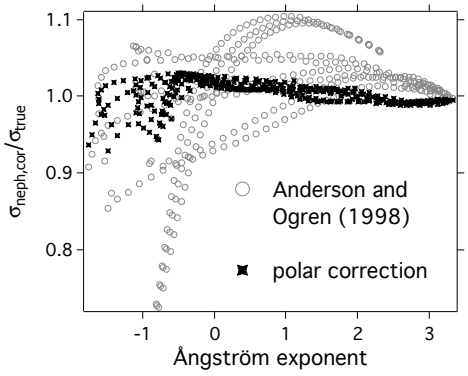

Figure 1: Ratios of truncation corrected and true scattering coefficient for a variety of particle sizes and refractive indices. Shown are results for the Anderson and Ogren (1998) and the new polar correction.

Feasibility study of a Differential Aerodynamic Diameter Analyzer

D. Kiesler and F.E. Kruis
Institute for Technology of Nanostructures and Center for Nanointegration Duisburg-Essen (CENIDE),
University Duisburg-Essen, Duisburg, 47057, Germany
Keywords: Aerodynamic focusing, Nanoparticles, CFD, DMA, ELPI, Instrument development, Size Measurement.

The aerodynamic diameter is an important property in studies of particle deposition, or agglomerate structure. But still no instrument exists, which has a differential transfer characteristic and can separate particles by their aerodynamic diameter like a DMA does for the mobility. Current measurement methods like the low-pressure impactor or ELPI have an integral transfer characteristic, or time of flight measurements like the APS do not separate the particles at all.

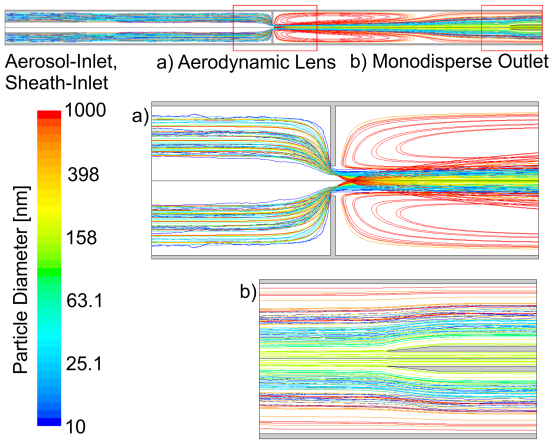

Figure 1: *Setup for the differential aerodynamic diameter analyzer tube. The polydisperse particles and the central sheath gas are introduced in the left. The aerodynamic lens a) sorts the particles by their aerodynamic diameters. Sampling at the tube center b) leads to a monodisperse particle distribution.*

In this work we want to combine the working principle of a DMA with the properties of an aerodynamic lens. Figure 1 gives an overview of the setup. The inlet on the left is designed like a DMA: The insertion of additional sheath air in the center of our tube creates a particle free zone. The polydisperse aerosol is inserted on the outer ring. But instead of applying an electric field, we use an orifice plate of an aerodynamic lens to apply a well defined force on the particles. This needs to be done in a low pressure environment in a laminar flow. The theory of the aerodynamic lens developed by Liu *et. al* (1995) shows, that particles in an accelerated gas stream can be separated from the gas streamlines due to their inertia. They showed, that one Stokes-Diameter d_f of the particles exists, which is focused to the center line. Particles smaller than d_f follow the streamlines and leave the center again. If the particles are too heavy, they overshoot the center and get defocused again (see figure 1 a). Downstream of the orifice we find only one diameter on the centerline. These particles can be sampled as monodispersed aerosol(see figure 1 b).

First, the aerodynamic lens orifice plate was designed with the aerodynamic lens calculator (Wang *et. al*, 2005, 2006). A further evaluation of this setup has been done by CFD simulations with particle tracking in a Lagrangian frame. A transfer function could be evaluated, which shows a clear differential characteristic. Figure 2 shows these transfer functions for titanium particles and different pressures behind the orifice plate. The selected diameter can be shifted by changing the pressure behind the orifice plate. The system can separate aerodynamic diameters from around 45nm to 1000nm, for pressures between 200Pa to 1200Pa.

While these first transfer functions are quite wide and have a broad geometric standard deviation of around $\sigma_g =$ 1.2 to 1.15 the design needs to be optimized. Based on a better evaluation of the aerodynamic lens, we tried different geometries in the simulation and found a design that leads to a σ_g of 1.04 which is clearly monodisperse.

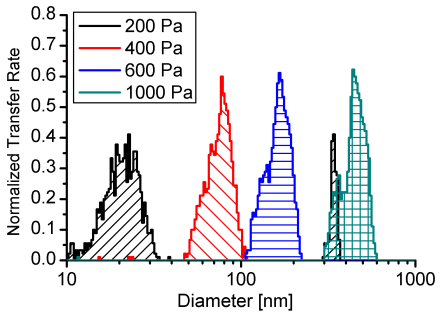

Figure 2: *The simulation results show a clear differential transfer characteristic. Different pressures behind the aerodynamic lens shift the sampled particle diameter.*

Experimental comparison of two Very Long DMAs

J. Uin, E. Tamm
Laboratory of Environmental Physics, Institute of Physics, University of Tartu, Tartu, Estonia
Keywords: Aerosol instrumentation, DMA, transfer function, laboratory experiments.
Presenting author email: janek.uin@ut.ee

The Very Long DMA is a Vienna-design based DMA, developed in University of Tartu, which can be used for experiments involving aerosol particles with sizes up to 10 µm (Uin and Tamm, 2011). It's main characteristics are: inner and outer diameters of the electrodes - 84 and 100 mm, working length - 1200 mm. Due to the instrument's size, the cylindrical electrodes of the DMA could not be made out of single piece of metal and instead a sectional design was implemented. This can cause some geometrical non-idealities that can distort the transfer function of the DMA. As there are now two VLDMAs in existence, a question arises, whether the working parameters of the two instruments are similar enough that the two DMAs can be treated as identical and used as such in the experiments.

To compare the two VLDMAs, two sets of experiments were done. First, a simple measurement of an aerosol size distribution was done with both instruments. Here silver + DOP particles with mean diameter around 800 nm were generated using the setup that avoids multiply charged particles (Uin et al., 2009). The results are shown in Fig. 1. As can be seen, the measurement results of the two DMAs are very similar. The minor visible differences can be attributed to the dissimilar length of the input tubing (and thus different particle losses) and to the small errors in setting the sheath flows of the DMAs.

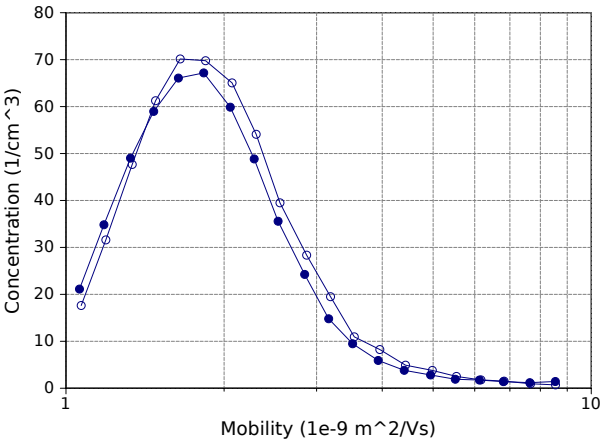

Figure 1: Aerosol distribution measurement results of the two VLDMAs in similar experimental setup.

Next, the two VLDMAs were paired with a known instrument – a TSI Long DMA and the transfer functions of the VLDMAs were measured using a tandem DMA setup (Stratmann et al., 1997; Birmili et al., 1997). In this setup, the known instrument was set to separate particles with a given modal diameter (around 800 nm in this case) and the aerosol distribution produced was measured with both VLDMAs. From the measurement results, the relative half-width β of the VLDMA transfer function was calculated for both instruments (due to technical reasons, it was not possible to accurately determine the transfer function height). The results for both instruments are identical with $\beta = 0.40$. This value, however, differs from the theoretical $\beta = 0.1$ (given by the airflows used) and from the experimental result $\beta = 0.17$ obtained with latex particles (Uin and Tamm, 2011).

The most likely reason for this is the presence of the electric wind between the electrodes of any of the three DMAs. The TSI Long DMA was operated using voltages > 9 kV and, considering the very high particle concentrations required by a tandem DMA experiment, the presence of the electric wind in that instrument is very likely.The voltages for the VLDMAs were around 5 kV and previous experiments show, that electric wind can readily arise in such conditions. However, as the experimental setup for both VLDMAs was the same, the effect of the electric wind on the registered aerosol distribution is also the same (regardless whether the electric wind was in the TSI Long DMA or in both of the VLDMAs). Thus, if any difference between the results for the two VLDMAs would have been detected it would have only been due to the differences between the actual instruments.

There is a very good agreement between the experimental results obtained using both VLDMAs, despite the potential non-idealities coming from the methods of their manufacturing. The conclusion of this investigation is, that the two VLDMAs can be considered identical and thus can be used in the experiments that require identical instruments. This opens up new possibilities for experimental work, as both VLDMAs are capable of operating in the particle size range of up to 10 µm.

Applying Particle Size Magnifier to nano-particle measurements

J. Mikkilä[1], K. Lehtipalo[1,2], J. Kangasluoma[2], J. Vanhanen[1], T. Petäjä[2] and M. Kulmala[2]

[1]Airmodus Oy, Gustaf Hällströmin katu 2a, 00560, Helsinki, Finland
[2]Department of Physics, University of Helsinki, P.O. Box 64, 00014, Helsinki, Finland
Keywords: nano-particle, nano-CN, instrumentation, CPC
Presenting author email: jyri.mikkila@airmodus.com

The Airmodus A09 particle size magnifier (PSM) was developed for detection of nano-CN as small as ~1nm in mobility diameter (Vanhanen *et al.*, 2011). Being able to measure even the smallest particles is crucial for example when studying atmospheric new particle formation. Inside the instrument a high super-saturation is achieved by mixing cooled sample flow Q_a turbulently with heated clean air flow saturated with working fluid Q_s. Diethylene glycol was chosen as the working fluid in order to activate nano-CN without homogeneous nucleation (Iida *et al.*, 2009). With the selected working fluid, the particles grow to a mean diameter of 90 nm, after which they can be easily counted with any conventional condensation particle counter (CPC) (McMurry, 2000). The instrument combining the functionality of the PSM and a CPC is called a nano condensation nucleus counter (nCNC).

Besides the relatively high inlet flow rate and low diffusion losses compared to laminar flow type CPCs, the mixing type nCNC benefits of its capability to rapidly change the saturation ratio at the point of activation. This is done simply by controlling the flow rates inside the instrument, so that the mixing ratio

$$\frac{Q_s}{Q_s + Q_a}$$

is changed. The sample flow rate Q_a is always kept constant at 2.5lpm. The *Figure 1* shows an example how the 50% activation diameter changes with the saturator flow Q_s i.e. with the mixing ratio. Thus the particle size distribution between 1 and 3.5nm can be determined by comparing the results with different mixing ratios. Generally, size information from about 1 to 3nm can be obtained with this method.

The results in *Figure 1* were obtained by using ammonium sulphate particles generated in a tube-furnace (Petäjä *et al.*, 2006). The composition was verified measuring simultaneously with APi-TOF mass spectrometer (Junninen *et al.*, 2010). Also the chemical composition plays a role in the activation of nano-CN. For example the mobility standards (ammonium halide salts) (Ude & Fernández de la Mora, 2005) and silver particles have somewhat different size dependence. This needs to be kept in mind when comparing ambient measurements to calibration results, which give the mobility equivalent diameter for a certain composition. On the other hand the possibility to tune Airmodus A09 to detect even some large molecules, such as ammonium halide salts, can give an alternative way to monitor and develop industrial processes.

To some extent the composition effect can be overcome by using a nano-DMA in front of a fixed flow nCNC when they work together as a nano-DMPS. Then the size of the particles is definitely mobility equivalent but the concentration data in the smallest sizes can still have some uncertainty, and thus the detection efficiency curve of the nCNC might vary according to the composition of the nano-CN. Below about 1.5nm the charger ions start to dominate the sample aerosol in a DMPS system. However with correct selection of the mixing ratio, the nCNC does not detect the charger ions, but can still have for example detection efficiency of 20% for negatively charged 1.2nm NaCl particles and 50% detection efficiency at 1.35nm. On the other hand the losses inside the sampling and DMA section might be too high at some occasions, so that scanning of the saturation ratio is the only way to get size information of the smallest particles.

Using a switchable ion filter in front of the inlet the nCNC can be used to measure the amount of charged versus neutral particles, which is interesting especially in nucleation studies. Thus by combining different applications of the nCNC it's possible to study not only the effect of charge but also the chemical composition in sub-3nm size range.

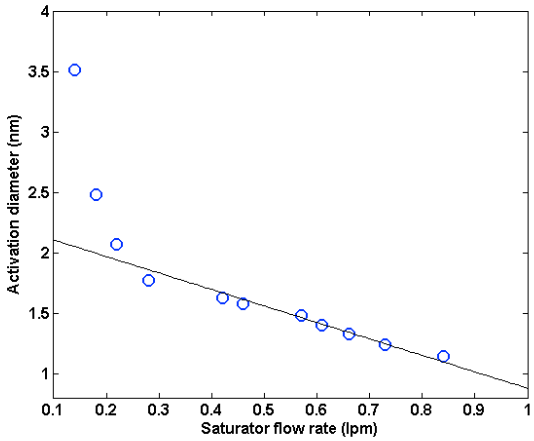

Figure 1. Activation diameter for ammonium sulphate given by 50% activation efficiency as a function saturator flow rate Q_s.

Novel continuous ambient air quality monitoring system that simultaneously reports multiple PM-fractions, number concentration and size distribution

M. Weiss, J. Spielvogel

Palas GmbH, Karlsruhe, 76229, Germany
Keywords: aerosol instrumentation, air quality network, fine particulate matter, particulate mass, particle size
Presenting author email: weiss@palas.de

Real time continuous and accurate measurements of atmospheric particles are important when complying with regulation or in the context of source apportionment; e.g in determining how much is contributed by traffic, industry or residential heating. If the time resolution is high enough it allows reliable transport modelling based on actual data. A lack of this information was causing the closure of the European air space when the Iceland volcano Eyjafjallajökull erupted in April 2010.

We will present the Fidas®, a new fine dust monitoring system based on optical light scattering. The Fidas® is equipped with a white light LED as stable light source with long lifetime and an integrated filter holder. A Sigma-2 sampling inlet (described in detail in VDI 2119-4) and intelligent aerosol drying system leads to representative sampling. The Fidas® allows the continuous recording of the particle number and particulate mass (simultaneously PM_1, $PM_{2.5}$, PM_4, PM_{10}, TSP) with a time resolution of two minutes providing the opportunity to monitor dynamic changes. Also recorded is the particle size distribution that can provide additional information for health related risk assessments.

We will report on a number of comparison measurements and compare results with other monitoring techniques. In the context of these comparisons we will also show the first results from the on-going European aptitude and equivalency test.

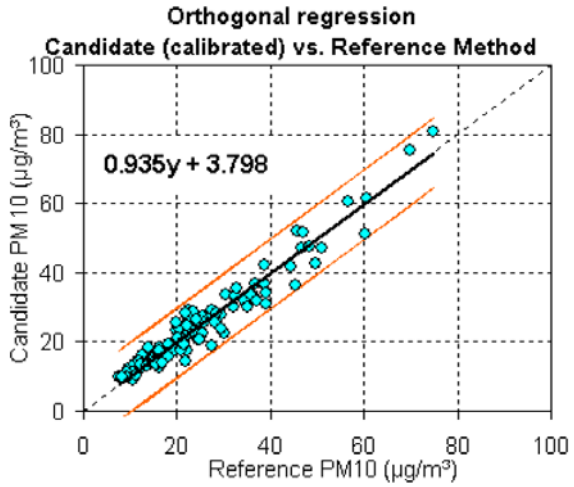

Figure 1. Orthogonal regression of the Candidate Method against the Reference Method. Confidence interval (99 %) indicated in orange.

In a second part we will show an example where the additionally provided information on particle size distribution is used to analyse special events (here in this abstract only one example is mentioned briefly).

Figure 2 shows the particulate mass and particle number distributions corresponding to before, during and after fireworks. As can be seen, the mass concentration of small particles increases significantly and is caused by a factor of 10 increase in particle number. These small particles (< 400 nm) are primarily caused by the combustion process of the rockets and explosives.

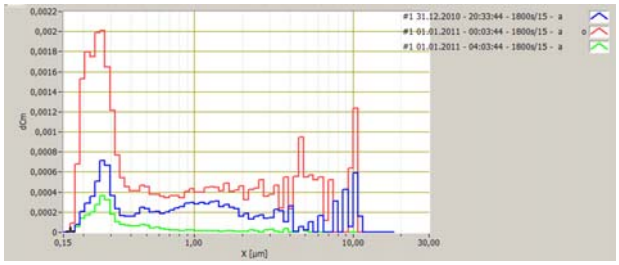

Figure 2. Particle mass distributions in mg/cm^3 before (blue), during (red) and after (green) new year 2011

Due to the implemented filter holder in the Fidas®, a gravimetric filter can be used to analyse the sample further, e.g. by chemical analysis, and to verify the optically measured data.

Direct probing of aerosol surfaces by synchrotron-radiation-based XPS

Aerosols are complex finite systems, with properties determined by the interplay between their size, structure and stoichiometry. The microscopic spatial distributions of the chemical species is important; the three aerosol particles composed of yellow and red species, schematically illustrated in fig. 1, have different radial distribution of the component species. Even with the same total composition, their properties would be different.

Fig. 1. Three different radial distributions in aerosols with the same total stoichiometric composition

Many of the compounds, both inorganic and organic, identified in atmospheric aerosol particles are from studies of macroscopic aqueous systems known to have either positive or negative surface propensity. This means that the composition of the surface will be different than in the bulk. Since the surface fraction increases with decreasing aerosol size, such surface phenomena will become increasingly important for the properties of the system, and in the small-size limit determine the properties. In contrast to macroscopic systems with a virtually infinite bulk, the finite size of microscopic aerosols means that surface segregation phenomena also will affect bulk composition. Enrichment of a species at the surface means depletion of the same species in the bulk.

We have developed a novel laboratory set-up for direct probing of the surface propensity and speciation of aerosols. As schematically shown in fig. 2, we produce aerosols in an atomizer, dry them and use an aerodynamic lens system to focus them into a beam. Further downstream, the aerosols are exposed to x-rays from a synchrotron radiation (SR) beamline, allowing core-level X-ray Photoelectron Spectroscopy (XPS), which is well-established and very successful technique to characterize solids, surfaces, molecules, clusters and liquids (Hüfner 1995). Some key advantages of XPS are that the measurement process is virtually instantaneous, meaning that the interpretation is not complicated by fragmentation upon ionization, and its chemical and surface sensitivity, implying that both the chemical state and the microscopic spatial distribution of the component species are probed. We have already used these properties of XPS to study how the surface composition of atmospherically relevant aqueous systems such as inorganic ions and carboxylic acids varies with factors such as pH, concentration and co-solvation (Ottosson N *et al* 2009, 2010, 2011, 2011).

The set-up will be taken into operation during spring 2012, and we will present the first results on how surface composition and speciation for model systems of both marine and continental aerosols vary with factors such as pH, concentration and co-solvation.

Liquid sample nanoparticle sizing system

J.E. Farnsworth[1], K. Erickson[1], B.L. Osmondson[1], and R. Caldow[1]

[1]TSI Incorporated, Shoreview, MN, 55126, USA
Keywords: nebuliser, SMPS, electrospray, nanoparticles characterization
Presenting author email: jim.farnsworth@tsi.com

Nanotechnology-based industries today require real-time and quantitative sizing of nanoparticles. Commonly, light scattering techniques such as dynamic light scattering (DLS), laser diffraction, and optical particle counting are used to size nanoparticles suspended in liquids. These techniques have limited size resolution, sensitivity, and accuracy, since results are dependent on the optical properties of the sample. This is a critical shortcoming of real-time, liquid phase sizing instrumentation.

Aerosol particle technology is an enabling discipline for these applications. By converting the sample from liquid phase to gas phase, one can take advantage of the high resolution sizing and single particle sensitivity afforded by Differential Mobility Analysis (DMA) based sizing. This paper presents two options for liquid sample particle sizing using aerosol instrumentation.

The first configuration (TSI LiquiScan NP) combines a new nanoparticle nebulizer with a Scanning Mobility Particle Sizer spectrometer (SMPS). This system configuration allows size distribution measurements to be made from 5-500 nm with higher resolution and sensitivity than can be obtained from liquid phase sizers (Figure 1), and avoids sub-100 nm residue interference issues experienced by traditional nebulizers by controlling the median droplet diameter to ~300 nm and by using ultrapure water for sample dilution (Grant and Beuscher, 2009). The nebulizer comprises a peristaltic pump for 0.3-1.5 mL/min sample introduction, 20:1-20000:1 liquid sample dilution, ultrafine nebulization under controlled temperature and pressure conditions, and an internal dryer to remove solvent from solute. The dried aerosol is pulled from the nebulizer by the SMPS at 0.6-1.5 L/min. Software is used for system control, data inversion, calibration and statistical analysis. Additionally, the nebulizer-SMPS system provides quantitative hydrosol concentrations, accomplished via calibration to a standard solution of known particle volume concentration.

The second configuration (TSI LiquiScan ES) combines an electrospray with an SMPS. The electrospray creates droplets ~150 nm median diameter with a narrow size distribution ~1.2 geometric standard deviation (σ_g). The small, uniform droplets make the system well suited to measuring small nanoparticles. Additionally, electrical mobility has shown excellent correlation to molecular mass from 4MDa to 12 MDa (Allmaier et al, 2008) for large molecules (macromolecules such as proteins or lipids). Therefore using the electrospray/SMPS system, data distributions can be displayed as particle diameter or molecular mass (using a correlation constant). Software is used for data inversion and analyses.

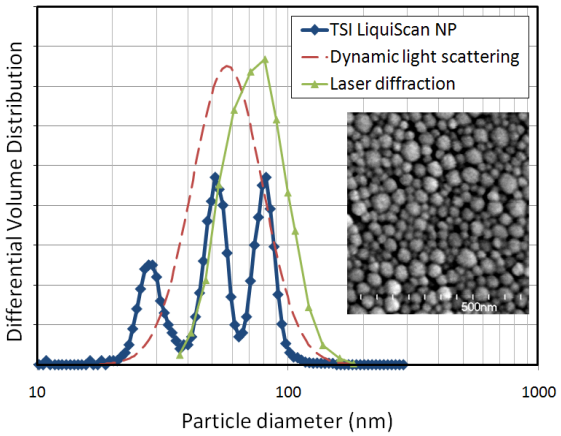

Figure 1. Size distribution data of a tri-modal polishing slurry measured via 1) nanoparticle nebulizer/SMPS, 2) Dynamic Light Scatter (DLS) and 3) Laser Diffraction. A SEM micrograph of the slurry is shown as a reference. As can be seen, the nanoparticle nebulizer/SMPS is able to resolve all three modes of the slurry, while the two optical techniques indicate only a mean diameter.

Liquid sizing via aerosol technology has proven useful for a wide array of applications such as nanoparticle size characterization, colloidal solution kinetic investigations, nanoparticle coating evaluation, characterization of chemical mechanical planarization (CMP) slurries (Figure 1), water purity investigations, particle retention of liquid filters, macromolecule characterization, and virus identification.

Data from both system configurations is presented. Advantages and disadvantages of each technique are discussed.

Approximate relationship between mobility and voltage for Brownian particles in a cylindrical DMA

M. Alonso[1], F.J. Alguacil[1] and C.H. Huang[2]

[1]National Center for Metallurgical Research (CENIM-CSIC). Gregorio del Amo, 8. 28040 Madrid, Spain
[2]Department of Environmental Engineering and Health, Yuanpei University, 30015 Hsinchu, Taiwan

Keywords: DMA, Brownian diffusion, central mobility, applied voltage
Presenting author email: malonso@cenim.csic.es

In the case of non-diffusing particles, the relationship between mobility and voltage in a concentric cylindrical DMA is given by the well known expression $Z = Q_c \ln(R_2/R_1)/2\pi LV$ for balanced flows (aerosol = classified; sheath = excess). When particle diffusion can not be neglected, the mobility of the classified aerosol is a bit smaller. An approximate expression for a more correct relationship between *Z* and *V* will be given here.

Consider a Brownian particle moving in the radial direction, starting from a given point R_i, and let us determine the mean time $\tau(r)$ required for a particle placed at *r* to reach a specified location R_f for the first time. This definition implies that, obviously, $\tau(R_f) = 0$. During a time interval Δt, the particle travels a deterministic distance $ZE\Delta t$ and also suffers a superimposed random displacement which, for simplicity, will be considered of constant length Δr and equal probabilities in both the positive and negative radial directions. For the particle to be at *r* at time *t* it is necessary that, at an earlier time $t - \Delta t$, it was at either $r_1 = r - ZE\Delta t + \Delta r$ or $r_2 = r - ZE\Delta t - \Delta r$. Therefore,

$$\tau(r) = \Delta t + \tfrac{1}{2}\left[\tau(r - ZE\Delta t + \Delta r) + \tau(r - ZE\Delta t - \Delta r)\right].$$

Expanding in Taylor's series up to second order, dividing through by Δt and taking the limit $\Delta t \to 0$ yields

$$\beta \frac{d^2\tau}{dr^2} - 2ZE\frac{d\tau}{dr} + 2 = 0, \qquad (1)$$

where

$$\beta = \lim_{\Delta t \to 0} \frac{\Delta^2 r}{\Delta t} = 2D\left[1 + h(r)\right]. \qquad (2)$$

In the last expression, *D* is the particle diffusion coefficient, and $h(r)$ takes into account the non uniformity of the electric field, $E = -V/r\ln(R_2/R_1)$. For the conventional cylindrical DMA, where the particles travel toward the inner electrode, $h(r) > 1$, so that the "effective" diffusion coefficient is larger than *D*. Since no analytical expression is available for the function $h(r)$, we will take, as a first approximation, $h(r) = 0$ thus assuming that the particle spreading rate occurs as if the field were uniform (or as if there were no field at all acting on the particle).

With this approximation, the solution of (1) with boundary condition $\tau(R_f) = 0$ is

$$\tau(r) = \frac{r^2 - R_f^2}{2\left[D + VZ/\ln(R_2/R_1)\right]}. \qquad (3)$$

The particle of central mobility enters the DMA at position $r = R_i$, where

$$R_i^2 - R_f^2 = Q_c/\pi\bar{u}. \qquad (4)$$

In the last equation, Q_c is the sheath air flow rate, and $\bar{u}$ the mean axial flow velocity. Equation (3) for the particle of central mobility can be written as

$$\frac{L}{\bar{u}} = \frac{R_i^2 - R_f^2}{2\left[D + VZ_c/\ln(R_2/R_1)\right]}. \qquad (5)$$

From expressions (4) and (5) we arrive at the approximate equation relating central mobility and applied voltage:

$$Z_c = \frac{Q_c \ln(R_2/R_1)}{2\pi LV} - \frac{D}{V}\ln(R_2/R_1). \qquad (6)$$

The first term in the r.h.s. of (6) is the classical expression for non diffusing particles, and the last one is the approximate correction accounting for the effect of diffusion. Finally, using the relation $D = kTZ_c/pe$, where *kT* is twice the thermal energy of the particle and *pe* its charge, one finds

$$Z_c = \frac{Z_{c,nd}}{1 + \dfrac{kT}{peV}\ln\dfrac{R_2}{R_1}}, \qquad (7)$$

where the subscript *nd* refeers to no diffusion. For a typical DMA with electrode radii R_1 = 0.937 cm and R_2 = 1.958 cm, the $Z_c/Z_{c,nd}$ ratios are 0.9817, 0.9981 and 0.9998 for applied voltages of 1, 10 and 100 volts, respectively. The differences are thus very small, but it must be noted that these figures have been obtained using the approximate equation (7), derived from the assumption that the function *h*(*r*) in (2) is zero. As said before, *h*(*r*) is actually larger than unit for the cylindrical DMA, that is $\beta > 2D$ and, furthermore, since β depends on *r*, the solution of (1) is not (3). In the absence of an analytical expression for *h*(*r*), the actual values of $Z_c/Z_{c,nd}$ will be determined by computer simulations.

Evaluation of Size Selective PM_{10} Sampling Inlets in Aerosol Wind Tunnel

Sangil Lee*, Miae Yu, Hyun Ho Kim
Center for Gas Analysis, Division of Metrology for Quality of Life, Korea Research Institute of Standards and Science, 305-340, Republic of Korea
Corresponding to Sangil Lee (slee@kriss.re.kr)

Size selective particulate matter (PM) sampling inlets play an important role in PM measurement system. Improper designs of the sampling inlets result in collecting PM in undesired size, leading to significant errors in the measurement of PM mass concentrations. Therefore, the performance of PM inlets should be carefully evaluated in a proper environment prior to their field application.

In this study, a new aerosol wind tunnel system is designed and evaluated for the uniformity of wind speed distribution and aerosol concentration in the test section of the aerosol wind tunnel. Results for the wind speed distribution show that the deviation from the mean (DOM) at three different wind speeds is less than 10 % with turbulence intensity less than 5 %. Results for the aerosol concentrations show that DOM at three different wind speeds is less than 10 %. A PM_{10} sampling inlet is designed according to the U.S. Environmental Protection Agency (40 CFR Part 53 Appendix L) and its performance is evaluated in the newly developed aerosol wind tunnel. Results show that the PM_{10} inlet is characterized to meet the performance specifications for PM_{10} inlets in the 40 CFR Part 53.

Enhanced multiple charge inversion algorithm for mobility size spectrometers

S. Pfeifer[1], T. Müller[1] and A. Wiedensohler[1]

[1]Leibniz Institute for Tropospheric Research, Leipzig, 04318, Germany
Keywords: Charged particles, DMA, SMPS, DMPS, Coarse particles, Size distribution
Presenting author email: pfeifer@tropos.de

Differential or scanning mobility size spectrometer (DMPS/SMPS) are often used to measure the particle number size distribution in the sub-micron range. Due to the measuring principle, particles are classified by their size to charge ratio. To obtain a “true” size distribution with the particles diameter as the independent variable, an inversion algorithm to account for single and multiple charged particles is used

Many inversion algorithms are operating with explicit interpolation and discretization of the particle number size distribution (PNSD). This numerical step is an unnecessary calculation and a reduction of physical information content of the raw data. Furthermore, possible multiply charged particles in the largest size bins as well as possible aerodynamic shape factors are often ignored. We present a new algorithm without these mentioned limitations.

improvements of the new algorithm:

- based on operation with the measured grid points of the continuous PNSD, therefore an explicit interpolation and integration isn't necessary
- the algorithm only consists of an inversion of a clever occupied matrix, therefore it is a strict linear problem with the potential to transform the variance of the counting statistics of the raw data for the inverted size distribution
- the algorithm is able to consider an aerodynamic shape factor for the particles, both a linear value and a dynamic course over the whole range of the size distribution
- we can also consider multiply charged particles in the upper range of the DMPS/SMPS for the inversion using information of an additional size distribution for larger particles, e.g. aerodynamic particle sizer (APS) or optical particle sizer (OPC)

Results

The new multiply charge inversion algorithm was compared to other codes in Wiedensohler et al (2011). A good agreement over the whole size range with deviations smaller than 5% was found.

Figure 1 shows the necessity for using information from other instruments to simulate the multiple charged distribution for larger size bins of the SMPS. The data of that example were measured with a SMPS and an APS at the Cap Verde Islands during an event with high Saharan dust concentrations. We used a density of 2.5 g/cm³ and an aerodynamic shape factor of 1.2 to describe the mineral particles. Ignoring the multiply charged particles in the upper SMPS bins leads to erroneous results and even to negative concentrations.

In contrast to this, the result of enhanced multiply charge inversion is much smoother without these implausible peaks. There are no negative concentrations and the SMPS and the APS data fits together in the overlap range.

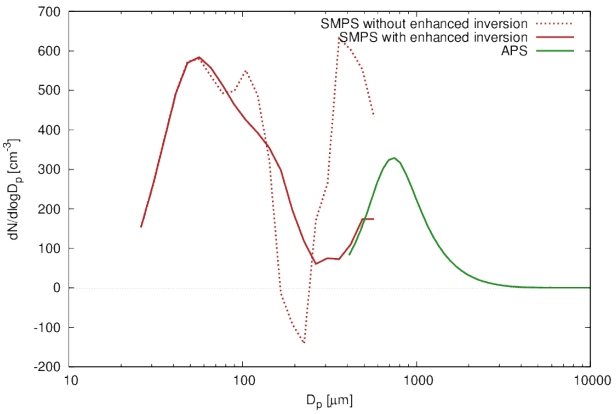

Figure 1. Comparison between the results without and with the enhanced multiply charge inversion algorithm using additional information from coarse mode size distribution measured with an APS.

There are still few open questions and limitations. We used the approximation by Wiedensohler (1988) for the charge probability distribution, with its upper limit for the particle size of 1µm. Although a mathematical deconvolution of the DMA transfer function has a negligibly influence for measurements under natural conditions, it would be useful for laboratory condition, e.g. for calibrations purpose using particle with a narrow size distribution, e.g. PSL spheres.

The occurrence of Saharan dust intrusions over the Iberian Peninsula is well known. This work characterizes the thermodynamic atmospheric conditions prevailing during the CLIMARENO campaign carried out in June 2011. This campaign combined remote sensing and aero-transported instrumentation aiming to measure atmospheric variables in the presence and absence of a Saharan dust outbreak.

Measurements were taken at two sites in South Spain: "El Arenosillo" (37.1N, 6.7W in Huelva) and CEAMA (37.2N, 3.6W in Granada). Selected dates for the campaign were chosen based on an atmospheric dust alert system using information from different models (BSC/Dream, UoA/SKIRON and NRL/NAAPS). Dates 13 and 14 June 2011 were representative of no atmospheric dust while 26 and 27 June 2011 were representative of Saharan dust intrusion.

The characterization of the air masses was done by the use of a new and recently acquired CAPS atmospheric probe (Droplet Measurements Technology, Boulder, CO). The CAPS probe measures temperature, pressure, relative humidity, aerosols (0.5-50 mμ) and other miscellaneous data. This probe was installed on the CASA C-212 aircraft, instrumented for airborne atmospheric measurements and owned by the "Instituto Nacional de Técnica Aerospacial" (INTA). Additionally, radio sondes were launched from "El Arenosillo" Atmospheric Sounding Station, and humidity and temperature profiles from a ground-based passive microwave radiometer (RPG-HATPRO, Germany) were used at Granada.

Two distinct conditions were clearly identified due to the presence or absence of Saharan dust at both sites. The sample collection was made during the ascendant profiles of the C-212 aircraft. Atmospheric profiles, with or without Saharan dust, were characterized for temperature, relative humidity and aerosols. Data from the CAPS probe were compared with a radio sonde (Huelva) and the passive microwave radiometer (Granada). Temperature profiles showed higher gradient on days with intrusion (average 7º per 1000 m) compared to no-intrusion (average 5º per 1000 m) at both sites. Moreover, the temperature gradient increases further from around 1800 m asl on day without intrusion. It is noteworthy that the temperature profiles have better agreement at lower altitudes but the discrepancies at higher altitudes are close to the error limits.

The number of aerosol particles measured by the CAPS probe is low for both scenarios due to the relatively high lower limit of the probe in relation with the type of aerosol present in the atmosphere during these days. On the dates without intrusion there were traces of particles (fire smoke from North America) at high altitudes (around 6000 m asl) when a completely clear profile was expected. Figure 1 shows particles and temperature profiles during the campaign at both sites.

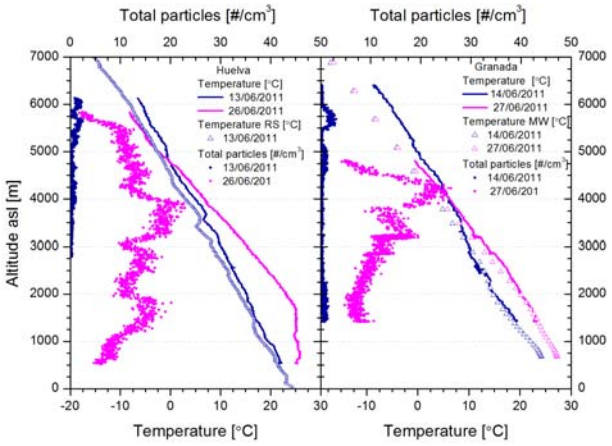

Figure 1: Temperature and total number of particles profiles during the CLIMARENO campaign. The left hand side shows details for Huelva and the right hand side for Granada. Temperature from both the CAPS and the radio sonde (RS) at Huelva as well as temperature from the CAPS and the passive microwave radiometer (MW) at Granada are also shown.

The authors of this study are grateful to the CLAEX unit of the Spanish Air Force for operating the C-212.

Aerosol experiments large chambers like CLOUD motivate the gathering of several different measurement instruments during special data taking periods. The cloud team has developed an integrated data acquisition and control system that address the challenges of online monitoring and data plotting while providing a centralized data repository with unified tools for data access and visualization.

The system is optimized for rapid instrument integration and flexible data format processing. It was developed using several open architecture components including a computing cluster monitoring and a open database management system.

Supervisory control and data acquisition (SCADA) systems have been around for long time with the traditional hardware being increasingly replaced by software components. While industrial systems use mainly PLC controllers or Real Time Systems according to the performance requirements, laboratory equipment and control systems have seen in recent years a predominance of LabView based systems from National Instruments. During the last decade with the CERN LHC development a common effort between the LHC control and the experiments resulted in the use a common framework that was chosen to be PVSS from ETH. The described systems are proprietary, tend to behave as complete independent frameworks and are strictly incompatible in terms of modular development.

The CLOUD monitoring and control implementation has in fact delivered a high performance scada system, much like PVSS, but based on an open source system: ZABBIX (www.zabbix.com). Some trigger programs were made to connect the ZABBIX interfaces with the instruments. Specific patches were applied to zabbix to include an advanced scientific plotting capabilities.

Alongside with the low level components of the CLOUD DAQ integration toolkit, that includes open sources components, Zabbix extensions for monitoring and control, web based configuration toolkit for Mysql database tables and partitions, tuned for aerosol instrument data and a modular data access API, a high level gui interface was developed for data retrieval, data visualization and basic aerosol data analysis.

The Cloud data retrieval GUI interface is a Qt based application that directly interfaces with the central databases and it is designed to allow the development to became a general application for atmospheric aerosol analysis.

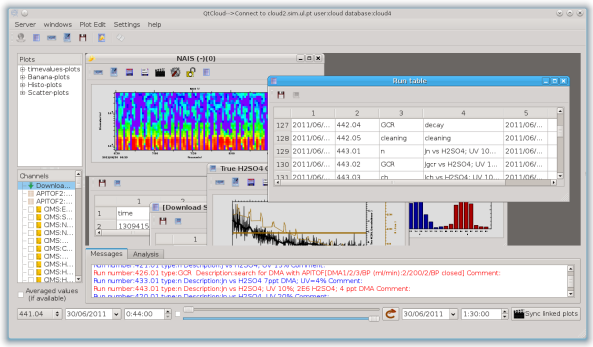

Figure 1. Screenshot of the Cloud Gui tool for data retrieval and data visualization. This is a comparison between theory and experimental data.

The developed CLOUD DAQ toolkit is released under GPL public license and is freely available. It was developed with the aim of making it easy to be used in any type of aerosol experiment that brings together several instruments.

In order to find the relationships between cloud properties and different meteorological parameters and aerosols we need reliable measurements on cloud droplet concentration. One of the instruments that can be used to measure cloud droplet concentration is Cloud Droplet Probe (CDP) manufactured by Droplet Measurement Technologies, Inc., Boulder, CO, USA.

Cloud droplet measurements can be subject to a wide variety of instrument biases, uncertainties and limitations (Lance at al., 2010). These biasing factors cause additional uncertainties in further analysis of the measurement data, e.g. computing the liquid water content or finding correlations between cloud droplet concentrations and the factors assumed to influence into the cloud formation. Our main goal is to find the factors affecting to the cloud droplet concentration and thus we have to reduce the bias of the measurements.

The cloud droplet measurements were made in Puijo measurement station in the town of Kuopio in central Finland. The station is located on the top of an observation tower (306 m a.s.l.) and the station is detected to be in-cloud approximately 15% of the time. The station has produced continuous data on aerosol cloud interactions since June 2006 (Portin et al., 2009). An intensive measurement period was conducted between 14 October and 7 March 2009. Within this period the CDP was measuring concentrations in 1Hz frequency and in total 16 cloud event days were detected.

Lance et al. (2010) found out that the CDP underestimates high cloud droplet concentrations due to coincidence, when two or more droplets pass through the CDP laser beam within a very short time. In addition our results indicate that measured cloud droplet concentration time series contains random bias, which affects the interpretation of the time series.

The method used in reducing the bias in the measured data is called “Time series decomposition using eigenvector filtering” (EVF). The eigenvector filtering decomposes the signal by applying a principal component analysis (PCA) on the original signal and a certain number of copies of it incrementally lagged, collected in a multivariate matrix. Reconstructing the signal using only the most representative eigenvectors allows filtering it (Ibanez and Grosjean, 2009).

Figure 1 shows a 30 minute sequence of a measured time series within a cloud event which took place in March 6th 2009. The original measured time series in presented in the top panel, the filtered time series is in the middle and the residual time series, presenting the random bias, is shown in the lowest panel. The results indicate that the bias in a single observation may be as high as 50% of the measured cloud droplet concentration. The average bias of the measurements was around 10%.

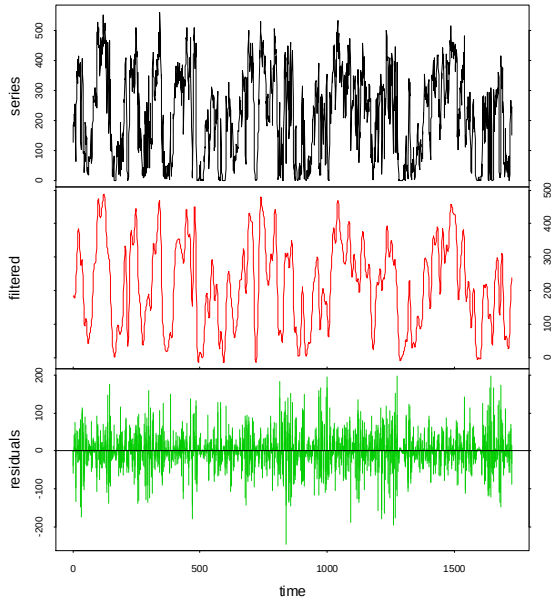

Figure 1. Original series in topmost panel, filtered series in the middle and the residual series in the bottom panel.

Proper filtering of the time series was found to increase the correlations between cloud droplet concentration and meteorological parameters suggested to influence in the cloud droplet concentration (e.g. wind conditions). The residual time series was found to be uncorrelated with these other parameters, which indicates that no information was lost in the filtering but all the information contained in the measured time series was passed to the filtered series. This indicates that the filtered time series can be used for example studying the effect of aerosol particles on the cloud formation.

The Academy of Finland Center of Excellence program (project number 1118615) is acknowledged.

Off-line organic aerosol analyses of filter samples using aerosol mass spectrometry

I. El Haddad[1], J. Slowik[1], U. Baltensperger[1], A.S.H. Prévôt[1]

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, Villigen, Switzerland

Keywords: Source apportionment, innovative analysis method

Presenting author email: andre.prevot@psi.ch

Organic aerosol (OA), emitted directly from primary sources (primary OA, POA) or formed in-situ in the atmosphere from the oxidation of trace gas precursors (secondary OA, SOA), makes up a major component of submicrometer particulate matter (PM). Development of effective air quality control strategies intended to mitigate adverse effects is hampered without an accurate knowledge of the main sources and evolution processes of OA.

Field deployments of the Aerodyne Aerosol Mass Spectrometer (AMS) in the last years have advanced the real-time measurement of PM. Statistical methods like positive matrix factorization and multi-linear engine 2 applied on OA spectra demonstrate that these contain sufficient information to differentiate several OA sources and/or components (e.g. Lanz et al., 2010). These components include primary emissions from traffic, biomass burning, cooking and oxygenated OOAs interpreted to be mostly secondary. The high cost of the AMS and the complexity of its deployment in certain environments greatly limit the spatial coverage of AMS measurements and make the collection of long-term, continuous datasets not easily achievable. Recently, a new, moderately expensive, aerosol chemical speciation monitor (ACSM) was developed to overcome these shortcomings. However, the low mass resolution of this instrument prevents the assessment of OA elemental ratios and hence the assessment of the oxidation state.

These limitations motivated us to explore the application of laboratory AMS measurements on aerosol filter samples. Such samples are relatively easy and inexpensive to collect and store, and are already routinely collected at many air quality stations worldwide. In the meantime, Mihara and Mochida (2011) have described a similar method as used here.

The approach consists of water or organic solvent extraction of the particulate matter from the filter samples (here quartz Pall filters) and subsequent atomization of resulting solutions into the AMS. Using only water, we found typically an extraction efficiency of about 70%.

The obtained mass spectra from the off-line analyses were compared to average mass spectra taken from on-line mass spectrometer measurements. We found very similar mass spectra (Fig. 1), with correlation coefficients (R^2) higher than 97% (Fig. 2). These comparisons were done for both summer and winter samples. Both online and offline methods show for instance higher contributions from m/z related to biomass burning organic aerosol (e.g. m/z 60, 73) and hydrocarbon-like organic aerosol (e.g. m/z55, 57, 69) for the winter sample and higher contributions from OOA-related m/z ratios (e.g. m/z 43, 44) for the summer samples.

Further, we will present the first application of this method on filter samples collected at different stations in Switzerland with different exposure characteristics. Source apportionment results using these data will be discussed.

ACTRIS Research Infrastructure for coordinated long-term observation of aerosols, cloud-aerosol interactions, and trace gases in Europe

Gelsomina Pappalardo[1] and Paolo Laj[2]

[1]Consiglio Nazionale delle Ricerche-Istituto di Metodologie per l'Analisi Ambientale (CNR-IMAA), Tito Scalo, Potenza, Italy

Keywords: in-situ measurements, lidar, remote sensing
Presenting author email: pappalardo@imaa.cnr.it

Climate change is for a large part governed by atmospheric processes, in particular the interaction between radiation and atmospheric components (e.g. aerosols, clouds, greenhouse, and trace gases). Some of these components are also those with adverse health effects influencing air quality. Strengthening the ground-based component of the Earth Observing System for these key atmospheric variables has been unambiguously asserted in the IPCC Fourth Assessment Report and Thematic Strategy on air pollution of the EU. However, a coordinated research infrastructure for these observations is presently lacking.

ACTRIS (Aerosols, Clouds and Trace gases Research InfraStructure Network) aims to fill this observational gap through the coordination of European ground-based network of stations equipped with advanced atmospheric probing instrumentation for aerosols, clouds and short-lived gas-phase species (Figure 1). ACTRIS will have the essential role to support building of new knowledge as well as policy issues on climate change, air quality and long-range transport of pollutants.

The main objectives of ACTRIS are:

- To provide long-term observational data relevant to climate and air quality research on the regional scale produced with standardized or comparable procedures throughout the network.
- To provide a coordinated framework to support trans-national access to large infrastructures strengthening high-quality collaboration in and outside the EU and access to high-quality information and services for the user communities (research, Environmental protection agencies, etc.).
- To develop new integration tools to fully exploit the use of multiple atmospheric techniques at ground-based stations, in particular for the calibration/validation/integration of satellite sensors and for the improvement of the parameterizations used in global and regional-scale climate and air quality models.
- To enhance training of new scientists and new users in particular students, young scientists, and scientists from eastern European and non-EU developing countries in the field of atmospheric observation.
- To promote development of new technologies for atmospheric observation of aerosols, clouds and trace gases through close partnership with EU SMEs.

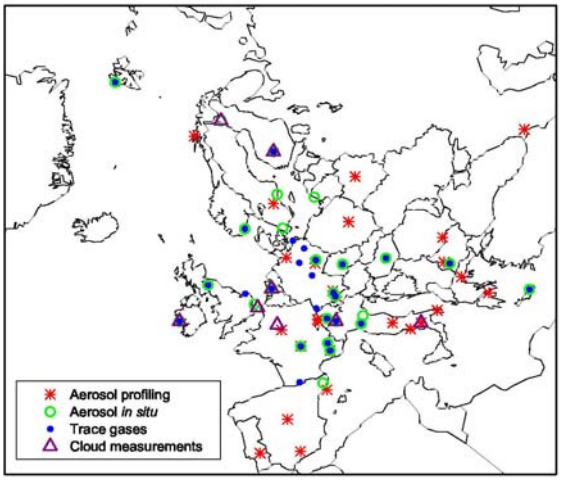

Figure1. Map of measurement sites contributing to ACTRIS.

A key for ACTRIS success is to build a new research infrastructure on the basis of a consortium joining existing networks/observatories that are already providing consistent datasets of observations and that are performed using state-of-the-art measurement technology and data processing. In particular the ACTRIS consortium merge two existing research infrastructures funded by the European Commission under FP6: EUSAAR (European Supersites for Atmospheric Aerosol Research) and EARLINET (European Aerosol Research Lidar Network). ACTRIS also includes the distributed infrastructure on aerosol – cloud interaction existing from a previous EU Research project CLOUDNET and by grouping the existing EU ground-based monitoring capacity for short-lived trace gases which is, at present, not coordinated at any level, besides EMEP (European Monitoring and Evaluation Programme) and GAW (Global Atmosphere Watch) caring for a few specific compounds. Therefore, ACTRIS represents an unprecedented effort towards integration of a distributed network of ground-based stations, covering most climatic regions of Europe, and responding to a strong demand from the atmospheric

research community. ACTRIS will be a step towards better integration of aerosol, cloud and trace gases communities in Europe necessary to match the integration of high-quality long-term observations of aerosol, clouds and short-lived gas-phase species and for assessing their impact on climate and environment. ACTRIS outcomes will be used for supporting decisions in a wide range of policy areas, including air quality but also health, international protocols and research requirements.

ACTRIS is organized in Networking Activities, Transnational Access and Service Activities, and Joint Research Activities as reported in Figure 2.

The data provision structure in ACTRIS involves four networking activities (NAs) that will feed the data centre:
WP2: Remote sensing of vertical aerosol distribution
WP3: In-situ chemical, physical and optical properties of aerosols
WP4: Trace gases networking: Volatile organic carbon and nitrogen oxides
WP5: Clouds and aerosol quality-controlled observations

These networking activities are completed by a fifth networking activity aimed at integrating information from *WP2-5* into a higher level of products required by users in the modelling and satellite-validation communities: *WP6: Integration, outreach, and sustainability.*

The activities of the research infrastructure will be oriented to a rigorous quality assurance program addressing both instruments and evaluation algorithms, and a standardized data exchange format. ACTRIS will also found and strongly sustain effective partnership between users and data providers and will pursue innovative initiatives to address the need of users. Moreover, standardization of procedures for the different measurement techniques and best practices across all stations and all European climatic regimes are paramount to facilitate the coordinated expansion of the network in a sustainable and efficient way.

Transnational access activities and service activities will enable users to conduct high-quality research by:

- Offering access to infrastructures with an excellent combination of instruments and expertise. This gives the opportunity to perform experiments using the state-of-art equipment in atmospheric research which could be used for measurement campaigns or instrument tests (*WP7-17*: *Trans-National Access*).

- Training a new generation of scientists. ACTRIS activities are aimed at enhancing the accessibility to the observatories and the exploitation of technical resources and knowledge. This is organized through *WP6* and *WP7-17*.

- Offering to the whole scientific community the use of a unique sun photometer calibration facility currently operational in the frame of PHOTONS/AERONET. This is performed in WP18: AERONET-EUROPE Calibration Service.

- Enhancing access to information on advanced aerosols, clouds and trace gases high-quality data in Europe through a Service Activity (*WP19: The ACTRIS Service Centre: Access to observations and service products of the infrastructure). The data centre* integrates measurement data from the ACTRIS infrastructure and other highly relevant networks. In addition to free access to atmospheric high-quality data, the data centre will provide tools and applications for end users to facilitate the use of all measurements for broad user communities, offer a direct interface towards external users (e.g., MACC, GMES in-situ), and take into account the principles outlined in SEIS, INSPIRE, WIS and GEOSS.

Joint research activities are intended to support and promote the ACTRIS infrastructure by taking advantage of the synergistic effects of coordinating different observation capabilities. WP20 and WP22 address novel techniques and algorithms using a multi-sensor approach to improve observation performances and define new data products. WP21 focuses on investigating technological and methodological aspects of simultaneously networking real-time chemical composition of aerosols and trace gases. These JRAs are topically connected with networking activities and in cooperation with WP6 to ensure their results are assimilated for the whole ACTRIS infrastructure benefit.

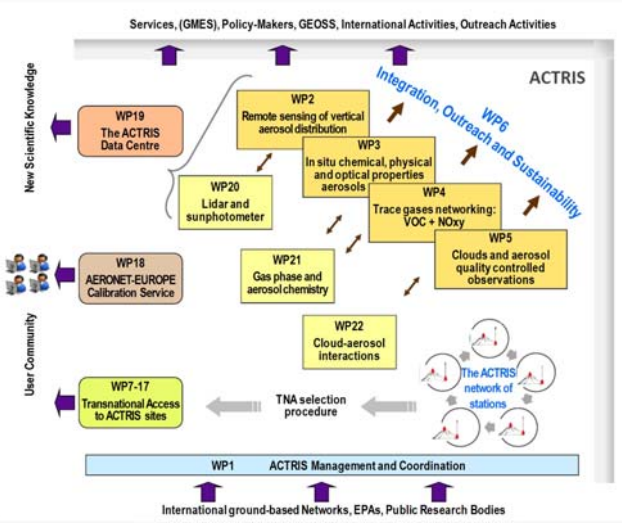

Figure 2. Interdependence of activities and tasks within ACTRIS.

At international level ACTRIS operates in strong cooperation with the Global Atmospheric Watch Program of the WMO, the ARM Climate Research Program and all the relevant research networks as (i.e. AERONET, GALION, NDACC, etc.) for the establishment of the ground-based component of the Global Earth Observation System of Systems.

ACTRIS is supported by the the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 262254.

Keywords: Long term trends, number concentration, GAW stations
Presenting author email: ari.asmi@helsinki.fi

Aerosol number concentration (CN) measurements provide a unique view of the sources of ultrafine particles and on the processes affecting aerosol indirect effects in the climate system. CN trends can thus provide information of changes in aerosol and aerosol precursor emissions, give opportunity to test aerosol model ability to produce realistic changes in aerosol concentrations on decadal time scales and provide important insight into the uncertainties related to indirect aerosol climate effects.

The global network of long-term aerosol number concentration measurements is concentrated in the northern hemisphere, especially in Europe and North America (Figure 1). The longest continuous time series of aerosol number concentrations start in the late 1970s, with the majority starting in the 2000s. Long-term aerosol size distribution measurements series are scarcer, with all long period (over 10 years of data) measurements done in or near Europe. Most of the stations are involved in the Global Atmospheric Watch (GAW) partnership.

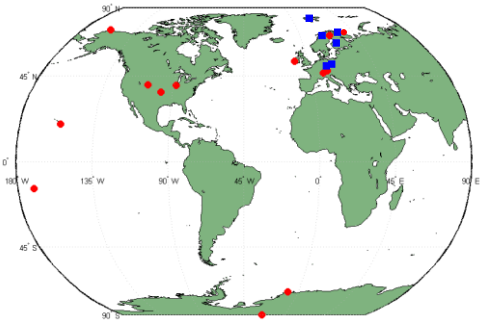

Figure 1: Locations of stations with long-term (>10 years of data) of aerosol number concentration (red circles) and aerosol size distribution (blue squares).

High variability of aerosol number concentrations creates additional challenges for trend detection, especially for significance testing (see the accompanying abstract by Collaud Coen, *et al.*, 2012). The trend analyses of aerosol optical properties and number size distributions are done with the same methodology, taking into account instrumental differences.

Figure 2 shows an example of aerosol number concentration trends in the 100-500 nm diameter range indicative of cloud condensation nuclei (CCN), measured at Värriö in Northern Europe. The CCN-sized particles exhibit a downward trend, likely connected to decreases of SO_2 emissions in Europe. The decreasing trend is steeper during summer, suggesting that a decrease of secondary aerosol formation could be a significant factor in this process. This is in agreement with earlier studies showing significant reduction in the occurrence of new particle formation in central Europe resulting from a decrease in anthropogenic SO_2 emissions (Hamed et al., 2010). This kind of trend analysis illuminates possible adverse climate side effects of air pollution control policies in the past and in the future (Makkonen et al., 2012).

Collecting the available measurements together and analyzing them in a consistent way will give a comprehensive view of decadal variability of aerosol number concentrations. Together with aerosol optical properties (Collaud Coen et al., 2012), these results provide a previously unavailable spatial and temporal description of aerosol variability in a changing climate.

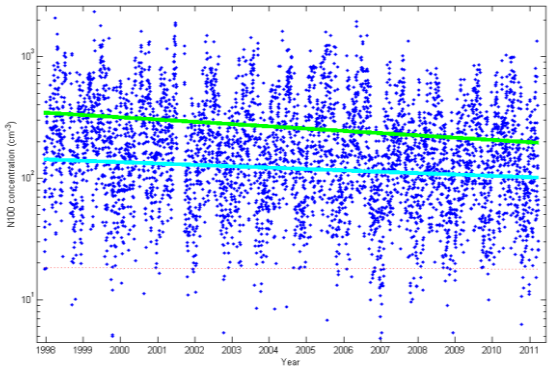

Figure 2: Particle number concentrations between 100 and 500 nm of diameter (N_{100}) at Värriö (preliminary data), showing summertime decreasing N_{100} trend of approximately 4%/year in summer time (green line) and smaller decreasing trend (~2 %/year) in wintertime.

Presenting author email: martine.collaud@meteoswiss.ch

Since the 1970s, aerosols have been considered as an important atmospheric parameter and operational measurements first began at several locations including the South Pole, Mauna Loa, Point Barrow [*Bodhaine, 1983*], Cape Grim and Mace Head [*Junker et al.*, 2006]. Awareness of the impact of aerosols on climate radiative forcing led to the extension of measured variables and to an increase of measurement sites in the 1990s. Currently many stations include measurements of aerosol physical and optical properties, resulting in more than 30 long-term aerosol measurement sites on five continents. Most of these sites measure the aerosol number concentration, the wavelength dependent scattering and backscattering coefficients and the absorption coefficients. The existence of these long-term datasets enables the analysis of trends in aerosol optical properties as described here.

Since the aerosol variables are approximately lognormally distributed, a non-parametric trend test and slope estimator, the seasonal Mann-Kendall test and the Sen's slope estimator, were applied to detect the long-term trends and their magnitudes for each month. The global trend was also estimated by a least-mean square (LMS) fit of the data logarithms [*Collaud Coen et al., 2007*, and references therein]. With these statistical tools, a global picture of the aerosol long-term variability can be obtained.

To allow a comparison among measurement sites with varying length of data records, trends of 5, 10 and 15 years periods are calculated. As an example, Figure 1 presents the Mann-Kendall monthly trends for the light scattering coefficient at the mountaintop sites Jungfraujoch (JFJ, 1995-2010) and Mauna Loa (MLO, 2000-2011) research stations. Over these time periods the two datasets do not contain significant break points. The 5-year trend slopes have a very high variability in comparison with longer time periods, which can lead to statistically significant but unrealistic trends of more than 20% per year. The longer periods (10 and 15 years) lead to smaller and more consistent trends.

The 2001-2010 and 1996-2010 trends of the scattering coefficient at the JFJ are consistent, with a statistically positive trend in April and negative trends in June and August. The JFJ LMS trend analysis shows no statistically significant trends for the considered periods. Compared to the former 1995-2004 analysis [*Collaud Coen et al., 2007*], the negative summer trends become statistically significant, whereas the positive fall trends are no more statistically significant.

The MLO scattering coefficient has statistically significant positive trends for most months, but particularly for October to April. The yearly trend can be considered as homogeneous with a positive slope of 3.8%/yr. This is confirmed by the LMS analysis which shows a statistically significant positive trend of 3.3%/yr for the 2000-2010 period.

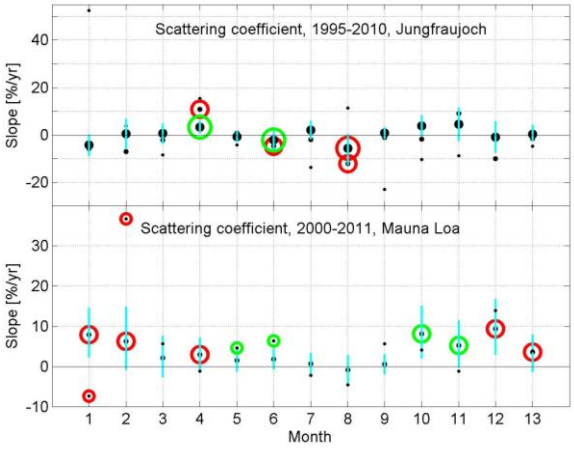

Figure 1: Long-term trends of the scattering coefficient at λ=450 nm at the JFJ and at MLO. Black dots correspond to Sen's slopes, cyan bars to their confidence limits and red and green circles to statistically significant Mann-Kendall trends at 95% and 90% confidence intervals, respectively. The size of the dots and circles is proportional to the length of the analyzed periods (5, 10 and 15 years).

An accurate estimate of the atmospheric aerosol direct effect on radiation is very important for the evaluation of the particle effect on climate. In particular, aerosol absorption contributes to the atmospheric warming and its quantification is still affected by high uncertainties. The principal light absorbing component is soot heating the atmosphere and thus playing an important role in the global climate system. The calculation of its radiative forcing strongly depends on absorption which in turn is a function of the spatial-temporal distribution of the aerosol mass, as well as the vertical distribution and the used radiative transfer scheme (Stier *et al*. 2007).

The aim of this work is to use *in-situ* measurements collected at European ground stations in the framework of the EU EUSAAR and ACTRIS projects to assess surface modeled concentrations and absorption coefficients from the global aerosol models participating in the AeroCom aerosol model inter-comparison (http://aerocom.met.no/Welcome.html). This is done using long-term elemental carbon (EC, as proxy for soot) concentrations and absorption coefficient measurements collected during 2008-2010 in the network of stations. The inter-comparison studies of instrumentations used for EC concentrations and absorption coefficient measurements allow determining uncertainties in the data sets in a homogeneous way (Müller *et al*., 2011).

The absorption coefficients were measured using MAAPs, aethalometers and PSAPs. Modeled absorption coefficients are given at 550 nm, therefore MAAP values (at 637 nm) had to be corrected for wavelength.

A preliminary comparison of model results to measurements shows a tendency of the models to overestimate EC concentrations in the remote stations in North Europe as well as in the more continental sites. The only exception is Ispra, a site at the edge of the polluted Po Valley (Italy) where the models do not capture the high concentrations in winter, most probably due to a wrong meteorological characterization in the models for this site. This European analysis confirms an evaluation of modelled black carbon prediction at global scale using previous versions of these models (Koch *et al*, 2009).

A novelty of this work is the evaluation of the schemes used in the models to compute the optical properties; it is done by looking at the ratio between the absorption coefficient and EC concentrations at the site were both are available, thus separating the model capability in predicting mass concentrations from the ability to calculate the absorption. The EUSAAR-ACTRIS dataset (available at http://ebas.nilu.no) is a unique collection that allows such an analysis with eight stations where this evaluation can be done. In Figure 1 some model results (green lines with symbols) are shown with the ratio observed in Ispra (blue line) for different seasons. The measured ratio has a seasonal variation with a maximum in summer. The models predict lower ratios up to a difference of a factor of 3-4 and this is independent from the modeled underestimation of EC concentrations at the site.

Such an analysis will be conducted for the eight stations to understand which factors in the calculations of the optical properties are responsible of the model behaviour.

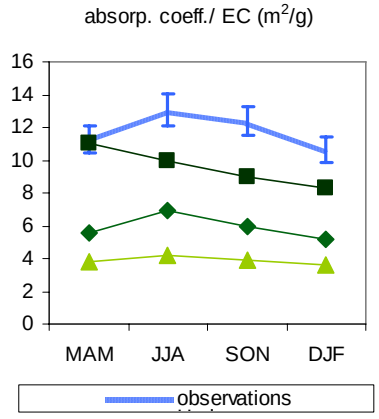

Figure 1. Seasonal ratio of absorption coefficient to EC at Ispra: observed and modelled (green lines) values

The research leading to these results has received funding from the EU 7th Framework Programme (FP7/2007-2013) under grant agreement n° 262254. The data providers of the stations and the AeroCom modelers are acknowledged for their contributions.

Merging air ion spectrometer and particle mobility size spectrometer measurements

H.E. Manninen[1], T. Petäjä[1], P. Aalto[1], W. Birmili[2], M. Kulmala[1] and A. Wiedensohler[2]

Presenting author email: hanna.manninen@helsinki.fi

We investigate the possibility to study sub-10 nm number size distributions using a Neutral cluster and Air Ion Spectrometer (NAIS, Manninen et al. 2010) together with Mobility Particle Size Spetrometers (MPSP, Wiedensohler et al. 2010). Our objective within the ACTRIS project (WP3, Task 3.1) is to ensure the implementation of the existing standardized protocols for high-quality-assured and -controlled aerosol number size distributions in the network and to develop procedures for its extension to the nucleation mode range.

The most common method to measure ultrafine particle number size distribution is Differential Mobility Particle Sizer (DMPS) and Scanning Mobility Particle Sizer (SMPS) in the size range of 10-800 nm. In laboratory verifications, the number size distribution from 20 to 200 nm determined by mobility size spectrometers of different design are within an uncertainty range of ±10% after correcting internal particle losses, while below and above this size range the discrepancies increased (Wiedensohler et al., 2010). Prior to the NAIS measurements, the particle number size distribution was typically measured with MPSPs. The ion spectrometers are widely used in atmospheric nucleation studies in sub-10 nm size ranges due to their ability to measure down to molecular sizes. With the NAIS, ions are measured in the size range of 0.8–42 nm, whereas total (i.e. charged plus neutral) particles are detected in the range of ~2–42 nm.

The electrical detection of sub-10 nm particles is a challenging task due to small concentrations, transport losses, and insufficient charging efficiency of small neutral particles. Thus, electrical instruments need to be sensitive enough to distinguish the minuscule signal brought in by the small particles from the instrument background. To tackle the difficulties in the electrical techniques, high flow rates are used to minimize the ion diffusion losses and also increase the sensitivity to the ion concentrations. By utilizing a unipolar charger, the charging efficiency can be improved by employing high ion concentrations. However, high particle loss within the charger, resulting in a small percentage of charged particles exiting the chargers, is typically the case for unipolar chargers.

The NAIS was calibrated and intercompared, and found to be in good agreement with the reference instruments both in the laboratory and in the field (Asmi et al., 2009). It was concluded that NAIS can be reliably used to measure small atmospheric ions and particles directly at the sizes where nucleation mode begins. Several NAIS systems have already been deployed simultaneously at 12 European measurement sites in parallel with MSP's within the EUCAARI project (Manninen et al., 2010) to quantify the spatial and temporal distribution of particle formation events. New Particle Formation (NPF) occurs when nucleated particles grow to detectable size range. Typical MSP particle size distributions together with NAIS derived ion distributions from Hyytiälä during NPF are presented in Fig. 1 which shows the particle and ion size distributions in the size range of 2-1000 nm and 0.8-40 nm, respectively, during 8–13 April 2007 in Hyytiälä, Finland. Our aim is to write a standard operating procedure for sub-10 nm particle number size distribution measurments.

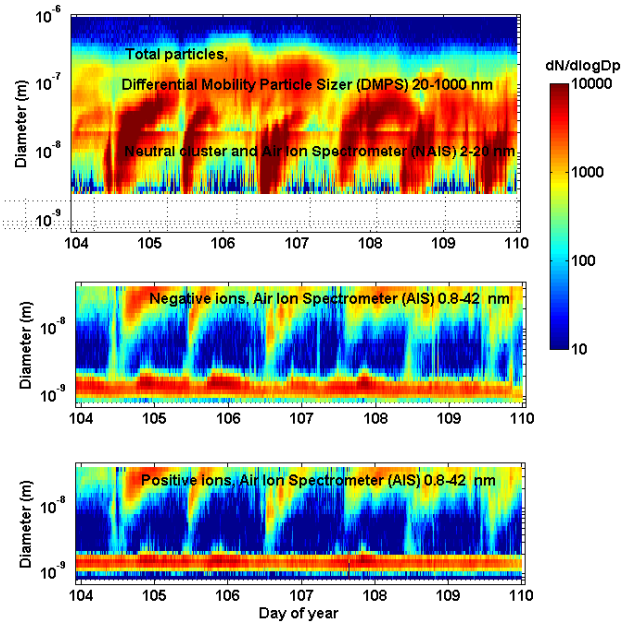

Figure 1. Particle number size distribution measured with the NAIS in the size range 0.8–20 nm and with a DMPS in the size range 20–1000 nm (top). Negative (middle) and positive (bottom) ion distributions were also measured with the NAIS (0.8–42 nm). NB: no fitting applied when merging the NAIS and DMPS data.

Keywords: lidar, sun photometer, microphysical profile.
Presenting author email: mjgranados@ugr.es

Sun photometers are a widespread tool to retrieve column integrated values of aerosol optical, microphysical and radiative properties. Lidars are powerful systems that allow for the vertical profiling of aerosols in the atmosphere. However, microphysical properties profiles are not easy to derive from lidar data. Within the frame of the European project ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) there are several working packages. Particularly WP20 includes the objective of developing tools that combine AERONET sun photometers measurements and EARLINET multiwavelength lidar data to obtain vertical profiles of aerosol microphysical properties. The retrieval algorithm developed in the National Academy of Sciences of Belarus is used in this study (Chaikovsky *et al.*, 2008).

The CEAMA station, in Granada (37.2ºN, 3.6ºW, 680 m a.s.l.), is equipped with a multiwavelength Raman lidar LR331D400 (Raymetrics S.A., Greece) and a collocated sun photometer (CIMEL Electronique). This station is part of the EARLINET and AERONET networks. It presents the advantage that during summer, an additional sun photometer is placed in Sierra Nevada, near the station, but at higher altitude (1800 m a.s.l.).

In this work, the combined retrieval algorithm is applied to lidar and sun photometer data to obtain vertical profiles of aerosol concentration in fine and coarse (spherical and spheroid) modes. The results are compared with simultaneous columnar size distributions obtained from the Cimel radiometers at two different height levels, for this purpose the retrieval algorithm proposed by Olmo *et al* (2006) has been used.

Several cases have been analyzed. Thus, vertical profiles of volume concentrations for fine and coarse modes are obtained during a Saharan dust outbreak on 30 June 2011(Figure 1). During this event, a plume from the Nabro volcano is also observed at 17 km a.s.l. A clear predominance of the coarse spheroid mode has been detected along the column, except for the volcanic plume, where the retrieval procedure determines a mixture of fine and coarse particles. Size distributions provided by the sun photometer at the high mountain place shows agreement with the retrieved concentration profiles. The retrieval procedure has also been applied to some backscatter profiles acquired during the arrival of the Eyjafjallajökull volcanic plume at Granada. Evolution of the retrieved profiles of fine and coarse concentration illustrates the changing contribution of ashes and sulphates to the volcanic plume during 7-8 May 2010.

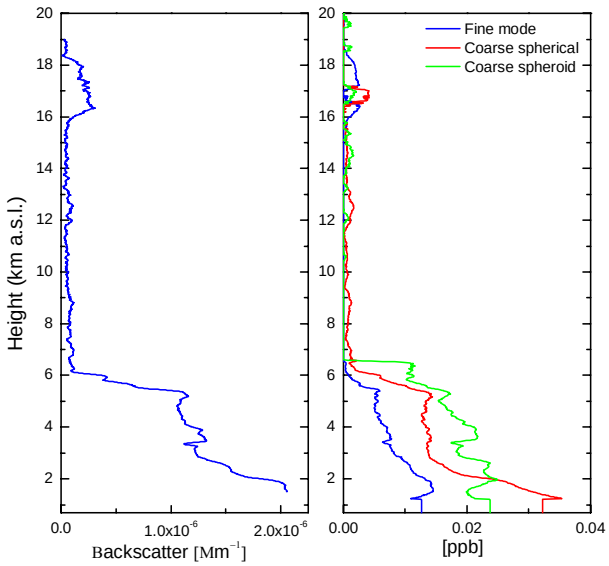

Figure 1. (left) Backscatter profile at 532 nm for 30 June 2011 between 20:00 and 20:30. (right) Vertical profile of the aerosol volume concentration in the fine, coarse spherical and spheroid modes for the same period.

The Eyjafjallajökull volcanic particles have been characterized with remote sensing techniques at different locations in Europe. A unique combination of Raman lidar, sun- and star-photometer is used in this work in order to characterize the optical and microphysical properties of the volcanic plume that was observed over Granada (Spain, 37.16º N, 3.6º W, 680 m height above sea level (asl)) from 5 to 8 May 2010. Our study reveals that mainly sulphate and sulphuric-acid particles were at least episodically present over Southwest Europe. Previous studies of volcanic plumes (*Mattis et al.*, 2010; *Wandinger et al.*, 1995) dealt with the characterization of sulphuric-acid droplets in the lower stratosphere and upper troposphere only. Additional importance of our study therefore arises from the fact that, to our knowledge, this is the first time that an optical and microphysical characterization of these particles has been performed in the lower troposphere with a multiwavelength Raman lidar.

Particle effective radius was derived with an inversion algorithm (Müller *et al.*, 1999). The methodology used to retrieve microphysical properties is based on the spectral information contained in the backscatter and extinction data at multiple wavelengths and its change with particle size. Actually, an important effort is being made within the frame of the European project ACTRIS (Aerosols, Clouds, and Trace gases Research InfraStructure Network) in order to retrieve microphysical properties from lidar techniques.

On 7 May, an increase in the AOD at 440 nm was observed, reaching maximum values (around 0.45) during night time. The corresponding Ångström exponent (AE) was in the range of 1.2-1.3, indicating a predominance of the fine-mode particles. An increase in the accumulation mode was also observed between the morning of 7 May and the morning of 8 May. Lidar observations allowed us to characterize the volcanic layers during the night from 7 to 8 of May 2010. Lidar ratio values were around 55 sr at 355 and 532 nm in the volcanic layers decoupled of the Planetary Boundary Layer. The large Ångström exponents and low linear particle depolarization ratios (4-7%) indicate the presence of small and spherical particles. The particle effective radii ranged between 0.30-0.55 μm. In situ instrumentation confirmed an increase of sulphate particles at ground level during this period.

Figure 1 shows effective radius versus the lidar ratio at 355 nm retrieved for different layers during this volcanic event. They are compared with fresh smoke particles measured at Granada and stratospheric volcanic particles observed over Leipzig (Mattis *et al.*, 2010). We can see that effective radii of the volcanic particles observed at our station are bigger than the effective radii of fresh smoke and stratospheric volcanic particles. A large variability of the lidar ratio at 355 nm is observed for the volcanic particles observed at Granada, ranging from 34 to 67 sr. These values are very similar to those observed for volcanic aerosol coming from different eruptions over Leipzig.

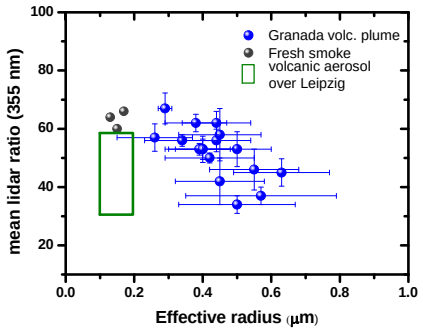

Figure 1. Effective radius versus lidar ratio at 355 nm for different types of aerosols.

ACTRIS Data Centre: An atmospheric data portal

Cathrine Lund Myhre[a], Aasmund Fahre Vik[a], Robert Logna[a], Kjetil Tørseth[a], Holger Linné[b], Ewan O'Connor[c]
[a]NILU - Norwegian Institute for Air Research, P.O. Box 100, N-2027 Kjeller, Norway
[b] Max-Planck Institute for Meteorology, Hamburg, Germany
[c] Department of Meteorology, University of Reading, Reading, United Kingdom

Keywords: measurements, data access, ACTRIS
Presenting author email: clm@nilu.no

The ACTRIS data centre (ACTRIS DC) provides free and open access to all data resulting from the ACTRIS infrastructure network, complemented with data from other relevant networks and data bases. The ACTRIS activities result in improved atmospheric measurement and data from more than 60 European sites, from numerous instruments and includes variables measured by ground based *in situ* and remote sensing technologies. Core variables are *in situ* aerosol optical, physical and chemical properties, short-lived trace gases (volatile organic carbon and nitrogen oxides), aerosol scattering and extinction profiles, and various cloud properties.

The backbone of the ACTRIS DC is the three core data bases:

- EARLINET Data Base hosting aerosol lidar data from more than 30 European sites
- EBAS hosting ground based atmospheric *in situ* data from more than 1000 sites globally
- Cloudnet hosting remote sensing cloud data and products from 5 European sites

A joint data portal is developed to combine information from various data sources to gain new information not presently available from standalone databases or networks. The data centre will also provide tools and services to facilitate the use of measurements for broad user communities. Higher level and integrated products will be developed stage-by-stage during the project, based on user requirements, interactions and feedbacks.

The first version of the ACTRIS DC allows users to search for atmospheric composition data from a multitude of data archives through a single user interface. Examples of data bases and frameworks included are EMEP, the GAW- world data centres, EARLINET, NDACC, CARIBIC-GEOmon, HTAP, AMAP amongst others. Currently the portal provides an overview of more than 800 000 data sets from almost 1700 different locations and more than 20 data bases/frameworks globally. For some of the databases included in the portal, the interface allows you to download data directly through the portal. A map functionality is implemented facilitating the identification of data and making it possible to search for collocation of observations, variables and sites both in time and space. The upper panel of Figure 1 shows the front page of the data portal, and the lower panel shows location of absorption coefficient (violet), scattering coefficient (green), and where both is available at same site (light blue).

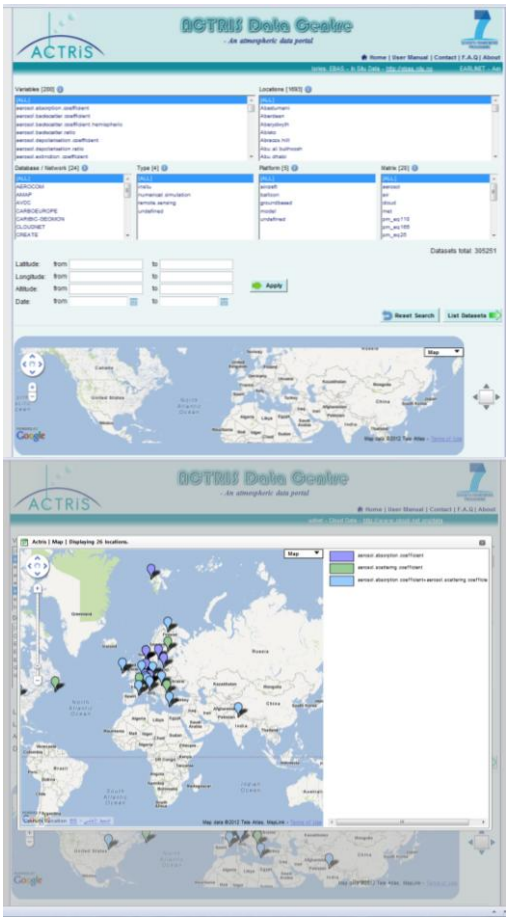

Figure 1: Examples from the ACTRIS joint data portal. Upper panel: front page, Lower panel: available absorption and scattering coefficient collocation of sites.

The data portal can serve as "one-stop-shop" of atmospheric high-quality data, also for larger data volumes. The portal will also offer a direct interface towards external users like the MACC II project and GMES in-situ. The data dissemination will take into account the principles outlined in SEIS, INSPIRE, WIS and GEOSS.

The presentation will explain and demonstrate the ACTRIS DC with the goal to strengthen the dialog with users for further development of the data centre in ACTRIS.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 262254."

Session WG02S3O. Urban Aerosol in Large Cities (I)

Spatial distribution of particle number concentrations measured with the AERO-TRAM

B. Vogel, R. Hagemann, R. Rinke, A. Wieser, U. Corsmeier, Ch. Kottmeier
Institute for Meteorology and Climate Research, Karlsruhe Institute for Technology,
Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany
Keywords: urban aerosols, mobile measurements, air quality.
Presenting author email: bernhard.vogel@kit.edu

The spatial and temporal variation of selected aerosol and gas phase parameters is assessed in long term measurements for the Karlsruhe (Germany) area with an automated self calibrating mobile laboratory. As measurement platform a tramway (AERO-TRAM) operating in the public transport is used. Beside the gas phase components O_3, CO, CO_2, NO, and NO_x particle number density and particle number distributions are measured. For the year 2010 measurements on more than 2300 runs are obtained resulting in an extraordinary dataset for ground based mobile applications. The AERO-TRAM operates on two selected lines. Both lines connect the rural and suburban hinterland of Karlsruhe with the city centre. They are crossing areas with high concentrations of particles and trace gases and areas where only background concentrations are expected. Therefore, the obtained comprehensive dataset is useful for determining regional variation of particles and trace gases as well as for the identification of source areas.

The analysis of the measured number densities gives a concentration gradient between the city centre and the suburban areas of only 30 %. In comparison the NO_x concentrations are about 50 % lower in the suburban.

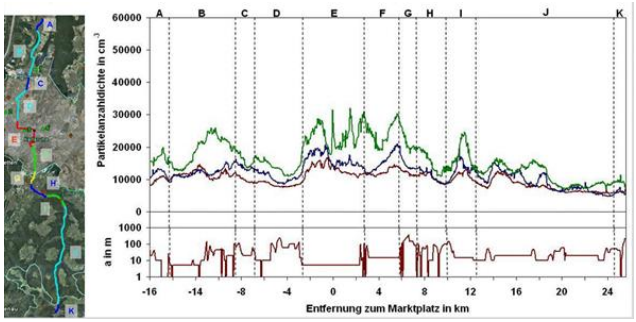

Figure 1. Median of the running mean of the particle number density for 2010 at different stability conditions. Green = stable stratification, blue = neutral stratification, red = unstable stratification (upper panel). Distance of the track to the next road (lower panel).

Figure 1 shows the distribution of the median of a running mean of number density for the year 2010 along the track and its dependence on the turbulence conditions. It can be seen that there is no remarkable gradient of the number densities between the distinct regions but the concentration level differs up to a factor of 2 in depending on the turbulence state of the atmosphere. This shows the difficulty of measuring an effect of emission reduction measures. Figure 2 gives the median values as a function of the wind velocity. As expected these concentrations are lower for the higher wind speeds but there is no uniform behaviour for the different areas. In the city centre there is almost no effect visible whereas in the northern vicinity the concentration level is considerable higher for the lower wind speeds.

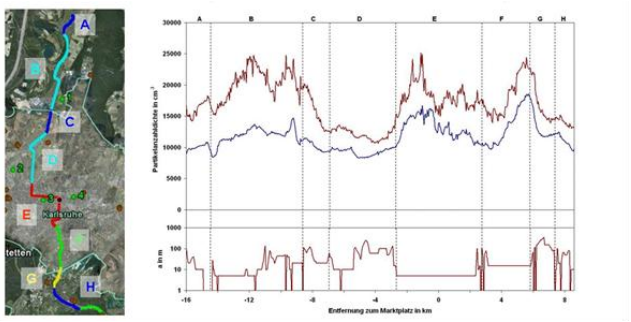

Figure 2. Median of the running mean of the particle number density for 2010 at different ranges of wind velocity. Red = 1-5 m s^{-1}, blue = > 5 m s^{-1} (upper panel). Distance of the next road (lower panel).

The investigation of the influence of the wind directions shows the impact of elevated single sources in the area on the number densities that so far could not be detected by the standard monitoring stations in that area.

SAPUSS: Solving Aerosol Problems by using synergistic strategies in Barcelona, Spain

Compared to other European regions, the metropolitan area of Barcelona sees relatively high particulate matter due to high anthropogenic emissions, a dry and warm Mediterranean climate and low dispersive conditions due to a unique topographical situation. State-of-the-art instruments such as particle mass spectrometers have been only recently deployed in the Southern and Western European regions. During the autumn of 2010, the SAPUSS experiment took place, involving measurements of aerosols with multiple techniques occurring simultaneously in order to deduce point source characteristics and to understand the atmospheric processes responsible for their modifications. Five sites were used: a main road, an urban background site, a regional background site and two towers within the city (150m and 450m above sea level, respectively, Figure 1). The use of the synergy of highly time-resolved instruments (such as 2 Aerosol Time-of-flight Mass Spectrometer and 2 HR-Aerosol Mass Spectrometer – ATOFMS and AMS) was coupled with traditional off-line techniques (11 high-volume samplers) in order to deduce all the information provided by them. The about 600 filters obtained during SAPUSS were analyzed by GC-MS, ICP-MS, ICP-AES and EC/OC analysis. A vast number of instruments were also deployed to characterize simultaneously all five sampling sites at hourly resolution, including black carbon, particle number and mass concentrations and size-resolved concentrations. Two cielometers were used simultaneously horizontally and vertically in order to get close to the full picture of the dynamics of the urban boundary layer.

This presentation aims: to present 3D distribution of PM_1, $PM_{2.5}$ and PM_{10} across Barcelona under different boundary layer conditions; to elucidate the fate of nanoparticles in the urban atmosphere – focusing on the evaporation of freshly traffic generated particles and the nucleation occurring at different altitudes within the urban boundary layer; to quantify the contribution of exaust and non-exaust traffic generated particles in the road site relative to the urban background; to understanding the physical and chemical differences of the aerosols detected at ground level and above the city. PMF results of co-located HR-TOF-AMS and ATOFMS mass spectrometers results are also shown, trying to elucidate further insights on cooking aerosols sources.

Simultaneous Single Particle Mass Spectrometry Measurements at Two Different Urban Sites and Comparison with Quantitative Techniques

Two Aerosol Time-of-Flight Mass Spectrometers (TSI ATOFMS) were deployed in Barcelona (Spain), during the SAPUSS (Solving Aerosol Problems by Using Synergistic Strategies) field campaign in autumn 2010. One ATOFMS, operated with a nozzle inlet, was deployed at an Urban Background (UB) site while the second one, operated with an aerodynamic lens, was located at a Roadside site (RS)

During the SAPUSS campaign the ATOFMS at UB and RS collected 274,974 and 1,042,331 single particle dual ion mass spectra respectively. The single particle mass spectra were subsequently analysed by using the ART-2a algorithm. Single particle mass spectra from the UB ATOFMS were also imported into ENCHILADA (Environmental Chemistry through Intelligent Data Analysis), a freeware single particle data analysis software package (Gross, Atlas et al. 2010) and clustered using the *K*-means algorithm, (*K*=80).

Several particle types were identified at both sites and assigned to both transported and local sources, including biomass burning, fossil fuel combustion, industrial processes, wind-blown dust, and sea salt. During the clustering analysis it was found that RS had a higher number of particle types (19) relative to the UB one (14). Along with the mass spectra, size ranges, temporal trends, wind direction and HYSPLIT back trajectories were also used to assist with source identification of each particle type.

Both ATOFMS datasets obtained were inter-compared with hourly average concentrations of numerous elements present in $PM_{2.5}$ collected with streaker samplers which were also simultaneously located at both sites. The $PM_{2.5}$ fraction was subsequently analysed using Particle-Induced X-ray Emission (PIXE) (Chiari, Lucarelli et al. 2005). Na, K, Ca, Ti, V, Cr, Mn, Fe, Zn and Pb measured by The PIXE data was used to validate the metal ion intensity temporal trends produced by the ATOFMS. Following the approach of Snyder el al (2009) we extend it for both type of instruments, and we extensively expand the number of data point with a data point for each hour of the campaign. The dual ion mass spectra measured by the ATOFMS provide information on the mixing state of the metal-containing particles and can thus facilitate identification of the particle sources. It was observed from the inter-comparison of the two techniques at the UB site that iron had inputs from both crustal and industrial sources. Manganese and lead occur with a similar temporality and the peaks in both elements belong to the same particle class, and are internally mixed. The source of vanadium appears to be from the combustion of heavy fuel oil such as that used in shipping.

Keywords: chemical composition, hourly resolution, $PM_{2.5}$, urban aerosols.
Presenting author email: lucarelli@fi.infn.it

The present study aims at evaluating the impact on PM chemistry of the emission sources present in the urban area of Barcelona. The vast majority of results in literature are limited to time resolution of the input samples typically 12 or 24 h. However, source emissions can heavily affect air quality with very high loading of toxic elements during a few hours: the knowledge of the timing and the intensity of certain episodes may be important for the assessment of human exposure as well as for source identification and apportionment. The novelty of this study stands on the hourly-resolved PM speciation data which can be a powerful tool to determine the source origin of atmospheric pollutants in urban environments.

Two different sites (a road site and an urban background site; RS and UB, respectively) were used within the SAPUSS (Solving Aerosol Problems by Using Synergistic Strategies) project, a European Union project involving measurements of aerosols with multiple techniques occurring simultaneously.

During SAPUSS campaign, PM2.5 samples with 1-hour resolution were collected between September 27, 2010 and October 19, 2010 for a total of 528 hours by a streaker sampler (PIXE International Corporation). Data coverage during this period was 80% at the UB and 57% at the RS. The overlap between the two sites was higher than 98%, making 57% of the time having simultaneous measurements. The PIXE analysis of these samples was done with the external beam set-up at the INFN LABEC laboratory in Florence; it allowed the assessment of hourly resolution elemental time trends of 17 elements: Na, Mg, Al, S, Cl, K, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Sr, Pb.

Several results will be discussed, for example: Cu diurnal profiles exhibited daily variations with peaks during traffic rush hours; Al showed a peak from October 8 till October 10, due to a Saharan dust intrusion; Zn showed peaks both in the morning and in the night, typical of an industrial source.

Positive Matrix Factorisation (PMF) was applied to the whole data set. Input data were prepared using the procedure suggested by Polissar and PMF results for multiple values of FPEAK were systematically explored to find out the most reasonable solution. Nine factors were found in both sites (in parenthesis the specific markers):

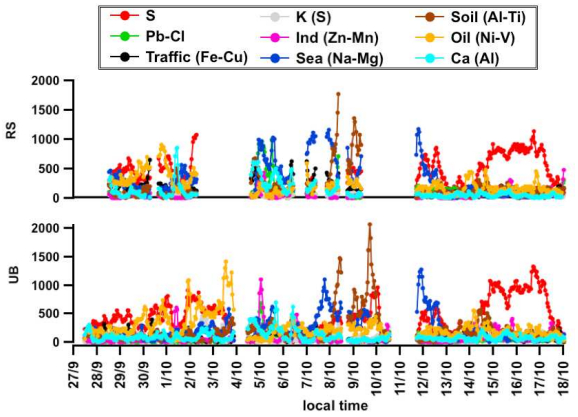

Figure 1: Hourly resolution time trend of the aerosol sources identified by PMF.

Regional sulphates (S); *two industrial sources*, one with Zn, Mn and a bit of Pb, a second one with Pb-Cl (also supported by concomitant single particle ATOFMS measurements); *traffic* (Fe-Cu and some Ca), as primary non exhaust particles; *Biomass burning* (K); *aged marine aerosol* (Na-Mg); *oil combustion* (V-Ni) with a small contribution from combustion (S); *two soil sources*, one characterized by Al-Ti (Saharan dust) and some Ca, whose temporal pattern clearly reflects a strong Saharan influence, the other characterized by Ca with small contribution of Al and Ti, with a time pattern which is a combination of traffic in the morning at RS, yet spiking in the afternoon at the UB, reflecting higher wind speed and contribution from construction activity. Strong correlation among RS and UB sites for some of the nine different PM sources supports the validity of the PMF solution, as well as regionality fingerprint associated with some of the sources.

The three different dust sources (Saharan dust, soil and primary non-exhaust particles) have an important contribution on the total measured mass of the 17 elements (12%, 6% and 7% of the total elements measured, respectively). However, neither primary non-exhaust traffic dust nor soil dust was found correlated with wind speed or with traffic counts, suggesting the resuspension of dust may have more complex relations linked to both wind speed, wetness conditions and traffic counts altogether.

Seasonal comparison of comprehensive aerosol measurements in London during ClearfLo

Elevated aerosol concentrations are frequently associated with atmospheric pollution and have serious implications for air quality, particularly in cities (Mayer, 1999). At present, the dominant source of primary particulates is the transport sector although there are many other causes of air pollution including solid fuel burning and cooking. The effects of aerosols on health and the mechanisms by which they occur are not well understood. The size distribution, chemical composition, and mixing state of atmospheric aerosols also influence their effect on climate (Forster *et al*, 2007), however the exact impacts of aerosols are difficult to determine due to their complex nature. Examination of various aerosol properties and how aerosols change spatially and temporally is essential for refining the quantification of aerosol effects in climate models, health policies, and legislations.

A suite of state-of-the-art instrumentation, measuring aerosols, gases, radicals and meteorological parameters was deployed as part of the Clean Air for London (ClearfLo) campaign for two major intensive observation periods (IOPs) during 2012 at a number of sites in and near London. One of the major aims of ClearfLo is to characterise the spatial and temporal evolution of boundary layer pollution in London. Here we report aerosol composition measurements from the main ClearfLo urban background supersite located in the grounds of a school in North Kensington, London for both of the four-week IOPs, which took place during different seasons. The winter IOP took place between 11 January and 8 February, a time when primary emissions dominate the aerosol loading, and the summer IOP took place between 18 July and 22 August, covering the 2012 Summer Olympic period. Measurements took place during both clean westerly conditions and more polluted conditions when transported European plumes influenced the site.

Comprehensive measurements of size segregated aerosol chemical composition, microphysical properties, and optical properties were taken to obtain high-resolution data sets on aerosol composition in conjunction with black carbon properties and hygroscopicity. Instrumentation included a 7-wavelength Aethalometer, Aerosol Particle Sizer (APS), Aerosol Particle Spectrometer with Depolarization (APSD), Condensation Cloud Nucleus counter (CCNc), Differential Mobility Particle Sizer (DMPS), GRIMM dust monitor, Hygroscopicity Tandem Differential Mobility Analyser (HTDMA), Multi Angle Absorption Photometer (MAAP), PhotoAcoustic Soot Photometer (PASS), Single Particle Soot Photometer (SP2), and a Soot Photometer Aerosol Mass Spectrometer (SP-AMS). In addition, a GRIMM dust monitor, a Wide Issue UV Fluorescence Bioaerosol Spectrometer (WIBS) and a Rotating Drum Impactor (RDI) were located on the container's exterior. The RDI samples were subjected to Synchrotron Radiation induced X-Ray Fluorescence Spectrometry (SR-XRF) analysis to determine trace elemental composition. A compact Time-of-Flight Aerosol Mass Spectrometer (cToF-AMS) was housed in the permanent monitoring station from January until August covering both IOPs providing long term measurements of aerosol chemical composition.

Preliminary data from both ClearfLo IOPs along with data from the long-term cToF-AMS measurements will be presented (Fig. 1), highlighting diurnal and seasonal characteristics of London urban background pollution. These data will be used to quantify the contribution by different urban activities in London to both local and regional air pollution.

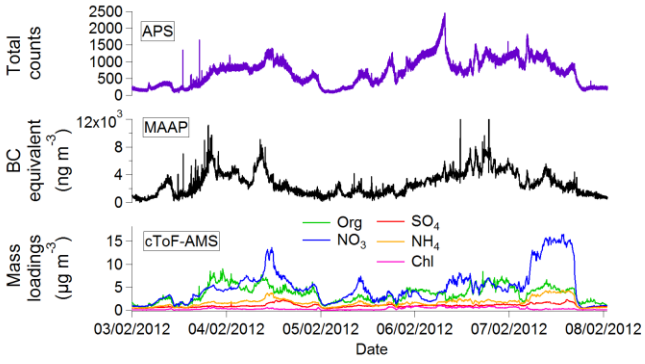

Figure 1. Preliminary data from the cToF-AMS, MAAP, and APS covering six days during the winter IOP with both relatively high and low aerosol concentrations.

A mobile measurement network for ultrafine particulate matter in the city of Zürich

A. Richard, P. Steigmeier, H. Burtscher and M. Fierz
University of Applied Sciences and Arts Northwestern Switzerland, Institute of Aerosol and Sensor Technology, 5210 Windisch

Keywords: Ambient aerosol measurement, Air quality network, Fine particulate matter, Number concentration
Presenting author email: agnes.richard@fhnw.ch

A mobile measurement network with ten miniDiSC devices is set up in the city of Zürich, Switzerland to assess the spatial and temporal evolution of ultrafine particle number concentrations. MiniDiSCs (Fierz, 2011) measure the number concentration of ultrafine particulate matter (size range 10-300nm), its average particle diameter and the lung deposited surface area with a time resolution of one second. The devices are installed on trams frequenting the main streets in Zürich as well as carried by deliverymen on bicycles, which drive along narrower streets.

A GPS/GPRS extension of the devices enables the transmission of measured data as well as its current location to a central web-server, where it is available online in real time. Measurement data in combination with the location can be viewed in Google Earth and are made publicly available on the project homepage: https://feinstaub.cs.technik.fhnw.ch/feinstaubmessnetz/.

In contrast to stationary measurements such a moving measurement network allows for capturing a more complete picture of different pollution scenarios within a city.

The project is a cooperation with the openSense network of ETH Zürich (Aberer, 2010), which is part of the Nano-Tera program, dealing with wireless sensor networks and publishing of sensor data on the internet. In the framework of this project CO, NO_2 and O_3 sensors are also positioned on the trams, which will finally complement the particle number concentration data.

Data will be divided into subsets to assess diurnal, weekly and seasonal variations as well as changes due to different meteorological situations. For this purpose the miniDiSC data will be compared to meteorological data such as temperature, wind direction, wind speed and precipitation. With measurements throughout the year 2012, seasonal variations can be examined.

Through the combination of the information about the position of the devices and the number concentration, pollution maps can be generated. Since concentrations rapidly change over relatively small distances a large repetitive data set is needed. The measurement period will last for approximately one year, such that enough data will be available to obtain a representative mean for each point along the paths.

Eventually, the measurements will be used to generate such a pollution map. This pollution map will be based on calculations with the Kriging algorithm (Pebesma, 2004) and will possibly also include information about the urban road system.

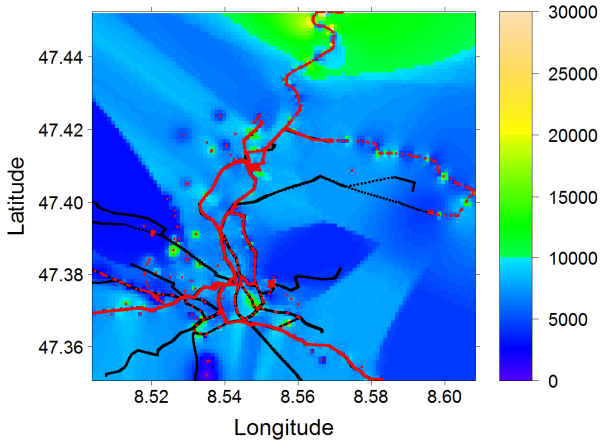

Figure 1.: First Kriging calculations with particle number concentration data obtained from tram rides on two different tram lines (data from Sept 2011 – Jan 2012). The red lines depict the two tram lines and the black ones show all tram lines in Zürich, which will also be frequented in a later stage of the project.

Figure 1 shows an example of a first Kriging calculation with the first particle number concentration data obtained during test rides on two tram lines in the city of Zürich from Sept 2011 – Jan 2012.
