1. Abstract

The kinetochore is a conserved eukaryotic organelle, pivotal during the cell cycle. In order to partition chromosomes equally during division, it provides a microtubule attachment platform that facilitates correct sister chromatid sorting and segregation. It is a complex structure, which in vertebrate cells is assembled during the course of the cell cycle from more than a hundred proteins onto a specialized chromosomal locus, the centromere. Many of these protein components are well conserved between yeast and man, most prominently those of the core microtubule attachment platform, the KMN network. Some of the centromere proximal proteins of the vertebrate CCAN have established homologues in the budding yeast Ctf19 complex but overall conservation appears weaker between these two protein networks. This could be due to different mechanisms yeast and vertebrate cells use to define the centromere locus. However, our bioinformatic analysis indicated hitherto unknown yeast CCAN homologues, including known Ctf19 complex proteins, budding yeast centromeric proteins and proteins that had not yet been identified as centromeric constituents in yeast. Here I aim to substantiate our theory, that the CCAN is a protein network conserved between yeast and man, through biochemical and proteomic analysis of recombinant and native proteins. Furthermore I investigate potential cell cycle dependent regulation of budding yeast CCAN proteins by CDK1. I found a number of functionally conserved relations within the budding yeast CCAN, supporting conservation of this protein network. I also identified a number of CDK1 phosphorylation sites within the budding yeast CCAN, the most striking being a cluster of CDK1 sites at the amino-terminus of ScCENP-U.

Das Kinetochor ist eine konservierte eukaryotische Organelle welches eine Schlüsselrolle im Zellzyklus spielt. Um die Chromosomen während der Zellteilung gleich aufzuteilen fungiert es als Mikrotubuli-Bindungsplattform, die das korrekte Sortieren und Segregieren der Schwesterchromatiden ermöglicht. Es ist ein komplexes Gefüge das, beispielsweise in Wirbeltier-Zellen, im Laufe des Zellzyklus aus über einhundert verschiedenen Proteinen an einem speziellen chromosomalen Locus, dem Zentromer, zusammengefügt wird. Viele dieser Protein-Bausteine sind wohl konserviert zwischen Pilzen und Menschen. Die zentrale Mikrotubuli-Bindungsplattform, das KMN Netzwerk, ist vermutlich das bemerkenswerteste Beispiel. Einige der Zentromernahen Proteine des Wirbeltier-CCAN's besitzen bekannte homologe im Ctf19-Komplex der Bäckerhefe, allerdings scheint die Konservierung zwischen diesen beiden Proteinnetzwerken insgesamt geringer. Ein Grund hierfür mögen die unterschiedlichen Mechanismen sein mit denen Hefezellen und Wirbeltierzellen den Locus ihres Zentromeres definieren. Unsere Bioinformatische Analyse jedoch wies auf bis dato unbekannte CCAN homologe in Hefe hin, einschließlich bekannter Ctf19-Komplex Proteine, Proteine des Hefe-Zentromeres und Hefeproteine die noch nicht als Zentromerproteine identifiziert wurden. Hier untermauere ich unsere Theorie, das das CCAN ein zwischen Hefe und Mensch konserviertes Proteinnetzwerk ist, durch biochemische und proteomische Analyse von rekombinanten und nativen Proteinen. Weiterhin untersuche ich eine mögliche Zellzyklus-abhängige Regulation des Hefe-CCAN's durch CDK1. Ich fand einige funktionell konservierte Zusammenhänge innerhalb des Hefe-CCAN's was eine Konservierung dieses Proteinnetzwerkes bestätigt. Weiterhin identifizierte ich einige von CDK1 phosphorylierte Stellen innerhalb des Hefe-CCAN's, wovon eine Ansammlung dieser am Amino-Terminus von ScCENP-U das hervorstechendste Merkmal ist.

2.Introduction

2.1 Preface

Walther Flemming, writing the first textbook on nuclear division, carefully noted that nuclear division is likely important for cell division as nuclear division can occur without cell division but the reverse is never observed^[1]. Almost 150 years later, the importance of nuclear division in either mitosis or meiosis can hardly be overstated. As the genome contains the information to make a new organism, be it through cell division in unicellular organisms or fusion of two gametes into a zygote that will ultimately develop into a human, it is paramount that each cell or gamete receives the full information of an entire genome and no part of it in excess. Errors during mitosis may lead to death of the individual in the case of a single celled organism or cancer in humans^[2]. Meiotic errors in turn are a leading cause for pregnancy loss and developmental defects^[3].

Faithful segregation of the complete duplicated genome into both daughter cells is a formidable problem for a eukaryotic cell as their genome comes encoded on a number of chromosomes, which it cannot discern or count^[4-8]. To overcome this, it employs an ingenious strategy: after replicating its chromosomes, the resulting two identical copies, the sister chromatids, remain cohesed^[9]. Cohesed chromosomes are subsequently attached to microtubules (MTs) of the mitotic spindle. The spindle is a bipolar structure and each pole defines a location within one of the future daughter cells, as cytokinesis will take place on a plane between both poles. Of the two sister chromatids, each one only attaches to one of the two opposite poles yielding a bioriented chromosome. This effectively sorts sister chromatids and targets one of them to each daughter cell. Once sorting is complete, cohesion between the two sisters is resolved and complementary chromatids move to opposite poles.

This work concerns itself with the budding yeast kinetochore. Kinetochores (KTs) are pivotal during mitosis as they integrate many of the functions required for faithful chromosome segregation. They not only provide a load bearing attachment point for spindle microtubules but also regulate the dynamics of the attached MTs. Importantly, they harbor an error correction mechanism to resolve erroneous attachments, the occurrence of which is increased by miniscule perturbations, such as small drops in temperature. When sister chromatids separate, the cell loses its ability to tell them apart. To ensure that anaphase only initiates once sorting is complete, kinetochores generate a checkpoint signal until all chromosomes are bioriented^[10]. Additionally, KTs are able to nucleate MTs and drive spindle assembly in absence of dominant microtubule organizing centers (MTOCs) such as centrosomes. Lastly, components of the kinetochore participate in an epigenetic mechanism that directs inheritance of the centromere locus.

Budding yeast affords the opportunity to study mitosis and specifically the kinetochore in a simplified system. Although its mitosis is morphologically very different from animal mitosis, many of the key components and mechanisms are conserved. Recently this list has been extended as bioinformatic analysis suggests extensive conservation of centromeric or inner kinetochore proteins between yeast and vertebrates. The constitutively centromere associated network (CCAN) of vertebrates appears to correspond to the budding yeast Ctf19 complex and the Sim4 complex of fission yeast^[11]. Here I aimed to firstly investigate interactions between Ctf19 complex proteins and other kinetochore proteins, DNA and microtubules to refine existing models of kinetochore assembly. Secondly I sought to support the notion that the CCAN is conserved between humans and budding yeast experimentally, by finding conserved interactions within the CCAN and between CCAN and other kinetochore proteins.

2.2 Cell cycle and mitosis in budding yeast

Mitosis in budding yeast differs from the animal system in a few important points. The mitotic spindle is assembled intra-nuclear. The poles are defined by spindle pole bodies (SPB), budding yeast centrosome equivalents, situated inside the nuclear envelope (NE). During mitosis, SPBs bracket a spindle that spans the nucleus while projecting astral MTs towards the cell cortex^[12-14]. The spindle is assembled before DNA replication is complete and the site of cytokinesis is not defined by astral microtubules or the midzone, but is predefined to be where the bud extrudes from the mother cell. The spindle aligns along the mother bud axis and cytokinesis takes place at the bud neck, the bridge connecting mother and bud after chromosomes have segregated^[15-18].

Generally, the cell cycle is divided into S and M phase, the time when DNA replicates and the time when mitosis and cytokinesis occur, respectively. Gap phases, G1 following M phase and G2 following S phase, separate S and M phase. Budding yeast does not have a clearly defined G2 phase and S and M partially overlap^[19, 20]. In G1 the future bud site is specified by placement of cortical landmark proteins and a precursor of the SPB assembles next to the mother SPB on a projection along the cytoplasmic face of the NE termed a half bridge^[14, 21-24]. Further, chromosomal origins are licensed for replication by assembly of a Pre-replicative complex (PreRC) during G1^[25-27]. Once the decision to duplicate is made, cells become insensitive to mating pheromones and are committed to mitosis, unable to undergo the alternative meiotic pathway until the current cell cycle has completed^[28, 29]. Commitment happens when a point in time termed START is traversed and S phase is initiated. This triggers three independent processes, SPB separation and spindle assembly, budding, which entails polarization of the actin cytoskeleton towards the bud site and polarized secretion, and DNA replication through conversion of PreRCs into pre-initiation

complexes (PreICs) and then into replisomes by loading of DNA polymerase^[14, 20, 21, 23, 26, 30-33]. Following the previous division, the old SPB faces away from the bud scar and needs to reorient towards the bud site, in haploid cells placed next to the previous bud site^[34, 35]. Astral MTs emanating from the old SPB and the half bridge interact with cortical myosin through the MT +end binding protein ScEB1 and the APC (Adenomatous polyposis coli) related protein Kar9. This allows the transport of astral MTs and thereby pulls the SPB towards the bud site along the same actin cables used for polarized secretion which supplies the bud site with membrane and cell wall material^[31, 36-40]. During this time the spindle is asymmetric, only one of the two SPBs accumulates Kar9 and is targeted towards the bud^[41-44].

Budding yeast enters M phase before S phase is completed, the spindle assembles and swiftly contacts kinetochores that have assembled on the early replicating centromeres^[45]. Many of the hallmarks of the 5 mitotic phases are absent in budding yeast. During prophase chromosomes do condense but not to the same extent as in other systems, they do not become visible under light or electron microscopy^[12, 13, 46]. Furthermore in animals the transition into prometaphase is marked by nuclear envelope breakdown (NEBD), followed by the individual biorientation of all chromosomes. NEBD never happens in budding yeast as the nucleus remains intact throughout mitosis^[47]. During prometaphase bioriented chromosomes do not congress to form a defined metaphase plate, which marks the onset of metaphase in animal cells^[48, 49]. Once DNA replication is complete and all chromosomes have bioriented, anaphase A is initiated, drawing chromosomes to the pole along shortening MTs, followed by anaphase B as the spindle expands into the bud^[43, 48]. The latter is aided by cortical Dynein pulling astral MTs of both SPBs into either mother or bud^[35, 50]. Once anaphase has completed, during telophase, the spindle is fully disassembled and the nucleus pinches off, followed by cytokinesis at the bud neck.

Some peculiarities of budding yeast prometaphase need to be mentioned. In addition to not displaying the same extent of chromosome condensation, centromeres in budding yeast separate as soon as they have become bioriented in an event termed transient separation^[51, 52]. In animals and budding yeast the Cohesin complex mediates sister chromatid cohesion. Cohesin is a ring-shaped complex that is loaded during replication and is thought to entrap both sisters topologically^[53-57]. Animal Cohesin is removed by two pathways prior to anaphase, the prophase pathway in which polo like kinase (Plk1) removes Cohesin along chromosome arms but spares two points of cohesion flanking the centromere. This last point of contact is severed at anaphase onset as separase becomes active and permits chromatid separation. The pool of Cohesin at the centromere is specifically protected from Plk1 by Shugoshin (Sgo), which recruits Protein phosphatase 2A (PP2A) to counteract phosphorylation by Plk1^[58-64]. Budding yeast removes all Cohesin by Separase cleavage in

anaphase of mitosis and requires Shugoshin for cohesion only in meiosis^[65, 66]. Furthermore in budding yeast Cohesin is loaded preferentially at the centromere and this requires a number of kinetochore proteins. As kinetochores undergo transient separation, a region of at least 18kb centered on the centromere separates while cohesion is retained at arms^[51, 52, 66-68].

2.3 The cell cycle control system

It is readily apparent that the events of the cell cycle need to proceed in an ordered and unidirectional fashion if they are to generate two viable daughter cells. Attempting chromosome segregation before DNA replication has initiated or completed will lead to aneuploidy or DNA damage. This illustrates two important points of the cell cycle control machinery. Firstly it drives unidirectional progression through a strictly defined series of events, some of which occur in parallel. Secondly it is gated at specific points during this series to allow all required parallel events to complete. In budding yeast for example budding, DNA replication and spindle assembly are independent parallel events. Each is monitored by a checkpoint that retards anaphase until the event has completed, ensuring that anaphase initiates only when all have completed^[69-72].

The cell cycle control system drives a cell forward through the cell cycle and the kinase CDK1 is central to its function^[33, 73-77]. CDK1 phosphorylation triggers many of the sequential events, yet its levels remain constant through the cell cycle^[78, 79]. CDK1 is activated by binding to one of the 9 sequentially expressed cyclins^[80-84]. The earliest cyclin, Cln3, appears during early G1 while Cln1 and Cln2 peak during late G1 before entry into S which roughly coincides with the appearance of the first two B cyclins Clb5 and Clb6. Subsequently, Clb3 and Clb4 appear, followed by Clb1 and Clb2 which peak shortly before anaphase onset^[15, 79, 83, 85-92]. Sequential association with cyclins is one possibility to explain control of a temporally ordered set of events by a kinase that does not change in abundance during the cell cycle. It would require cyclins to confer substrate specificity or specific localization. This has been demonstrated as Cln3 is primarily nuclear, Cln2 is also found in the cytoplasm, Clb4 localizes to the new SPB and Clb2 also localizes to the bud neck at late mitosis^[44, 93, 94]. Furthermore, a limited number of CDK1 substrates are preferentially targeted by the early Clb5-CDK1 rather than the late Clb2-CDK1, including Ase1 and Fin1 which have a role in stabilizing the central spindle during anaphase B elongation but are detrimental to viability when a loss of CDK1 phosphorylation allows them to bind the spindle before anaphase onset. Here suppression by Clb5-CDK1, activation by Cdc14 and subsequent destruction by the APC allows the restriction of their activity to a narrow window during anaphase B^[95-99]. A targeting subdomain of Clb5, the hydrophobic patch (HP), is one factor for substrate specificity. Clb5-HP interacts with RXL motifs to target CDK1 phosphorylation^[100]. An alternative explanation

for cell cycle regulation is that it is the rise in CDK1 activity that drives progression through the cell cycle, triggering the appropriate events once the required kinase activity threshold has been reached by accumulation of cyclins^[101]. In line with this, Clb2 is a much more potent activator for CDK1 than Clb5^[95]. Furthermore, only few CDK1 substrates are specifically targeted by Clb5-CDK1. In vivo, cyclins demonstrate considerable redundancy as a deletion of 2 of the three G1 cyclins generates viable mutants. Similarly, deletion experiments with B-type cyclins show that a single B cyclin, either Clb1 or Clb6, when overexpressed, is sufficient to trigger all essential events during the cell cycle^[15, 78, 90]. Sic1 serves as a model for how increased CDK1 activity may trigger a response that is not elicited at low CDK1 activity levels. Sic1 contains a cluster of CDK1 sites. Increasing CDK1 activity phosphorylates more sites within this cluster and it thus acts as a sensor that is responsive to the level of CDK1 activity and targets Sic1 for degradation only above a certain threshold^[102].

However, on-time appearance of the cyclins is required to maintain normal timing between the events of the cell cycle. The G1 cyclins Cln1 and Cln2 normally trigger polarization of the actin cytoskeleton and bud formation at the site specified during G1, duplication of the SPB and render the cell insensitive to mating pheromones^[23, 103-105]. Clb5 and Clb6 in turn trigger timely initiation of DNA replication at origins that have assembled a PreRC and simultaneously inhibit assembly of further PreRCs^[26, 87, 106]. Onset of DNA replication additionally requires phosphorylation by the Dbf4 dependent kinase (DDK) Cdc7 which associates with origins and promotes conversion from a Pre-RC to a Pre-IC. Analogous to the activation of CDK1 by cyclins, Cdc7 kinase levels are constant but the activating cofactor Dbf4 is a target of the APC/C and accumulates only after CDK1-dependent inactivation of Cdh1-APC in S phase^[26, 107-115]. It was suggested that Dbf4 serves to target Cdc7 to origins^[116-118]. Clb3 and Clb4 trigger spindle assembly and are required for spindle polarity by maintaining asymmetry of the SPBs^[15, 37, 44, 86, 87]. Clb1 and Clb2 are the final B cyclins to be expressed and they are required for progression through and completion of mitosis after spindle assembly, including Cohesin cleavage and ultimately B-type cyclin destruction by Cdc20-APC. In addition they randomize actin polarity, switching back from polarized to isotropic bud growth. Cyclin B destruction at anaphase re-focuses the actin cytoskeleton and vesicular traffic towards the bud neck, the site of future cytokinesis^[15, 23, 79, 119-121].

Expression of cyclins is regulated firstly by transcription of sequential regulons and secondly by ubiquitin mediated proteolysis through the SCF and APC/C ubiquitin ligases. Cln1 and Cln2 as well as Clb5 and Clb6 are part of the late G1 regulon while Clb2 is part of the Clb2 regulon, transcribed at the end of S-phase. Positive feedback loops and feedback inhibition of earlier regulons are thought to drive a switch-like transition from one regulon to the next, and thereby into the next cell cycle stage, while simultaneously suppressing the previous^[92, 122-127]. Ubiquitin mediated destruction has an important role during two major, irreversible

transitions in the cell cycle: commitment to mitosis at the G1/S transition and anaphase onset at the M/G1 transition. During G1, the ubiquitin ligase APC/C (anaphase promoting complex/cyclosome) with its co-activator Cdh1 targets B cyclins for destruction. An exception is Clb5 that is not a target of Cdh1-APC/C^[128-130]. Simultaneously, Clb-CDK1s are suppressed by the Clb-CDK1 inhibitor Sic1 in G1^[131-134]. Expression of Cln1 and Cln2 at the end of G1 allows Cln-CDK1 dependent phosphorylation of Sic1, which targets it for destruction by the SCF ubiquitin ligase^[103, 133, 135]. Decreasing Clb-CDK1 inhibition permits Cdh1 phosphorylation by CDK1 releasing it from the APC/C and thereby shuts off B-type cyclin proteolysis. This stabilizes B-type cyclins and permits progression into S and M phase. After chromosomes have been replicated and bioriented on the mitotic spindle, silencing of the spindle assembly checkpoint (SAC) permits the APC/C to use a second co-activator, Cdc20, to target its substrates^[120]. Intriguingly, Cdc20 binding to APC/C requires CDK1 phosphorylation and thereby cyclins set the stage for their own destruction^[120, 136]. In addition to B-type cyclins, Cdc20-APC/C targets the Separase inhibitor Securin for destruction^[137-139]. Separase in turn is a protease that cleaves the kleisin subunit of the Cohesin complex, resolving sister chromatid cohesion^[65, 140]. Cleavage of the kleisin is the only event required to trigger anaphase in budding yeast. However stabilization of the spindle during anaphase B, mitotic exit and reentry into G1 requires destruction of cyclins and reversal of CDK1 phosphorylation by the phosphatase Cdc14^[91, 141]. Cyclin destruction during mitotic exit proceeds in two steps, an initial phase that is mediated by Cdc20-APC/C and a later phase mediated by the G1 APC/C, Cdh1-APC/C^[120]. Similarly, release of the CDK1-antagonizing phosphatase Cdc14 from the nucleolus proceeds in two phases. Partial early release through the FEAR pathway (Cdc14 early release) and the later full release through the mitotic exit network (MEN)^[142, 143]. Like Cdc20-APC/C activity, Cdc14 release by the FEAR pathway requires CDK1 activity. Cdc14 is sequestered in the nucleolus, bound to Net1. CDK1 phosphorylates Net1 to liberate Cdc14 but this is suppressed by the phosphatase PP2A until anaphase onset. When the SAC is silenced and Separase is liberated from Securin, it downregulates PP2A mediated dephosphorylation of Net1 by a mechanism distinct of its protease activity and thereby permits CDK1 to release Cdc14^[144]. Were the FEAR pathway and Cdc20-APC the only mediators of mitotic exit, falling CDK1 activity would quickly deactivate both, re-sequestering Cdc14 into the nucleolus and removing Cdc20 from APC/C, leading to a failure to exit mitosis. Cdh1-APC/C and MEN allow cyclin B destruction and reversal of CDK1 phosphorylation in absence of CDK1 activity. Cdc14-dephosphorylated Cdh1 can bind to APC/C and target B-cyclins for destruction^[120]. Further the MEN triggers full, CDK1 independent Cdc14 release in response to a number of stimuli, which in part consist of signals generated by correct spindle positioning along the mother-bud axis thereby forming the spindle-positioning checkpoint. The GTPase-like protein Tem1 is placed at the

apex of this pathway and is thought to sense positional information from the spindle. It is asymmetrically localized to the daughter-bound SPB and thought to be activated once it enters the bud, triggering Cdc14 release through a signaling cascade consisting of cdc15 kinase and the Mob1/Dbf2 kinase complex which ultimately effects Cdc14 release^[143-145]. Falling CDK1 activity also allows the transcription factor Swi5 to re-enter the nucleus and initiate Sic1 expression, contributing to Clb-CDK1 inactivation and allowing reentry into G1^[146, 147].

2.4 The spindle assembly checkpoint

Chromosomes that have not correctly bioriented block the onset of anaphase through a pathway termed the spindle assembly checkpoint (SAC). This is generally vital for survival as disengaging sister chromatids before each one has become targeted to their respective pole will lead to missegregation and a loss of genomic stability. Budding yeast represents one exception to this rule. Here the SAC is not essential because its early spindle assembly allows kinetochores to attach before DNA replication is complete. Therefore, in an unperturbed cell cycle, budding yeast will have bioriented its chromosomes long before chromosome segregation is attempted^[148]. The intact SAC is able to block anaphase in the face of a single unattached kinetochore^[149-151]. While the simplistic view is that a single kinetochore generates an anaphase inhibitor potent enough to postpone anaphase indefinitely or until apoptosis is triggered in response to a prolonged arrest, multiple inhibitory mechanisms exist within the SAC. Further, a number of cases in which cells arrest either only transiently or only in response to multiple unattached kinetochores have been reported. One prominent example for this is found in the highly aneuploid HeLa cell line which is prone to initiate anaphase when few chromosomes are unattached but robustly arrests when all are unattached^[152]. This would suggest that instead of a single inhibitory pathway generating an "all or nothing"-response to a chromosome that has not bioriented, multiple pathways serve to inhibit anaphase onset. A number of SAC proteins have initially been identified in budding yeast and subsequently been found conserved in animals. These are Mad1, Mad2, Bub1, Bub3 and Mps1 as well as Mad3 which in animals has fused to a Bub1 related kinase domain and is therefore referred to as BubR1. Bub1, Mps1 and BubR1 are all active kinases^[72, 148, 153-169]. A deviation from this general statement is found in *C.elegans*, which possesses a Mad3 homologue that does not have any kinase domain and does not possess any Mps1 related kinase^[170].

2.4.1 The SAC blocks anaphase by inhibiting Cdc20-APC/C

The transition from metaphase to anaphase requires activation of Cdc20-APC and the degradation of its targets, Securin and B-type cyclins. The SAC blocks this transition by

inhibiting Cdc20-APC/C. Among the core checkpoint proteins, 3 inhibitory mechanisms are known. Bub1 is able to phosphorylate Cdc20 directly which inhibits Cdc20-APC/C in vitro. This phosphorylation is however not required for a SAC arrest in vivo^[171]. The related BubR1 kinase also phosphorylates Cdc20, this is however not inhibitory^[172]. Both BubR1^{Mad3} and Mad2 can bind to different sites on Cdc20 individually and act as a stoichiometric Cdc20-APC inhibitor. Inhibition of Cdc20-APC/C by Mad2 and BubR1^{Mad3} is synergistic and both binding of Mad2 or BubR1^{Mad3} enhances binding of the other^[172-177]. The mechanism of Cdc20-APC inhibition by BubR1^{Mad3} is well defined. It supplies degron motifs that compete with bona-fide Cdc20-APC/C substrates for recognition. Additionally it promotes APC/C mediated ubiquitination and destruction of Cdc20, and it has been suggested that it either acts to position Cdc20 as an APC/C substrate or that its degron sequences act in trans^[178-182]. It is important to note that an active SAC is a steady state in which both Cdc20 and SAC proteins are continuously synthesized and destruction of Cdc20 serves to tip the balance towards an arrest^[183]. The ability of Cdc20 to bind to both, Mad2 and BubR1^{Mad3} has fostered the idea of a mitotic checkpoint complex (MCC) to be the soluble inhibitor generated by unattached kinetochores. This complex consists of Mad2 bound to Cdc20 and a complex of BubR1^{Mad3} and Bub3 that binds to a second independent site on Cdc20 via BubR1^{Mad3} ^[184-186]. The recent crystal structure of the fission yeast MCC corroborates BubR1^{Mad3}'s function as pseudo-substrate inhibitor and demonstrates additionally that the full MCC shifts the position of Cdc20 of the APC/C, disrupting a second, composite, degron receptor site^[187]. However it should be noted that a number of investigators have reported BubR1^{Mad3}-Cdc20 and Mad2-Cdc20 stoichiometries which are inconsistent with a single entity, the MCC, formed as the product of a linear pathway. Most interesting, the amount of Mad2-Cdc20 relative to BubR1^{Mad3}-Cdc20 appears related to the nature of SAC arrest^[174, 180, 188, 189]. In Taxol arrested cells which are generally presumed to be arrested because of low tension, the amount of Mad2 associated with a Cdc20-BubR1^{Mad3} complex is lower than in a Nocodazole arrest where all kinetochores are unattached^[190]. Thus, the MCC, while isolatable from arrested cells and reconstitutable in vitro, may either be a dynamic entity i.e. different subunits join and leave at different timepoints or in response to different stimuli or alternatively it may be one of multiple checkpoint complexes.

2.4.2 Activating the SAC

How do kinetochores sense mal-attachment and activate the SAC? Mechanistically this is not well understood. Firstly it is known that the MCC assembles before mitosis in absence of functional kinetochores, as soon as Cdc20 is expressed. To reconcile this with the idea of a kinetochore generated signal it has been proposed that the MCC is assembled kinetochore-independent in interphase to give a baseline timer, a minimum duration of mitosis. Kinetochore-directed MCC assembly then extends this timer if it senses erroneous

attachment by synthesizing additional MCC^[185, 189, 191]. In this vein, loss of Mad2, BubR1^{Mad3} or the Mps1 kinase, which is required for MCC assembly in both interphase and mitosis, significantly decrease the duration of mitosis while loss of Mad1, Bub1 or Bub3 do not^[191, 192]. To generate a SAC signal based on the MCC, kinetochores would have to catalytically facilitate MCC assembly. Indeed an interesting catalytic mechanism has been partially delineated over the past years. Mad2 can adopt either of two conformer states, open or closed (O-Mad2 and C-Mad2), which slowly interconvert with a half life of about 9h in vitro. Only C-Mad2 binds Cdc20 with high affinity and promotes BubR1^{Mad3} binding. A tetramer Mad1/C-Mad2 is recruited to unattached kinetochores and the C-Mad2 in the tetramer is able to recruit additional O-Mad2. By an undefined mechanism that requires Mps1 kinase activity, the Mad1-C-Mad2 complex promotes the conversion of bound O-Mad2 to Cdc20 binding C-Mad2^[193]. In this model, unattached kinetochores would promote binding of Mad2 to Cdc20 and subsequently BubR1^{Mad3} would join the complex from the cytoplasm, supported by the fact that while BubR1^{Mad3} is required for a SAC response, a cytoplasmic fragment containing Cdc20 binding regions is sufficient^[194]. While in vitro isolated chromosomes amplify Cdc20-APC inhibition only through Mad2 but not through BubR1, it is questionable if Mad2-directed MCC assembly is the only active mechanism due to a number of reasons^[174, 195]. Firstly, Mad1 and Mad2 leave the kinetochore as soon as it becomes end-on attached. In experiments in which microtubule dynamics were perturbed by decreasing the temperature to 23°C, cells arrest dependent on BubR1 and Mad2 for up to 80min although both Mad1 and Mad2 were absent from the kinetochore^[196]. Further, while in budding yeast the assembly of the MCC in vivo seems linear insofar as Mad1 is required for Mad2 binding to Cdc20 and Mad2 is required for Mad3 binding to Cdc20 but itself is independent of Mad3, in *D.melanogaster* BubR1 or Mad2 can bind to Cdc20 in the absence of the respective other^[177, 184]. More important a loss of Mad2 in *D.melanogaster* fails initial establishment of a SAC but when arrested by a proteasome inhibitor and released into Nocodazole later, a sustained BubR1 dependent checkpoint is active^[197]. Lastly, when one assays the turnover kinetics of checkpoint proteins on vertebrate kinetochores, one observes that BubR1 and Cdc20, in contrast to Mad2, show a similar biphasic recovery from photobleaching and for Cdc20 this is dependent on BubR1^[198]. The slower recovery phase of BubR1 and Cdc20 is similar to Mad2 recovery and this has been equated to the event of MCC formation. The fast phase in contrast may equate to Cdc20 recruitment by BubR1. Cdc20 recruitment by BubR1 has been directly demonstrated in *D.melanogaster* and appears likely in vertebrates where the localization pattern of Cdc20 parallels that of BubR1. In detail, appearances of BubR1 and Cdc20 on the kinetochore coincide temporally. While Mad2 is lost on attachment, BubR1 and Cdc20 decrease only when tension is applied but persist at lower levels at kinetochores through anaphase^[177, 198-200]. Thus it is debatable if generation of Mad2-Cdc20 at unattached

kinetochores is the only pathway to synthesize MCC or if, for example, attached tensionless kinetochores that have lost Mad2 may achieve this through an alternate pathway involving an initial BubR1^{Mad3}-Cdc20 complex that is later joined by cytoplasmic Mad2. A further possibility is the assembly of the entire MCC at the kinetochore, suggested by the fact that SAC proteins upstream of BubR1^{Mad3} and Mad2, namely Bub3 which binds Bub1 and BubR1^{Mad3}, the Mad2 receptor Mad1 and Bub1, form a complex upon activation of the SAC that contains neither Mad2 nor BubR1^{Mad3} and could act as an assembly platform^[155, 201]. The function of this complex however is unknown. Lastly the APC/C localizes to unattached kinetochores. It localizes independently of Cdc20 and it has been argued that the APC itself may need to be sensitized for inhibition by the checkpoint at the kinetochore^[172, 199, 202].

2.5 The mitotic spindle

2.5.1 Microtubule dynamics and regulation by MT associated proteins

Microtubules are the basic building blocks of a mitotic spindle^[203-205]. These are tube-shaped self assembling biopolymers formed from α/β -tubulin heterodimers^[206-213]. Within a MT, tubulin heterodimers make head to tail longitudinal contacts forming elongated protofilaments while lateral bonds between dimers serve to generate sheets of 13 protofilaments that close into tubules^[214-223]. MTs display both structural and dynamic polarity^[224]. They grow preferentially and faster at one end, defined as the +end, while the -end requires a higher tubulin concentration to initiate growth^[225-228]. MTs differ from equilibrium polymers as polymerization does not simply proceed until free subunit concentration drops below the critical concentration. Rather they switch stochastically between polymerization and depolymerization. This property is termed dynamic instability and is a result of tubulins' GTPase activity and the conformational change it undergoes after hydrolyzing its bound nucleotide^[229, 230]. A GTP-tubulin heterodimer consists of two globular domains connected at an angle that increases on hydrolysis^[231-234]. In solution tubulin can exchange its nucleotide while when incorporated into the MT lattice, exchange is blocked^[235, 236]. After assembly into MTs, GTP tubulin converts to GDP tubulin. This renders its conformation less compatible with the extended MT structure. Incorporated into the MT, a preferentially curved protofilament is forced into an elongated conformation, which changes the lattice spacing of the MT and stores elastic energy in the structure in the form of lattice strain^[230, 237, 238]. Upon depolymerization this energy is released as lateral bonds are broken and GDP-protofilaments assume their preferred conformation, curling back from the shortening end^[231]. The stored elastic energy can be used to work, a shortening MT can pull two particles together if they are stably anchored to opposite ends. Conversely the decrease of free energy that drives polymerization allows a growing MT to push on particles located in its

path^[239-242]. Because there is a lag between incorporation into the lattice and hydrolysis of GTP, polymerizing MTs retain a region of GTP-tubulin crowing the growing end, a GTP cap^[243-245]. Further, MTs grow by closure of a leading, polymerizing tubulin sheet^[214, 246, 247]. Both structures, the GTP cap and the leading sheet, are believed to be stabilizing structures. The cap because its lateral bonds can hold the tips of protofilaments together against their tendency to curl apart, the sheet because its curvature is closer to that of an individual protofilament than a closed MT. A growing MT switches to shrinkage when hydrolysis catches up with polymerization and the GTP cap is lost. A fast rate of sheet closure may lead to a catastrophe as this stabilizing structure is lost. Very recently it has been reported that MTs have an intrinsic aging mechanism and that longer MTs are more prone to undergo catastrophe. Catastrophe requires at least three destabilizing events, possibly the acquisition of lattice defects or structural changes in the polymerizing +end^[248]. In vivo, dynamic instability is observable but MT dynamics are regulated by a plethora of microtubule associated proteins. Generally mitotic microtubules are more dynamic than interphase microtubules^[141, 249, 250]. Growth rate in vivo is faster than expected based on the cellular tubulin concentration alone and at growth rates where one observes virtually no catastrophes in vitro, they are frequent in vivo^[251-254]. Moreover, MTs are locally regulated, nucleated at specific subcellular structures during mitosis, i.e. centrosomes or chromosomes, selectively stabilized when they make contact with some structures, such as the kinetochore, or destabilized when contacting other structures such as the bud neck in yeast^[255]. Lastly, motor proteins and nonmotor proteins serve to crosslink MTs into bundles and sort them into a defined fusiform structure, the mitotic spindle.

The γ -tubulin ring complex (γ -TuRC) is a well-established MT nucleator^[256]. The γ -TuRC contains the α/β -tubulin related γ -tubulin^[257]. γ -Tubulin is thought to oligomerize into one turn of a helix corresponding to the lattice spacing of a MT and allow assembly of α/β -tubulin on top, providing a MT template and capping the -end to stabilize it against depolymerization^[258-260]. Budding yeast contains only a subcomplex of the γ -TuRC, the γ -tubulin small complex (γ -TuSC) which is thought to function similar to the γ -TuRC^[256, 261].

MT +end dynamics and interaction with subcellular structures or surfaces is thought to be primarily regulated by a number of MT +end localizing proteins or +tips^[262-264]. The prime +tip, the calponin homology domain protein EB1, is able to autonomously track polymerizing +ends by recognizing the GTP-cap of growing MTs. By interaction with other +tips, EB1 allows them to track +ends^[265-268]. In itself EB1 promotes dynamic instability. It binds to two adjacent protofilaments, promoting polymerization, increasing growth rate and preventing lattice defects. However, because it expedites leading sheet closure, this stabilizing structure is shortened, rendering MTs prone to catastrophe^[268-270]. Clip170 is a second well characterized but non-autonomous +tip. It requires EB1 and tyrosinated α -tubulin, the C-

termini of both form a composite binding site for Clip170 at MT +ends^[267, 271-274]. Clip170 in turn recruits p150^{glued} of the Dynactin complex, rendering recruitment of Dynein/Dynactin to +ends dependent on both EB1 and Clip170^[275-280].

The XMAP215/Dis1- and the CLASP- families are established MT polymerases^[281-286]. Both catalyze the addition of tubulin heterodimers to the +end. Under certain conditions XMAP215 can also catalyze the reverse reaction in vitro, removal of tubulin from ends. It increases both growth and shrinkage rate of MTs and thereby renders them more dynamic^[287-289]. Kinetochore-localized CLASP has been demonstrated to promote the incorporation of tubulin at the +end of kMTs and it may do so specifically under tension, allowing a switch to kMT growth in response to applied tension^[290, 291]. CLASPs bound to MT walls are thought to promote rescue if a depolymerizing MT +end passes by while XMAP215 decreases the frequency of rescues^[284, 288].

Depolymerases induce MT shrinkage. OP18^{Stathmin} may act by either sequestering tubulin dimers or inducing catastrophe by increasing protofilament curvature at +ends. Its mechanism of action is pH dependent^[292-295]. The kinesin-13 family has no motor activity and induces depolymerization from either +end or -end. A kinesin-13 utilizes its ATPase activity to trigger a catastrophe by inducing a GDP-tubulin protofilament like bend into the GTP- protofilaments at the +end. This turns catastrophe into a one-step event^[248, 296-299]. In contrast, members of the kinesin-8 family are +end directed motors^[41, 248, 300-302]. They are thought to walk along a MT until they reach the +end where they stop. When reached by following kinesin-8 motors, they are bumped off the tip, taking only one or two tubulin dimers with them. This slows MT growth and promotes aging, inducing a catastrophe through the MT inherent multistep process. Kinesin-8 family members are processive +end directed motors and longer MTs recruit higher amounts of kinesin-8. Thus they act as length-dependent, +end specific depolymerases.

Lastly, the assembly of a structure such as the mitotic spindle requires sorting and crosslinking of MTs. This is accomplished by a number of nonmotor MT crosslinkers such as APC (Adenomatous polyposis coli), NuMA, NuSAP, TPX2, HURP and molecular motors, some of which have intrinsic crosslinking activity^[303-313]. HURP has the notable ability to promote polymerization of an additional, stabilizing sheet of tubulin around a MT +end but it is not clear if this is an in vitro effect entirely^[314]. The tetrameric +end directed kinesin-5 motors are bipolar with two motor heads at either end. Although this conformation alone allows them to crosslink MTs, additional non-motor MT binding domains have been recently identified^[315-317]. The dimeric -end directed kinesin-14 family requires both the motor and the additional N-terminal nonmotor MT binding sites to crosslink MTs^[318-324]. Kinesin-12 is dimeric, +end directed and may be able to crosslink MTs when in complex with TPX2^[325, 326]. The -end directed Dynein in turn binds to the Dynactin complex, which serves as a cargo

adaptor and enhances processivity of Dynein^[327, 328]. In addition a complex of Lis1 and NudE/L associates with Dynein/Dynactin and strengthens Dynein's MT binding during its ATP cycle, which is thought to adapt it for high loads^[329-331]. The largest subunit of the Dynactin complex, p150^{glued}, has non-motor MT binding and crosslinking activity^[332, 333].

2.5.2 Spindle assembly and kinetochore attachment in yeast and animals

A spindle contains up to three distinct populations of MTs that emanate from each of its two poles with their +ends pointing outwards^[334-336]. Interpolar MTs (ipMTs) emanate from either pole and overlap in the spindle midzone, kinetochore MTs (kMTs) connect each sister kinetochore to one pole. Astral MTs (aMTs) are present only in astral spindles in which poles are organized by MTOCs while they are absent from anastral meiotic spindles or mitotic spindles of higher plants^[337]. aMTs project away from the spindle, radial in centrosome-containing spindles and as a bundle from yeast SPBs. They can mediate interaction with the cortex, facilitating spindle positioning within the cell.

Both spindle assembly and structure are considerably more complex in metazoa compared to budding yeast. Metazoan spindles may contain hundreds of MTs while budding yeast contains only about 40, 32 kMTs for each of the 32 sister chromatids and about 8 ipMTs^[338-340]. Further, animal spindles assemble by two superimposed pathways; one driven by centrosomes and one driven by chromosomes, while yeast only utilizes a single MTOC driven pathway^[341-343].

Classical MTOC driven spindle assembly begins in prophase, when two microtubule organizing centers (MTOCs), centrosomes in animals or SPB's in budding yeast, form a central spindle by interdigitating ipMTs. In budding yeast this is accomplished by three balanced forces. SPBs nucleate cytoplasmic aMTs and ipMTs through γ -TuSC tethered to receptors at both their cytoplasmic and nuclear face^[344]. Kinesin-5 is activated by CDK1, crosslinks and pushes anti-parallel overlapping ipMTs apart, separating the SPBs. Kinesin-14 in turn crosslinks ipMTs and provides a resisting force, counteracting spindle elongation^[345-349]. Astral pulling forces generated by Dynein are able to rescue mutants defective in kinesin-5 driven spindle elongation but Dynein's role in spindle elongation is likely limited to anaphase B where it serves mainly to pull the two nuclei into either mother or bud^[50]. Once chromosomes have bioriented, kinetochores are placed under tension drawing poles inward, evidenced by the stretched centromeric chromatin during normal metaphase and the elongated spindles observed when kinetochores are defective^[52, 350].

In animal spindles a similar collection of balanced forces drives spindle assembly. Initially, centrosomes nucleate microtubules via γ -TuRC and begin separation during prophase, which may not complete before NEBD, through transport along the Dynein-enriched NE^[351-353]. In human cells kinesin-5 assists prophase separation by anti-parallel MT sliding^[354-361]. At

NEBD kinesin-14 is liberated from the nucleus and provides a resisting force against spindle elongation by kinesin-5^[318, 360, 362-366]. However, in contrast to yeast, Dynein/Dynactin localized to +ends through Clip170, supplies the dominant collapsing force to counteract kinesin-5 in vertebrates.^[318, 360, 361, 367] In addition kinesin-12 functions in parallel with kinesin-5 to push poles apart^[368]. With the release of nuclear spindle assembly factors the balance of forces changes and if centrosomes have not separated sufficiently during prophase, they will collapse into a monopolar spindle. Recently, a kinetochore derived pushing force has been shown to promote bipolar spindle assembly specifically when centrosome separation does not complete before NEBD. This force is generated by continuous growth of the kMT +end anchored to the kinetochore which pushes the kMT -end outward^[369]. Like their yeast counterparts, bioriented chromosomes in animal cells will ultimately be placed under tension, resulting in a force resisting spindle elongation. Additionally, animal chromosomes are under the influence of polar ejection forces, which derive from growing ipMTs impinging on chromatin and chromatin bound +end directed kinesins^[370-373]. The budding yeast SPB is a relatively compact structure, where Microtubules are tethered, via intervening proteins, to a central plaque consisting of a 2-dimensional crystalline lattice of Spc42^[14, 374]. Animal spindle poles, centrosomal or acentrosomal, rely on active mechanisms that crosslink MT -ends to focus them into poles and attach them to centrosomes if present. They may fracture under abnormal traction or if a loss of spindle crosslinkers perturbs their integrity, yielding multipolar spindles^[375, 376].

In prometaphase chromosomes are captured and bioriented on the spindle. Dynamic MTOC-nucleated MTs probe the cyto- or nucleoplasm for kinetochores, a mechanism termed search and capture^[377, 378]. If a single MT contacts a KT, the chromosome is transported poleward, its kinetochore laterally attached to the MT wall^[379]. Budding yeast utilizes kinetochore-bound kinesin-14 for this form of transport. Upon lateral attachment, kinesin-8 is released from the kinetochore and, in complex with Stu2 of the XMAP215/Dis1 family of MT polymerases, walks to the plus end and promotes rescue of this MT^[380, 381]. It may however undergo catastrophe and depolymerize until it reaches the KT, whereupon either lateral attachment is converted to an end-on attachment or the MT undergoes a Stu2 dependent rescue^[382]. Although this event can be observed when kinetochores are conditionally activated, it is unclear to what extent search and capture takes place during unperturbed yeast mitosis as centromeres replicate early and there is only a very transient detachment from SPB nucleated MTs which in budding yeast persist throughout the cell cycle^[45, 382]. Animal chromosomes undergo search and capture after NEBD during normal mitosis, although poleward movement after lateral attachment is mediated by kinetochore-tethered Dynein^[379, 383, 384]. Once at the pole, the close proximity facilitates end-on attachment of one kinetochore, yielding a monoriented chromosome. In animals the monoriented chromosome can then be

pulled towards the spindle midzone by kinetochore tethered Kinesin-7 (CENP-E) where the likelihood of an end-on attachment by MTs from the opposite pole is increased^[385, 386]. End-on attached kMTs are selectively stabilized, once both kinetochores of a chromosome have attached, the chromosome is bioriented and congresses to the spindle equator where it remains stably attached until anaphase onset. Budding yeast exclusively utilizes this classical pathway for chromosome attachment, adding one twist: it can nucleate and tether +end distal MTs at its kinetochores, independent of the γ -TuSC, which then interact with spindle MTs and are transported polewards to assist biorientation. These MTs are lost once the +end of a SPB nucleated MT attaches^[387].

Animal cells employ a second pathway for spindle assembly, which is chromosome rather than centrosome driven^[341-343, 388, 389]. Here, upon NEBD, MTs are nucleated with random orientation in the vicinity of chromosomes. Subsequently, they become sorted and crosslinked into two bundles with their +ends overlapping in the vicinity of the chromosomes and their -ends projecting away, focused into two anastral poles lacking MTOCs. Chromosomal spindle assembly is initiated by two independent pathways, a RanGTP gradient emanating from chromosomes and the chromosomally located Aurora B kinase^[390-393]. Aurora B kinase localizes to chromatin and locally downregulates kinesin-13 and OP18/stathmin, permitting MT assembly^[394-396]. A RanGTP gradient centered on chromatin is generated by the chromosome bound Ran-GEF RCC1^[393, 397]. RanGTP in turn effects localized release of kinesin-14, NuMA, NuSAP, HURP and TPX2 from Importin^[306, 307, 310, 312, 398-402]. During chromosomal spindle assembly kinetochores are major MT nucleating sites and bundles of kMTs termed kFibers direct spindle assembly^[377, 403]. A local accumulation of RanGTP at the kinetochore induces nucleation of microtubules through the kinetochore-localized nuclear pore Nup107-160 complex which tethers and activates γ -TuRC in response to RanGTP^[403, 404]. RanGTP at the centromere is quickly hydrolyzed after MT nucleation by recruitment of the nuclear export receptor Crm1 in complex with RanBP2 and RanGAP1, which promotes local RanGTP hydrolysis and shuts off nucleation. Chromatin nucleated MTs are amplified by microtubule dependent microtubule nucleation. The augmin complex tethers γ -TuRC to existing MT walls and promotes further nucleation^[405]. The +end of a subpopulation of kinetochore-nucleated MTs will become embedded into the kinetochore and form kMTs. One may speculate that an outer kinetochore localized +end motor, such as CENP-E, could assist herein. The +end MT crosslinker HURP, which is required for the formation of kFibers, associates with kMTs and they elongate as tubulin is incorporated into their plus end by CLASPs^[152, 291, 311, 312, 369, 403]. kMTs form depolymerization resistant, highly crosslinked bundles, termed kFibers^[406-408]. HURP is found in a complex, termed EXTAK, containing in addition TPX2, XMAP215, Aurora A and kinesin-5. It has been suggested that, because this complex contains crosslinking, polymerase and sliding capabilities, it would be

ideally suited to promote assembly of a bipolar spindle, coupling MT elongation with outward movement of kMTs^[311]. However it is currently unclear if HURP is exclusively active on kFibers. While overexpression of HURP induces ectopic cold-stable kFiber-like bundles, the EXTAK complex was identified as a factor that promotes bipolar spindle assembly on chromatin coated beads devoid of kinetochores^[311, 312]. No structural component of the kinetochore is currently known to recruit HURP although it does show kinetochore specific localization, slightly distal from the core kinetochore microtubule binding site, the KMN network. A second crosslinker, APC (Adenomatous polyposis coli) localizes internal to the KMN network.^[409, 410]

Sorting and assembly of chromosomally nucleated MTs into a spindle is mediated by a similar set of factors involved in astral spindle assembly. Kinesin-5 preferentially generates anti-parallel bundles and slides -ends apart but stalls once it reaches the +end. Kinesin-14, which slides +ends apart, preferentially generates asters where -ends are clustered and +ends lie distal^[356, 411-413]. As is the case with spindle elongation, Dynein functions in parallel with kinesin-14 and in anastral spindles of *Xenopus* provides the major pole focussing activity^[413]. To generate a focused pole that can resist the applied forces the Dynein-Dynactin complex, which itself has intrinsic crosslinking ability additionally transports the crosslinkers TPX2 and NuMA polewards to support a stable structure^[305, 414-418].

RanGTP and Aurora B generate anastral meiotic spindles, but they function superimposed on the dominant MTOC-driven mechanism during mitosis. Chromosomally nucleated kMTs are threaded into the spindle that assembles between the two centrosomes by Dynein dependent poleward transport along ipMTs anchored at the centrosomes^[377, 403, 419, 420]. Both pathways cooperate, centrosomal MT nucleation is enhanced by the RanGTP pathway and centrosomal MTs show directional growth towards chromatin suggesting that MT stabilizing gradients of RanGTP and Aurora B downregulated depolymerases act as a guidance system^[377, 393, 421-423].

2.5.3 Poleward flux, kFibers and anaphase A

Considerable differences exist between the spindle dynamics of budding yeast and animals. One is the formation of kFibers mentioned in the preceding paragraph. In budding yeast only a single kMt attaches to each kinetochore^[13, 49]. -Ends are silenced, stably anchored to the y-TuSC at the SPB and only +ends are dynamic^[424]. kMT dynamics during metaphase and anaphase are more complex within the kFibers of animal cells. Firstly, kMTs and indeed all spindle MTs undergo poleward flux^[425, 426]. Poleward flux describes a net movement of tubulin towards spindle poles and can in principle arise from two processes, either the motor dependent transport of entire MTs towards the pole or simultaneous polymerization of a MT +end and depolymerization at its -end, allowing tubulin to flux through the polymer. Both

processes are active but the extent of their contribution to flux of kMTs and ipMTs differs. Anastral meiotic spindles contain a high number of ipMTs which flux dependent on kinesin-5. It is thought that they are nucleated in the vicinity of chromosomes, then pushed out of the midzone by kinesin-5, pulled polewards by Dynein and fed into the pole-localized kinesin-13 depolymerases MCAK and Kif2a^[427-432]. Dynein itself transports Kif2a poleward and thereby is responsible for pole focusing, MT transport and the localization of depolymerase activity to the pole^[430]. In spindles in which ipMTs are less abundant, one observes a motor independent flux that likely derives from kFibers fluxing by +end growth and depolymerization of -ends anchored at the pole^[385]. In line with this, most ipMTs are non-continuous and are thought to form a tiling array while most kMTs are continuous between pole and kinetochore^[339, 340, 433]. However it can't be excluded currently that ipMT and kMT flux may occur by overlapping mechanisms^[434].

kFibers are an integral structural component of the mitotic spindle and some of their roles have already been mentioned. They push on incompletely separated centrosomes during spindle assembly^[369]. Furthermore when spindles are placed under pressure, they elongate and this elongation seems to be driven by pushing kFibers. When pressure is decreased, kFibers resist a collapse of the spindle to its original size^[435]. This creates a conceptual problem. kFibers are thought to elongate when under tension and shrink in its absence^[436]. A dominant role in pushing poles apart would however require them to elongate in the absence of tension. It is unknown how such a switch may be regulated. In addition kFibers display significant autonomy. When severed from the pole and removed from the spindle, they maintain constant length and continue to flux^[437]. A possible factor that allows them to flux when disconnected from poles is Kif2a. Dynein-mediated poleward transport along kFibers places it at the right location to promote kFiber -end depolymerization and thereby flux^[430].

During anaphase A, budding yeast chromatids must move via a Pacman mechanism in which kinetochores remain stably attached to depolymerizing +ends, dragging them towards the pole because they do not exhibit flux and -end directed motors are not required for anaphase A^[424]. Animal spindles in turn can utilize flux to power chromosome movement. There are extreme cases in which kFibers continue to polymerize at the +end, while being reeled in by depolymerization of pole anchored kFiber -ends^[438]. Human cells use both flux and Pacman movement, a Pacman-flux mechanism, in which the kFiber shortens from both ends. However, flux based anaphase A movement constitutes only a minor component of poleward movement in human cells^[439]. Three models explain how a kinetochore may remain attached to a shrinking MT +end and harness the energy stored in the microtubule lattice to power chromosome movement. Biased diffusion posits that the force coupler is free to diffuse along the MT lattice but a high energy barrier prevents it from falling off the +end. A shortening MT +end will bias 1-dimensional diffusion towards the MT -end^[440]. The hill sleeve

is a special case of biased diffusion and assumes closely spaced linear arranged tubulin binding sites in the linker. The initial model was based on a sleeve encircling the MT. Thermal motion will allow the MT to penetrate into the sleeve and every additional tubulin-sleeve bond that is formed will decrease the free energy of the system. Therefore the sleeve has a tendency to move towards the -end. However because for each additional bond to be formed the entire sleeve must move along the MT, which requires all existing bonds to be broken, there is a limit to how deep the MT can penetrate before the MT-sleeve bonds become too stable to be broken by thermal energy. A hill sleeve coupler would therefore track both growing and shrinking +ends and not diffuse freely along the MT^[441]. Lastly the forced walk model suggests that protofilaments curling back from the depolymerizing +end of a shrinking MT impinge on the force coupler, pushing it backward along the MT^[442].

2.5.4 Chromosome oscillation during animal prometaphase and metaphase

Budding yeast kinetochores immediately undergo transient separation following biorientation. During transient separation kinetochores move uncoordinated, coupled to the +end dynamics of their individual kMT^[424]. However, rarely does one kinetochore cross over into the other half spindle. It is thought that a spatial catastrophe gradient is active and the frequency of catastrophe increases with distance to the pole. At the same time, attached kinetochores under tension promote rescue and elongation of their kMT. Thus, whenever a kMT grows toward the spindle equator, it is prone to catastrophe while when shrinking to close to the pole it will undergo a tension dependent rescue^[443]. The kinesin-8 Kip3 would be an ideal candidate to generate such a catastrophe gradient. Surprisingly it appears to be the kinesin-5 Cin8, which in yeast is distributed in a gradient along spindle MTs and facilitates length dependent depolymerization of kMTs^[444]. Kip3 in turn suppresses kMT plus end dynamics ensuring KT clustering between the spindle midzone and pole, a role that is also emerging for animal kinesin-8^[445]. During anaphase A however Kip3 may be shortening kMTs as a loss of Kip-3 leads to lagging chromosomes^[446].

In contrast to the uncoordinated movements in budding yeast, animal kinetochores undergo coordinated oscillations. Oscillation is observed on monoriented chromosomes and on bioriented chromosomes in spindles that display a low flux rate. It has been suggested that at high flux rates tension is sufficient to switch both kinetochores to permanent polymerization. However at lower flux rates polymerization from one kinetochore is sufficient to balance the net loss of tubulin polymer to pole localized depolymerases. In this case one of the two sister kinetochores is attached to a polymerizing kFiber while the other kFiber is depolymerizing and the two kinetochores switch between growth and shrinkage coordinately, leading to chromosome oscillation back and forth on the metaphase plate ^[436, 447, 448]. During one oscillation period the centromere remains stretched, but the magnitude of this stretch

increases and the shrinking kFiber at the leading KT undergoes rescue when stretch is maximal, suggesting that at this point tension has increased far enough to switch both KTs to polymerization. The trailing KT switches to depolymerization after a short lag, when tension has sufficiently decreased^[449, 450]. If both kinetochores have an equal probability to switch to depolymerization when tension is low, one would expect directional movement, on average, to cancel out and the chromosome to oscillate around a relatively stable position. A number of factors have been identified that affect oscillation and some of them, such as Sgo2 and MCAK, accumulate specifically on the leading kinetochore while CENP-I accumulates on the trailing kinetochore^[451, 452]. Thus, oscillation may be molecularly controlled rather than just a stochastic switch between growth and shrinkage of the kFibers. Principally, oscillation appears to be driven by two motors. The two kinesin-13s, MCAK and Kif2b, promote oscillation. The kinesin-8 Kif18A in turn dampens oscillations, which contrasts with the established role of kinesin-8s as depolymerases^[453-457]. Kif2b and MCAK are temporally controlled, Kif2b is only active in prophase while MCAKs activity is restricted to metaphase^[458, 459]. The observed temporal regulation of Kif2b and MCAK is likely a response to applied tension and therefore not globally restricted to prometaphase or metaphase but rather regulated at individual kinetochores in response to attachment state^[458-462].

2.6 The kinetochore

The kinetochore integrates many of the mitotic functions described including spindle assembly, SAC signaling and chromosome congression. It may not be surprising then that animal kinetochores are complex machines thought to contain over 100 different components^[463-466]. The repeat subunit model states that the large animal kinetochores are compound structures formed by multiplication of autonomous core structures which are functionally equivalent^[467]. Budding yeast kinetochores are thought to constitute a single copy of this core structure for a number of reasons: budding yeast kinetochores only attach to a single microtubule while human kinetochores attach to ~25. Animal kinetochores can fracture but retain core functions, such as the ability to bind MTs and align on the metaphase plate, demonstrating that they can be subdivided^[467]. Additionally, not only are the identities of core kinetochore components conserved, but their relative stoichiometry and localization within the kinetochore are too^[468-471]. Classical electron micrographs depict the animal kinetochore as a trilaminar structure, two electron dense circular layers separated by an electron-translucent layer. One of the two electron dense layers, the inner plate, abuts the chromatin, while kMTs terminate in the outer plate. Corona fibers project distal from the outer plate^[472]. This appearance is an artifact of chromosome dehydration during conventional sample preparation and new techniques visualize the outer plate as a mat-like structure abutting the centromere, embedded in a clear ribosome free zone surrounding the outer plate^[473]. Fibrils

emanating from this mat contact KMTs directly, but there is no apparent repetitive motif that would correspond to a core structure^[474]. Although an artifact, the classical plate structure serves well for comparative localization studies and descriptive purposes as it illustrates an important point. Kinetochore assemble in a hierarchical manner during the animal cell cycle and a chromatin-bound base recruits microtubule binding components to interact with the spindle. The structural kinetochore can conceptually be split into 3 parts, the chromatin proximal CCAN (constitutively centromere associated network), which is recruited by the CENP-A containing centromeric nucleosome, the KMN network (Kn1-Mis12-Ndc80), which provides the core microtubule binding site within the kinetochore required for end-on attachment and additional outer kinetochore/corona proteins that facilitate initial lateral and the conversion to end-on attachment, many of which are recruited by the KMN network^[475]. It is important to note that this model is an oversimplification, as multiple examples for a bypass of this hierarchy exist, the formin mDia3 for example binds directly to both, centromeric histones and microtubules^[476, 477]. It does, however, present a convenient framework for discussion. While the KMN network is conserved between yeast and animals, further outer kinetochore/corona proteins are not. Recently, Dr. Alexander Schleiffer was able to demonstrate new, albeit distant, homologies among the budding yeast Ctf19 complex, the fission yeast Sim4 complex and the vertebrate CCAN suggesting that this supermolecular network may too be conserved almost entirely between yeast and human.

2.6.1 The KMN network

Because of the central position of the well-investigated KMN network within the kinetochore and its role as core microtubule binding site, it is well suited as an entry point for this discussion^[478]. It consists of two complexes, the Ndc80 complex (NDC80C) and the Mis12 complex (MIS12C) and additionally the protein Kn1. Budding yeast Mtw1 and MTW1C will be referred to as ScMis12 and ScMIS12C, budding yeast Spc105 as ScKn1. NDC80C is a 4 protein complex consisting of Ndc80, Nuf2, Spc24 and Spc25. Ndc80 and Nuf2 both contain CH-domains at their N-termini and dimerize via their C-terminal coiled coil (CC) regions. The C-termini of Spc24 and Spc25 fold into a globular domain that contains a groove lined with conserved hydrophobic residues. N-terminal CC-domains of Spc24 and Spc25 allow tetramerization with the CC domains of Nuf2/Ndc80 generating an elongated complex in which the two globular heads formed by Ndc80/Nuf2 and by Spc24/25 are separated by an elongated flexible rod domain^[479-484]. An internal loop disrupts Ndc80's CC domain and introduces a kink into the rod close to the Ndc80/Nuf2 head^[485]. The Spc24/25 head connects the NDC80C to the rest of the KMN network while the Ndc80/Nuf2 head binds microtubules directly^[478, 486-488]. MT binding requires a number of conserved lysine residues in both CH domains as well as a short tail domain extending N-terminally from the Ndc80 CH domain^[489]. Human NDC80C binds MTs cooperatively and is able to oligomerize on the MT lattice. In

electron-tomographic reconstructions the Ndc80 CH domain can be observed to contact the gap between α - and β -tubulin monomers, both within and between dimers. The Nuf2 head does not directly contact the lattice but might be involved in electrostatic interactions with the lattice. Additionally it was suggested that the Ndc80 tail mediates oligomerization of NDC80C on the lattice by interaction with a Nuf2 head of an adjacent NDC80C^[490, 491]. Oligomerization of Ndc80/Nuf2 heads on the MT lattice is an important feature, as it may explain how a filamentous mat-like kinetochore reorganizes in response to kMT attachment and may provide multiple linearly arranged tubulin binding sites, forming a pliable hill sleeve which on the one hand needs to closely appose tubulin binding sites to the MT wall but on the other hand must adapt to the curling end of a shrinking kMT^[442, 492]. Because the Ndc80 CH domain contacts the gaps between tubulin monomers, its binding to MTs is conformation sensitive. This has been suggested to be the basis of NDC80C's biased diffusion. Rather than the progressive loss of Ndc80 binding sites by loss of tubulin dimers at the +end of a depolymerizing MT, protofilament curling progressively occludes binding sites^[491]. In contrast to the NDC80C, little structural information is available on Knl1. Its C-terminus is required for localization to the kinetochore and binds to the MIS12C^[478]. NDC80C and Knl1 target to kinetochores independently in budding yeast and humans but NDC80C localization is dependent on Knl1 in *C.elegans*^[493-496]. Importantly, like NDC80C, Knl1 has intrinsic MT-binding activity^[478, 493]. The final KMN subcomplex is the heterotetrameric MIS12C complex, consisting of Mis12, Dsn1, Nnf1 and Nsl1, which has the shape of an asymmetric dumbbell. The structural contributions of the individual components in MIS12C are less clearly defined as for NDC80C, but the larger globular domain of the dumbbell is composed of Dsn1, Mis12 and Nsl1, the latter of which extends into the smaller globular domain together with Nnf1^[497]. MIS12C binds both the c-terminal region of Knl1 and the Spc24/25 head of the NDC80C. Crosslinking experiments suggest that a Dsn1/Nsl1 dimer binds to Spc24/25 while Mtw1/Nnf1 in turn connects the KMN network to the kinetochore^[475, 488]. Affinity purification of an epitope tagged ScDsn1 yields a supercomplex of ScNDC80C, ScMIS12C, ScKnl1 and Kre28, a protein that has been suggested to be the yeast homologue of Zwint-1. This supercomplex is equi-stoichiometric, containing one copy of each, ScNDC80C, ScMIS12C and ScKnl1, which suggests that the KMN network may comprise a linking fiber that is recruited to the kinetochore en bloc^[493, 498]. A similar supercomplex is present in *Xenopus* cell lysates, supporting this idea^[499]. Thus, in a model of the KMN network, the Mtw1 complex serves to connect the microtubule binding NDC80C and Knl1 to the inner kinetochore, which is consistent with NDC80C localizing to the outer plate and MIS12C localizing to the central plate in vertebrate kinetochores^[500, 501].

2.6.2 Outer kinetochore and corona components

A number of proteins that are either recruited by the KMN network or, at least in part, by the underlying CCAN localize to the outer plate and corona fibers of the kinetochore. These serve to facilitate initial lateral attachment, kinetochore mobility on the microtubule wall and subsequently the conversion to end-on attachment by the KMN network. Lateral attachment and poleward transport of an animal chromosome is facilitated by kinetochore-tethered Dynein^[379, 383, 384]. Dynein and Dynactin recruitment requires the KMN network, the RZZ complex (Rod1-ZW10-Zwilch), Spindly and Zwint-1^[502-509]. Zwint-1 may have up to 3 contact points on the KMN network, binding to NDC80C, MIS12C and Knl-1 and it recruits the RZZ via a direct interaction with ZW10^[496, 504, 506, 510-513]. It thereby links the RZZ complex to the KMN network, which in turn recruits Dynein and Dynactin. Because ZW10 interacts with both p50^{dynamitin} of the Dynactin complex and the Dynein intermediate chain, it is likely responsible for their independent recruitment to unattached kinetochores. However, multiple pools of Dynein may exist at kinetochores^[460, 507, 514]. Spindly recently was identified as an additional factor required for Dynein/Dynactin recruitment and demonstrated to require the RZZ complex for localization^[508, 509, 515]. Because direct interactions between the RZZ and both Dynein and Dynactin have been described, it is not yet clear if Spindly simply provides an additional link between RZZ and Dynein/Dynactin or if it has a regulatory role in Dynein/Dynactin recruitment. The RZZ complex has been suggested to suppress KMN network microtubule binding as loss of Spindly leads to a severe end-on attachment defect that can be partially rescued by the loss of the RZZ complex^[515]. Once a kinetochore is able to support tension, Dynein/Dynactin are no longer recruited and stream away along the kFiber, stripping the RZZ complex and SAC proteins from the kinetochore in the process. In contrast to poleward transport of chromosomes, stripping of outer kinetochore/corona proteins by Dynein does require Dynactin^[516-520]. Removal of the RZZ complex requires Spindly and is thought to activate the KMN network, facilitating a hand over from lateral to end-on attachment. A second Dynein recruitment pathway rests on CENP-F. CENP-F recruitment is independent from the NDC80C but requires Knl1, Bub1, which is recruited to Knl1 and possibly CENP-H/I/K of the underlying CCAN although the latter is disputed. Because Bub1 does not require CENP-H/I/K to localize, these may be two individual requirements.^[521-524] CENP-F has MT binding activity and recruits Lis1, Nde1 and Ndel1. Nde1 is required for Dynein recruitment and Dynein mediated stripping^[525, 526]. CENP-F, like the RZZ complex, is stripped by Dynein following end-on attachment^[527]. Monooriented chromosomes can congress to the metaphase plate through the kinetochore bound +end directed kinesin-7 CENP-E^[385, 386]. Human CENP-E appears to be recruited to kinetochores through interaction with NDC80C and to a lesser extent through interaction with BubR1. It contains a SUMO interacting motif required for its localization and both Nuf2 and BubR1 are SUMOylated^[528].

Additional requirements for CENP-E recruitment have been described, such as the kinetochore localized Septin-7 and CENP-F, which is partially required for CENP-E localization and interacts with CENP-E^[149, 529-531]. Like the RZZ, Spindly, CENP-F, and SAC proteins, CENP-E is stripped by Dynein from end-on attached kinetochores^[516].

None of the discussed outer kinetochore/corona components are present at the budding yeast kinetochore^[532]. Instead, it recruits two kinesin motors. The kinesin-14 Kar-3 may be linked to the MTW12C via Cik1 and allows poleward transport of laterally attached KTs analogous to Dynein in animal systems. The kinesin-8 Kip3 transports Stu2 to MT +ends promoting a rescue event^[381, 446, 533]. An interactor for Kip3 at the kinetochore has not yet been suggested.

2.6.3 The Dam1 and Ska complexes

NDC80C is critical for end-on attachment and recruits two complexes that are similarly required for end-on attachment and that have been suggested to be functional but not evolutionary homologues, the animal Ska complex (SKA-C), composed of Ska1-3, and the yeast specific heterodecameric Dam1 complex (DAM1C)^[532, 534-544]. End-on attachment and recruitment of both complexes requires the Ndc80 internal loop^[381, 485, 545]. Both SKA-C and DAM1C can couple beads to depolymerizing MT +ends facilitating movement^[534, 546, 547]. While both SKA-C and DAM1C oligomerize on the MT lattice, the structure of a DAM1C oligomer is much more striking as it forms ring or helix like structures on a MT wall^[534, 548, 549]. This has inspired the idea that it may serve to act as a force coupler, either through biased diffusion or by forced walk, remaining connected to the kinetochore via NDC80C^[242, 440, 442, 550, 551]. DAM1C and ScNDC80C interact and bind microtubules cooperatively^[552, 553]. ScNDC80C binding to microtubules is highly sensitive to physiological salt concentrations and shows no specificity for +ends. Further, ScNDC80C only weakly binds to the DAM1C. However, in presence of microtubules and the DAM1C, ScNDC80C-MT interaction is strongly enhanced and NDC80C in complex with DAM1C is now able to track shrinking +ends. Interaction with DAM1C may obviate the need for ScNDC80C oligomerization in budding yeast.

2.6.4 The constitutive chromatin associated network (CCAN)

The Constitutive Centromere Associated CCAN network defines a group of 16 proteins recently identified in vertebrate kinetochores by their co-purification with the centromeric nucleosome^[554-558]. These proteins localize internal to the KMN network and remain at the kinetochore during interphase in contrast to outer kinetochore and corona components^[501, 559]. Earlier genetic studies and more recent biochemical studies in budding yeast identified the 12 kinetochore proteins of the Ctf19 complex and in a number of publications sequence homologies between the budding yeast Ctf19 complex, the fission yeast Sim4 complex and

the vertebrate CCAN have accumulated, most recently expanded by Dr. Alexander Schleiffer^[463, 532, 560-571]. The full list of putative orthologues is given in Table1. ScCENP-W is included in this list for clarity although its identification and characterization is undertaken and described later in this work. Notably, CCAN proteins with the exception of CENP-C have not been found in *D.melanogaster* or *C.elegans*^[572]. Vertebrate CCAN proteins were assigned to groups depending on the requirements for their centromere localization, biochemical interactions and their requirement for cell viability. In vertebrate cells, many CCAN proteins are essential, though loss of some members of the CCAN has a less severe effect on viability. CENP-C and the CENP-T/W complex target kinetochores independently but require the centromeric nucleosome for localization. Chicken cells that have lost either CENP-C or CENP-T/W stop proliferating after 36-48 hrs and undergo apoptosis^[556, 573-577].

Table 1: CCAN protein orthologues in vertebrates, budding and fission yeast

	Vertebrate	<i>S.cerevisiae</i>	<i>S.pombe</i>
CENP-C:	CENP-C	Mif2	Cnp3
CENP-T/W:	CENP-T	Cnn1	Cnp20
	CENP-W	Wip1	SPAC17G8.15
CENP-H/I/K:	CENP-I	Ctf3	Mis6
	CENP-H	Mcm16	Fta3
	CENP-K	Mcm22	Sim4
CENP-N/M/L:	CENP-N	Chl4	Mis15
	CENP-M		
	CENP-L	Iml3	Fta1
CENP-Q/U/P/O/R:	CENP-Q	Okp1	Fta7
	CENP-U	Ame1	Mis17
	CENP-P	Ctf19	Fta2
	CENP-O	Mcm21	Mal2
	CENP-R		
CENP-S/X:	CENP-S	YOL086W-A	SPBC2D10.16
	CENP-X	YDL160C-A	SPCC576.12c
Unassigned:		Nkp1	Fta4
		Nkp2	Cnl2
			Fta5
			Fta6

Sources for the assigned orthologues are: Schleiffer et al, 2012, McClelland et al, 2007, Meraldi et al 2006

Further downstream the CENP-H/I/K and the CENP-L/M/N group of proteins localize to kinetochores interdependently. CENP-K, CENP-H and CENP-I knockouts impact viability severely with cells ceasing to proliferate after 36-48hrs while CENP-M knockouts are less severe and cells stop proliferating after 72 hrs^[556, 578]. Interestingly, it has been shown that CENP-H/I/K is required for centromere localization of CENP-C during interphase but not mitosis^[573]. Conversely, during kinetochore assembly onto frog sperm chromatin, which likely represents a de novo kinetochore assembly onto the centromeric nucleosome, CENP-C is required to recruit CENP-H/I/K^[579]. In fission yeast localization of both, CENP-L/M/N and CENP-H/I/K group proteins, depends partially on CENP-C and CENP-T, suggesting a two-pronged recruitment pathway^[580]. Similarly, both CENP-T and CENP-C depletion lead to a loss of CENP-H from HeLa centromeres and CENP-N can be recruited by ectopically tethering the N-terminus of either CENP-T or CENP-C to a chromosomal site^[577]. Lastly, both CENP-H/I/K and CENP-L/M/N are required for recruitment of the CENP-S/X complex and the CENP-Q/U/O/P/R complex, which localize independently of one another. Chicken cells that have lost CENP-Q/U/O/P/R components are viable and continue to proliferate at an increased generation time. An apparent cell type specific difference has been observed for loss of CENP-S/X, which in chicken cells only leads to minor mitotic defects while strong congression defects are observed in HeLa cells^[581]. As a rule, if any of the members of a given group or complex is lost, all members of the respective group as well as the downstream groups/complexes are lost from the centromere. Exceptions to these localization requirements are CENP-M, which in chicken DT40 cells but not in human cells additionally requires the CENP-Q/U/P/O/R complex but is not required for CENP-L localization, as well as CENP-R, which can be lost from the CENP-Q/U/P/O/R complex without delocalizing the other members from the centromere^[555, 556, 582]. Supporting localization data, the CENP-T/W, CENP-S/X and the CENP-Q/U/P/O/R complexes have been biochemically demonstrated to form stable complexes^[576, 581, 582]. CENP-T/W are histone fold proteins, as are CENP-S/X^[11, 576, 581]. CENP-C is a DNA binding protein^[583-585]. ScCENP-U was initially described as an actin-related protein (Arp100)^[586]. CENP-C and CENP-N have additionally been demonstrated to bind directly to centromeric nucleosomes^[587, 588]. All investigated vertebrate CCAN proteins localize to the inner kinetochore, between centromeric nucleosomes and the KMN network, suggesting a DNA proximal structure possibly corresponding to the inner plate^[470, 501, 559]. The only known exception to this is CENP-T. While its histone fold is located at the inner kinetochore, its flexible N-terminal domain stretches towards the outer kinetochore^[501]. In budding yeast subcomplex identity may be conserved, but recruitment dependency and the loss-of-function impact on viability seems to have been turned upside down with respect to the vertebrate and fission yeast CCAN. ScCENP-Q/U, whose vertebrate counterparts have a mild effect on cell viability when lost, are the only essential

CCAN proteins in budding yeast^[568, 589]. The nonessential members of ScCCAN were identified initially in genetic screens for factors that are required for faithful chromosome transmission. It appears that ScCENP-P/O mutants have the most severe defect in chromosome segregation, while an intermediate defect is observed for ScCENP-N and a relatively weak defect for ScCENP-H/I/K and ScCENP-L^[590]. A quadruple deletion of ScCENP-P and ScCENP-H/I/K, which is expected to remove all ScCCAN components except ScCENP-Q/U, is viable and shows no additive phenotypes^[566, 567, 590]. ScCENP-Q and ScCENP-U are interdependent for centromere localization and required for targeting of ScCENP-O/P. ScCENP-Q/U and ScCENP-O/P have been suggested to form dimeric subcomplexes and to associate into a ScCENP-Q/U/P/O complex following transition of START^[463, 569, 591]. Some of these observations parallel those in vertebrates. In both, vertebrates and budding yeast, depletion of CENP-Q also affects CENP-U protein levels while a loss of CENP-O affects CENP-P protein levels^[463, 582]. ScCENP-Q/U is the most upstream complex within the budding yeast CCAN and requires the CBF3 complex as the most upstream factor in budding yeast kinetochore assembly. The CBF3 complex is required for localization of the centromeric nucleosome and ScCENP-C and indeed all other known components of the yeast kinetochore. The evolutionary origins of the CBF3 complex are mysterious, but, because it is only found in budding yeasts where it plays a pivotal role in kinetochore assembly, its appearance may underlie the change in CCAN recruitment hierarchy^[532]. ScCENP-C in turn is required for recruitment of CENP-P. As ScCENP-P/O are lost in ScCENP-Q/U mutants it seems reasonable to propose that ScCENP-C is required for CENP-Q/U recruitment^[568, 591, 592]. ScCENP-O/P are required to localize ScCENP-N/L and both ScCENP-O and ScCENP-N are required to target ScCENP-I to kinetochores. ScCENP-N may be in complex with ScCENP-L because the latter requires ScCENP-N to localize and this if conserved would be equivalent to the vertebrate CENP-N/M/L group. ScCENP-I has been suggested to form a complex with ScCENP-H and ScCENP-K by yeast two hybrid analysis, the putative budding yeast equivalent of the vertebrate CENP-H/I/K group^[566, 567, 593]. When epitope-tagged ScCCAN proteins are purified from budding yeast, they are isolated in a complex named the Ctf19 complex, after one of its components, ScCENP-O^{Ctf19}. The Ctf19 complex does not contain ScCENP-C but does contain ScCENP-Q/U/P/O, also known as COMA complex, ScCENP-N/L, ScCENP-H/I/K and additionally Nkp1 and Nkp1 for which no homologies have been established. Additionally, affinity-purified Ctf19 complex contained ScMis12 as the only KMN member. Conversely, affinity-purified ScMis12 proteins co-purify ScCCAN members and ScCENP-C^[569, 592, 594]. This would suggest that either the ScCCAN interacts with the KMN network or that the established subcomplex architecture is not absolute and kinetochore proteins may exist in multiple distinct assemblies. Similar to the vertebrate CCAN, the Ctf19 complex and ScCENP-C co-purify with the centromeric

nucleosome^[595]. Recently, Dr. Alexander Schleiffer proposed budding yeast Cnn1 and the products of the uncharacterized ORFs YDL086W-A and Yol160C-A to be homologous to CENP-T, CENP-S and CENP-X respectively. This led us to believe that most of the vertebrate CCAN was conserved in budding yeast and we renamed the Ctf19 complex to ScCCAN, incorporating the novel homologues. However while ScCENP-T^{Cnn1} has been localized to the kinetochore, ScCENP-T, ScCENP-S and ScCENP-X had not yet been detected in association with the Ctf19 complex^[11, 463]. Furthermore, for reasons explained in the results section, a budding yeast CENP-W orthologue eluded identification by a bioinformatics approach.

2.6.5 The CCAN as a recruitment platform for outer kinetochore assembly

With the CCAN located between centromeric nucleosome and the outer kinetochore, it seems plausible that one of its functions would be to supply a binding platform for outer kinetochore components including the KMN network. Loss of function studies, however, have yielded ambiguous results. A number of publications argue CENP-C, CENP-T, CENP-S, CENP-H/I/K and CENP-M depletions to have an effect on centromere targeting of KMN components. Specifically CENP-C depletions lead to a corresponding loss of MIS12C with a less pronounced effect on NDC80C^[573]. Conversely, CENP-T, CENP-S and CENP-H/I/K depletions strongly, but not fully, loose NDC80C localization but have a weak effect on MIS12C localization. Knl1 kinetochore localization is decreased when either CENP-C, CENP-T/W or CENP-H/I/K is depleted^[524, 577, 581, 596]. This asymmetry in KMN network recruitment is also observed when either CENP-C, which recruits high amounts of MIS12C and Knl1, or CENP-T, which recruits high amounts of Ndc80, are force-localized to ectopic chromosomal loci and argues against recruitment of the KMN network as a single entity. CENP-I depletions further lose Mps1 and Mad1 and Mad2 from the kinetochore. This is not unexpected as Mps1 requires NDC80C to localize while Mad1 and Mad2 require NDC80C to be retained at kinetochores against Dynein mediated stripping. CENP-I is also required to recruit Dynactin and possibly CENP-F but not Bub1 or BubR1 and surprisingly not the RZZ complex or CENP-E which do require NDC80C. CENP-C in turn is required CENP-E and to a lesser extent NDC80C as well as both Mad1, Mad2, Bub1 and BubR1. Note that Mad1, Mad2 and BubR1 require Bub1 for localization. CENP-C is furthermore required for RZZ complex and Dynactin recruitment^[451, 524, 579, 596]. CENP-I recruitment weakly depends on MIS12C only during mitosis, which is interesting as the major MIS12C recruitment factor, CENP-C, depends on CENP-I for localization only during interphase but not mitosis^[573, 579, 596-599]. One study in budding yeast suggests that ScCCAN, ScMTW12C and ScNDC80 target to kinetochores independently on the grounds that temperature sensitive ScNdc80, ScMis12 or ScCENP-Q do not loose localization of the respective other complexes^[463]. Another study

suggests interdependence; ScMIS12C is lost in the absence of ScCENP-Q and vice versa. ScNDC80C in turn requires ScMIS12C for kinetochore localization^[600].

2.6.6 Recruitment and tension/attachment sensitivity of kintochore-bound kinases

A number of kinases localize to kinetochores and regulate kinetochore assembly, attachment state and SAC signaling. These include Aurora B, Mps1 and Bub1 in budding yeast and additionally Polo-like kinase 1 (Plk1), BubR1, CDK1 and Nek2a in animals. Localization of many of these kinases is strongly interdependent in animals, connected by multiple feedback loops in which one kinase increases either activity or localization of the other. In yeast however, a relatively simple linear recruitment pathway has been delineated. Here Mps1 is likely recruited to NDC80C. Phosphorylation of unattached NDC80C by Aurora B may promote but not be required for Mps1 recruitment, as is the case in vertebrates.^[601-603] Mps1 in turn phosphorylates Knl1, which allows binding of Bub1^[604, 605]. This linear pathway may be conserved in animals as some studies suggest that NDC80C is required to recruit Mps1, Aurora B accelerates but is not required for recruitment of Mps1 to unattached kintochores and Bub1 is not required for Mps1 recruitment. Mps1, NDC80C, Aurora B and Knl1 in turn would be required to recruit Bub1^[191, 496, 523, 531, 603, 606, 607]. However, significant discord exists on this subject as other studies argue Bub1 localization to be codependent with Mps1 in *Xenopus* extract or independent of either NDC80C or Mps1 in human cell lines. Furthermore, Bub1 persists at kinetochores into anaphase while Mps1 needs to be released before anaphase onset^[191, 531, 602, 608-612]. It is possible that additional localization pathways exist, that localization dependency changes during the course of mitosis or that feedback loops obscure results. In animals three feedback loops have been identified that allow Bub1, Mps1, Plk1 and Haspin kinase to potentiate Aurora B localization and activity. Aurora B localizes in a complex termed the centromeric passenger complex (CPC) including Survivin, Borealin, INCENP and Aurora B itself^[613]. The CPC recognizes two histone phosphorylation marks, namely phosphorylated H3T3, which is generated by Haspin kinase and read by Survivin, and Bub1 phosphorylated H2A, in humans on T120, read by Shugoshin which in turn binds to Survivin^[614-619]. Because Haspin is recruited to Cohesin by Pds5, its H3pT3 mark is placed along the long axis of condensing chromsosomes while the Bub1 placed H2ApT130 spans the inner centromere, the chromatin between two kinetochores. It is thought that the CPC localizes to the intersection of these two marks at the inner centromere. The animal CPC can amplify its own localization by a feedback loop in which it phosphorylates Haspin, increasing its activity, by a feedback loop in which Mps1 promotes Bub1 mediated formation of H2ApT130 and a feedback loop including Plk1 which enriches the CPC on unaligned chromosomes in a Plk1 and Aurora B dependent manner^[620-622]. The latter Plk1 feedback

loop may also be reasonably direct as Plk1 is phosphorylated and activated by Aurora B^[623]. Mps1 can further phosphorylate Borealin, enhancing Aurora B activity and phosphorylation of the CPC by CDK1 is required for it to bind Shugoshin^[610, 617]. Subtle hints suggest that there may be additional factors active in targeting animal CPC. A construct that contains a full length Survivin but only the N-termini of INCENP and Borealin does not target centromeres, suggesting an involvement of Borealins C-terminus^[624]. Furthermore under tension the CPC partially re-localizes from the centromere to the inner kinetochore and a second binding site has been invoked to explain this^[625]. In contrast to animals and fission yeast, budding yeast CPC localization appears to be controlled by none of the described pathways. Neither Haspin nor Bub1 are needed for its recruitment to centromeres. However, budding yeast Survivin binds directly to the Ndc10 subunit of CBF3^[532, 626]. Because INCENP and Aurora B but not Survivin are lost from centromeres when ScCENP-U is absent a second interaction between ScCENP-U and the CPC, distinct from the interaction between CBF3 and Survivin, has been suggested.^[627]

Plk1 appears on animal centromeres before Aurora B. It binds phosphoepitopes via its polo-box binding domain. These epitopes are either generated by proline-directed kinases such as CDK1 or by Plk1 itself. The latter is known as self-primed recruitment and thought to amplify the localization of Plk1 via a product activated feed-forward mechanism while non-self-priming recruitment by CDK1 would be responsible for initial recruitment^[628, 629]. CDK1 primed binding sites are found on INCENP, Bub1 and on BubR1 while self primed binding sites are found on CENP-U and the Dynein/Dynactin associated NudC^[630-635]. A loss of NudC has been described to lose focused localization of Plk1 to the centromere while a loss of CENP-U leads to a loss of Plk1 from interphase centromeres but only to a decrease from mitotic centromeres. While BubR1 does not appear to be generally required for Plk1 recruitment, a loss of Bub1 reduces Plk1 at the centromere and INCENP has been described as absolutely required for Plk1 recruitment.

Similarly to Bub1, the requirements for kinetochore recruitment of BubR1^{Mad3} are debated. It is generally agreed upon that recruitment of BubR1 requires Bub1, Bub3 and Knl1. However, results conflict, even in the same cell line, as to whether Mps1 and Aurora B are required for its recruitment^[160, 192, 496, 522, 530, 531, 606, 608, 610, 636-639].

Lastly, in animals, CDK1 localizes to kinetochores via cyclinB1. No binding partner at the kinetochore is known, but it requires the NDC80C and surprisingly Mad2, which is thought to have no role in attachment besides SAC signaling^[640, 641].

Some of the introduced kinases demonstrate either tension or attachment sensitive behavior. This behavior manifests either in the tension or attachment dependent phosphorylation of substrates or in tension or attachment dependent localization. Bub1 and BubR1 display

tension sensitivity and their levels decrease as kinetochores come under tension. Bub1, additionally, is attachment sensitive and is partially lost from kinetochores upon attachment. CDK1 and Mps1 are attachment sensitive and lost from attached kinetochores^[611, 641]. Tension sensitive phosphorylation is established for both Aurora B and Plk1. Aurora B phosphorylates, among others, NDC80C in response to a lack of tension while these phosphoepitopes are lost when tension is applied^[642, 643]. Although not all of its targets are phosphorylated in a tension dependent manner, Plk1 generates the 3F3/2 epitope on BubR1 which is lost under tension^[633, 644-647]. The basis of Aurora B's tension sensitivity is well investigated. Within the CPC, Aurora B is bound to the C-terminal IN box of INCENP, while the N-terminus of INCENP forms a three helix bundle with Survivin and Borealin, required for the centromere localization of the CPC. INCENP is thought to form a long flexible bridge between kinase activity and centromere targeting activity of the CPC and thereby to act as a "nanoruler". It tethers Aurora B to the centromere and limits its range. Once tension is applied to the kinetochore it stretches, moving Aurora B substrates out of Aurora B's range^[466, 569, 624, 648-652]. The basis of Plk1's tension sensitivity is not known yet.

2.6.7 Regulation of kMT dynamics, attachment and error correction

The kinetochore components introduced above facilitate and regulate attachment, kMT dynamics and error correction. Error correction is an important component of a system that relies on stochastic encounters of microtubules with kinetochores to achieve biorientation of chromosomes. The error correction mechanism reverses failed, syntelic, attachments in which both kinetochores are attached to a single pole. It discriminates between correctly and incorrectly attached kinetochores by their ability to support tension. Only amphitelic attachment, in which each kinetochore is pulled to one of the opposing poles, is stabilized. Syntelic attachments are destabilized by the tension sensitive Aurora B kinase^[638, 653-662]. This entails phosphorylation of KMN components, the N-terminus of Ndc80 implicated in MT binding and oligomerization on the MT lattice, the MT binding domain of Knl1 and the Dsn1 subunit of the MIS12C, decreasing the KMN networks' affinity for MTs^[478, 569, 643, 663]. In budding yeast Aurora B additionally phosphorylates DAM1C, severing its link to NDC80C and thereby to the kinetochore^[552, 569, 652, 664, 665]. The animal SKA-C is phosphorylated by Aurora B and this inhibits its KMN dependent accumulation at kinetochores, suggesting a similar mechanism controlling interactions between the KMN network and Ska complex^[666]. Under tension, DAM1C/SKA-C and the KMN network are stretched away from the inner kinetochore and separated from Aurora B kinase, stabilizing the amphitelic attachment.

Cells that attach multiple kMTs to their kinetochores, such as animal cells or fission yeast, face an additional problem, merotelic attachments, in which one kinetochore is attached to both poles. To overcome this they employ additional error correction mechanisms. Release

of kMTs from the KMN network is a specific response to tension. Merotelic attachments in contrast generate significant tension as two portions of the KT are stretched to opposite poles, rendering them invisible to the SAC^[667]. Thus, the stimulus that activates merotelic error correction is currently ill defined. In addition to mere release of a kMT, animal cells are able to induce kMT depolymerization, either of an entire kFiber or of individual kMTs within a kFiber. The first is observed for syntelic chromosome attachments, which, after moving to the pole, depolymerize an entire kFiber, freeing the kinetochore for MT capture from the other pole^[668]. The second may be a continuous process in which individual kMTs are released from the KT and then re-grow, while the rest of the bundle remains attached, resulting in net turnover of the stable kFiber +end^[669]. kFiber +ends show a high turnover in prometaphase, a lower turnover in metaphase which then abruptly decreases further at anaphase onset^[458, 670]. Prometaphase turnover has been ascribed to the kinesin-13 Kif2b, while the slower metaphase turnover has been ascribed to the activity of MCAK^[459]. Because a loss of Kif2b leads to a failure to correct syntelic attachments, an error that presumably arises early during prometaphase, Kif2b is thought to facilitate the destabilization of an entire kFiber. In contrast, a loss of MCAK allows correction of syntelic attachments but leads to an accumulation of merotelic attachments and therefore MCAK is thought to be active during a less stringent error correction phase later in prometaphase congression^[456, 459, 671]. It is questionable if the error correction mechanism actively senses merotelic attachments. Aurora B is enriched at merotelic attached KTs and recruits additional MCAK, however because both MCAK and the CPC recruiting Sgo2 are also enriched at leading KTs of bioriented chromosomes this may not be a specific effect^[452, 672]. One may speculate that a nonselective turnover of individual kMTs by MCAK allows the abnormally stretched and distorted kinetochore to reorient slowly under the applied tension until one of the two kFibers "wins out", generating either an amphitelic or syntelic attached chromosome^[457]. Kinesin-13 based error correction remains under control of Aurora B. Kif2b is evicted under tension by astrin and astrin localization in turn is negatively regulated by Aurora B in absence of tension^[458, 460]. Aurora B phosphorylation further inhibits MCAK activity and MCAK relocates from the centromere to the inner kinetochore under tension, potentially escaping inhibition by Aurora B^[461, 673]. Therefore, Aurora B regulates a tension dependent switch to an error correction phase that deals mainly with merotelic attachment. It is interesting to note that the two kinesin-13s implicated in error correction are those that drive chromosome oscillation. Oscillation may be a result of MT turnover by Kif2b and MCAK and a manifestation of error correction. As only a subset of chromosomes oscillate, those located centrally in the spindle, there appears to be no requirement for oscillation per se^[450, 487, 657, 674]. Mps1 is involved in error correction and biorientation in both yeast and man. In vertebrate cells Mps1 operates

upstream of Aurora B and displays a similar loss of function phenotype, the inability to correct syntelic attachments. Thus it may act via its feedback pathway on Aurora B^[607].

Beyond error correction, a number of factors promote the formation of stable kFibers and stable attachments. These include components of the SAC, Bub1, Bub3 and BubR1^{Mad3}, structural components of the kinetochore, such as the KMN network and the CCAN as well as MAPs such as EB1, APC and CLASPs. Although relations among these components are not well defined, some regulatory pathways are beginning to emerge.

Among structural kinetochore components, the NDC80C is absolutely required for kFiber formation and loss of MIS12C or Knl1 decreases the number of stable kFibers, in line with their requirement for end-on attachment^[496, 500, 675, 676]. An Ndc80 mutant that is immune to Aurora B phosphorylation and error correction displays dampened chromosome oscillations while antibody injections against Ndc80 abolish oscillation and lead to increased tension, suggesting that attachment stability increases when NDC80C cannot be released from kMTs^[487, 625]. Loss of the CCAN groups CENP-H/I/K and CENP-L/M/N, which have a role in but are not absolutely required for NDC80C recruitment, surprisingly leads to the opposite phenotype, hyperstable kFibers^[451]. Therefore, CENP-H/I/K and CENP-L/M/N appear to have destabilizing function on kFibers. When CENP-O is depleted, kFibers indeed become unstable, dependent on CENP-H/I/K and CENP-L/N/M^[570]. If this was due to an effect on NDC80C, CENP-O could inhibit CENP-H/I/K's and CENP-L/N/M's action on the NDC80C. Supporting this idea, vertebrate CENP-U is degraded by ubiquitin mediated destruction before the onset of anaphase in response to CENP-U phosphorylation by Plk1^[582, 632]. This could conceptually be a regulatory mechanism affecting kFiber dynamics. This line of argument, however, is troubled by the fact that while CENP-O depletions do show increased NDC80C recruitment to the kinetochore that is dependent on CENP-H/I/K and CENP-L/M/N and both CENP-H and CENP-U have been shown to interact with Ndc80, Ndc80 contains the MT binding domain of the NDC80C, not its kinetochore localization domain and an increase of NDC80C on a kinetochore would be predicted to increase, rather than decrease, kMT stability^[570, 677-679]. Because a loss of CENP-H had no effect on recruitment of kinetochore components known to affect kMT stability such as Aurora B, Shugoshin, MCAK, Bub1, BubR1, Kif18a or CENP-F and because CENP-Q was demonstrated to bind MTs directly, it has been suggested that the CCAN's effect on kFiber stability may be direct rather than mediated through the KMN network or other kinetochore proteins. However, not all kinetochore localized potential MT regulators have been exhaustively tested yet^[451, 596].

While kMT destabilizing mechanisms have been described, i.e. release and depolymerization, mechanisms that promote stabilization are still very much speculative. Conceptually, this could happen by simply escaping the error correction mechanism when tension is applied. Furthermore, classical theoretical biochemistry demonstrates that applying

traction to a MT +end promotes growth and disfavors shrinkage^[239]. Molecularly, the kinesin CENP-E can promote ATP-dependent MT growth, while CLASPs and the yeast Dam1 complex support MT elongation under tension^[290, 291, 680, 681]. Although this would explain stable attachment and polymerization under tension, together with current models of error correction it does not account for a range of effects. Firstly, in absence of attachment, the KMN network should be Aurora B phosphorylated and initial MT capture therefore should be suppressed. The kinase Nek2a has recently been described as a factor that increases NDC80C affinity for MT by phosphorylation and may allow NDC80C attachment to MTs despite being phosphorylated by Aurora B. However upstream regulators of Nek2A are so far unknown^[682]. Secondly, the observed kFiber pushing on poles as well as the maintenance of stable kFibers attached to kinetochores on monopolar spindles or after severing kFibers from poles should, according to current models, not exist. In the absence of tension these structures should undergo Aurora B based error correction and be released from the KT.

An emerging pathway that opposes Aurora B mediated kFiber destabilization and promotes stable kFibers rests on BubR1, Bub1 and Bub3, the latter two being required for localization of BubR1. In absence of either the occurrence of lateral attachments increases over the observed end-on attachments to stable kMTs. Aurora B has been demonstrated to operate antagonistic to BubR1 as inhibition of Aurora B rescues unstable kFibers in BubR1 depleted cells^[683-687]. BubR1 receives upstream input and its kinase activity has been reported to be enhanced by multiple factors, by binding of CENP-E, weakly by a CDK1 priming phosphorylation and strongly by the Plk1 phosphorylation following priming phosphorylation by CDK1^[633, 688]. Therefore Bub1, Bub3 and BubR1 may integrate multiple signals to stabilize kFibers and they are well positioned within the kinetochore to do so. Bub1 and BubR1^{Mad3} bind to Knl1 and interact individually with Bub3^[496, 689]. One recently identified mechanism by which BubR1 opposes Aurora B mediated kFiber destabilization operates by counteracting Aurora B phosphorylation via Plk1 and Protein phosphatase 2A (PP2A). Like a loss of Bub1, Bub3 and BubR1, a loss of Plk1 leads to increased lateral attachments and BubR1 phosphorylation by Plk1 is required for chromosome alignment^[690-692]. Plk1 phosphorylates the kinetochore attachment regulator domain (KARD) of BubR1 that promotes PP2A recruitment, leading to dephosphorylation of Aurora B substrates in the KMN and placing the kinetochore in an attachment competent state. This work also questioned the long established kinase activity of BubR1 and suggested it to be a pseudokinase that, although it retains a catalytic triad in humans, has lost its kinase activity. BubR1's previously described kinase activity may be entirely due to contaminating kinases and its scaffold function may be more important^[693, 694]. Indeed the involvement of BubR1's possible kinase activity has been debated for some time. Surprisingly, PP2A depletion can be rescued by inhibiting Plk1 and PP2A reciprocally controls Plk1 localization to the kinetochore, likely by

dephosphorylating PBDs. The role of this apparent feedback inhibition remains to be investigated but suggests upstream components in this pathway^[693]. BubR1 additionally interacts with CENP-E via its kinase domain and both are found in complex with the kinesin-8 Kif18a^[688, 695]. Furthermore BubR1, Bub1 and Bub3 are found in complex with APC and BubR1 is required for APC recruitment. APC is a highly specific substrate for phosphorylation by Bub1 and possibly BubR1 although the mentioned recent evidence against BubR1's kinase activity now questions the latter^[696, 697]. APC in turn interacts with EB1 and the formin mDia3 and all three bind MTs directly. On top of that, mDia3 binds to the centromeric nucleosome by direct interaction with CENP-A^[477, 698]. No comprehensive study to date investigates the relationship among all of these components. It is therefore unclear if they are part of the Plk1-BubR1-PP2A kFiber stabilizing pathway or act in parallel. APC, EB1 and BubR1 were initially described to be active in the same kFiber-stabilizing pathway, but a recent study demonstrates that in absence of APC, kFibers become hyperstable, counterintuitive, given APC's crosslinking and MT stabilizing function in vitro and in vivo at the cell cortex^[669, 696, 698-701]. This may be explainable by APC's association with MCAK in *Xenopus*, although in human cells over-expression of Kif2b, but not MCAK, rescues hyperstable kFibers^[410, 669].

Animal kinases regulate not only error correction and kFiber stability but also the recruitment and ejection of kinetochore proteins in response to attachment state. Mps1 is required for the initial localization of the RZZ complex but not its maintenance at unattached kinetochores. CENP-E recruitment requires Bub1 and is partially dependent on BubR1 while Mps1 requirement is debated^[530, 531, 606, 607, 609, 683, 688, 702-706]. Bub1 is also required for recruitment of CENP-F^[522, 531]. Aurora B is required for recruitment of both CENP-E and the RZZ complex, which is not surprising, as it localizes Mps1 and Bub1. However it has a direct role in at least the recruitment of the RZZ complex as Aurora B phosphorylation of Zwint-1 is required for recruitment of RZZ and, downstream, of Dynein and Dynactin^[531, 638, 707]. Aurora B's role in the recruitment of MCAK and Kif2b has been mentioned previously^[460, 673]. In addition, Plk1 is required for Kif2b localization and activation^[708]. Furthermore, Plk1 phosphorylates Dynein, decreasing its affinity for ZW10 and promoting binding to Dynactin, inducing Dynein mediated stripping of kinetochore components^[514, 520].

Taking these observations together, one may imagine a mechanism in which a Plk1 based early and an Aurora B based late pathway regulates kMT attachment. Initially, Plk1 places Dynein/Dynactin in a stripping competent state, promotes kFiber attachment and stabilization to the KMN network by antagonizing Aurora B via BubR1 and PP2A as well as early error correction via Kif2b. Following initial end-on attachment, Dynein stripping commences, removing BubR1 and permitting Aurora B phosphorylation. Aurora B inhibits further loading of RZZ in response to tension, deactivates Kif2b mediated error correction by permitting

astrin to localize to the kinetochore and activates MCAK and KMN dependent error correction.

The work demonstrating CENP-H/I/K's involvement in kFiber dynamics additionally showed that kFibers were not only hyperstable following a loss of CENP-H, but that kFiber flux was entirely absent^[451]. While +end kFiber turnover and kinetochore movement speed was increased, chromosomes ceased coordinated oscillations. Similarly, loss-of-flux and loss of oscillation phenotypes have been described for a number of factors active in error correction, some of which do interact with the CCAN. Aurora B is required for flux and oscillation and in its absence kFibers become hyperstable^[657]. A loss of Shugoshin leads to unstable kFibers, which may be explained by one of its additional roles, recruitment of PP2A^[674, 693, 709]. Antibody injection against Shugoshin produced a phenotype very similar to Aurora B/MCAK or CENP-H depletions, a loss of oscillation, hyperstable kFibers and an absence of flux. Loss of MCAK or Kif2b leads to a loss of kMT turnover and oscillations. More specifically loss of Kif2b leads to an absence of oscillations of mono-oriented chromosomes, while a loss of MCAK has been described to decrease KT movement speed and to interfere with oscillation of bioriented chromosomes because kinetochores become unable to sustain poleward movement^[427, 453, 456]. Interestingly, MCAK and Sgo2 display kinetochore localization reciprocal to CENP-I during oscillation, concentrating at the leading kinetochore while CENP-I is increased at the trailing kinetochore^[451, 452]. If both MCAK and CENP-H/I/K have kFiber destabilizing activity, this would suggest that in order for chromosomes to move or oscillate, leading and trailing kFibers need to be differentially destabilized. An alternate mechanism for oscillation would be for all MTs of a kFiber to switch coordinately between growth and shrinkage, allowing the entire kFiber at the leading KT to shrink while the kFiber at the trailing KT grows. Such a mechanism has become untenable with the demonstration that two thirds of the kMTs within a kFiber are depolymerizing even when a kFiber grows and an alternative model suggests that a subpopulation of kMTs needs to be detached from kinetochores to permit oscillation^[457, 710].

Although the CCAN's influence on kFiber stability has been suggested to be independent of Aurora B and downstream effectors such as MCAK and NDC80C, direct interactions between CENP-H and both Ndc80C and MCAK have been demonstrated^[677]. As mentioned previously, when tension is applied to a kinetochore, Aurora B and MCAK delocalize from the centromere to the inner kinetochore and a second binding site has been suggested. Because MCAK relocalization requires dephosphorylation of Aurora B generated phosphoepitopes this positional shift is not simply a response to kinetochore stretching under tension^[452, 461]. Speculatively, the vertebrate CCAN may play a role in relocalization of MCAK and/or Aurora B to the kinetochore but not be absolutely required for its localization to the centromere. This is based on an observation in budding yeast. Here as, previously mentioned, the CBF3

complex is absolutely required and ScCENP-U is partially required for CPC recruitment. ScCENP-O in turn has been suggested to promote the timely eviction of the CPC from the centromere in response to Cdc14 release by the FEAR. Ndc10 of the CBF3 complex, ScSurvivin and ScCENP-O are SUMOylated. SUMOylation of ScCENP-O is not required for kinetochore recruitment of the CPC but may rather play a role in its eviction at anaphase, hinting at a possible SUMOylation pathway that includes the ScCCAN and regulates CPC localization^[711-713]. Similarly, Boralin in human cells is SUMOylated by RanBP2, though a role for this modification is not clear^[714]. The human CCAN, specifically CENP-I and -H are SUMOylated, however a loss of SUMOylation leads to a loss of CENP-H/I/K from the kinetochore and the expected gross kinetochore assembly defect^[715].

Lastly, the effect a loss of CCAN complexes has on kFiber stability affects the force balance required to form a bipolar spindle. The appearance of multipolar spindles by centrosome fragmentation has been described for depletions of CENP-H/I/K and CENP-M, as is often observed when traction on kFibers is high enough to shatter centrosomes^[554, 556, 578, 597, 716]. The opposite phenotype arises in CENP-Q/U/P/O/R complex depletions. A loss of CENP-P or CENP-O induces monopolar spindles. A depletion of either the CENP-H/I/K or the CENP-L/M/N group rescues not only unstable kFibers but also the monopolar spindle phenotype, underscoring the antagonistic relationship between CENP-Q/U/P/O/R and both CENP-H/I/K and CENP-L/M/N. The bipolarization defect resulting from a CENP-O depletion arises from an inability to generate kFiber pushing during prometaphase to separate centrosomes and is not specific to CENP-O, as it is also observed when NDC80C, CENP-E or both MCAK and Kif2a are lost. As double depletion of Kif2a and MCAK abolish flux, flux is thought to be required for prometaphase centrosome separation. Flux is however not required for chromosome oscillation^[369, 375, 439]. Thus, the activity that destabilizes kFibers and induces monopolar spindles rests on CENP-H/I/K and CENP-L/M/N. The multipolar spindle phenotype in CENP-H/I/K and CENP-L/M/N group depletions also suggests either an underlying or independent activity responsible for spindle pole shattering possibly due to traction^[570, 717].

Together these observations present a complex and incompletely defined interaction network regulating attachment and detachment of animal kinetochores. Budding yeast chromosome dynamics are less complex and many of the factors active at animal kinetochores are either not conserved or not present on yeast kinetochores^[532]. Specifically, many kinetochore components that mediate early attachment, conversion to end-on attachment and oscillation in animals, including CENP-E, CENP-F, Ndc1, Lis1, Dynein/Dynactin, Polo-like kinase, APC, Kif2b and MCAK are absent from budding yeast kinetochores. This may be due to its simplified prometaphase in which kinetochores are captured shortly after centromere replication as well as the requirement for only a simple error correction mechanism for

syntelic attachments. Yet, in addition to kMT capture and biorientation promoted by the KMN network and DAM1C and its regulation by Aurora B, a second pathway has been suggested to act independently of Aurora B through Bub1, Shugoshin and Mps1. A hint at how Mps1 would promote biorientation is provided by the observation that Mps1 is required to "lock" the DAM1C onto kMT +ends, but it is not known if this is an activity of Mps1 alone or the entire pathway. In addition to ScBub1, loss of ScBub3 and ScMad3 leads to a chromosome transmission fidelity defect. It will be interesting to determine whether the role of ScBub1, ScBub3 and ScMad3 in chromosome segregation is in any way reminiscent of that of Bub1, Bub3 and BubR1 in animals^[718-721]. The role of the budding yeast CCAN in chromosome biorientation is not well investigated. Initial characterization demonstrates that all nonessential ScCCAN proteins show chromosome transmission fidelity defects when lost^[561-564, 566]. Loss of ScCENP-Q/U leads to a biorientation and error correction defect explained by ScCENP-U's role in budding yeast CPC recruitment^[627]. More recently a weak biorientation defect upon loss of ScCENP-P has been demonstrated. The basis for this is a defect in centromeric loading of Cohesin observed upon loss of ScCENP-O/P or ScCENP-L/N, which then likely leads to misorientation of sister kinetochores^[590, 722].

2.6.8 Involvement of the structural kinetochore in SAC activation.

Although recruitment of SAC proteins to kinetochores is often used as a proxy for SAC activity in the literature, it cannot be directly equated with a SAC arrest. Mad1 and Mad2 leave the kinetochore before anaphase while Bub1 and BubR1 persist at low levels into anaphase^[196, 612, 723]. Kinetochore recruitment of SAC proteins depends firstly on upstream binding partners within the kinetochore and regulating kinases such as Aurora B and secondly is, by incompletely defined mechanisms, sensitive to attachment state and tension on the kinetochore. The observation that, in animals, kinetochore localization of Mad1 and Mad2 is responsive to attachment while localization of Bub1, Bub3 and BubR1 is responsive to tension has sparked a debate over whether the SAC is silenced by attachment or tension^[724, 725]. An enticingly simple model states that the SAC proper only recognizes unattached kinetochores^[663]. The error correction mechanism in turn stabilizes kinetochore-microtubule attachments that support tension while it severs microtubule attachments to kinetochores that do not support tension and thereby converts them back into their unattached state in which they generate a SAC signal. Mad1 and Mad2 display a localization behavior that is consistent with this idea, they are lost upon attachment even if tension on the kinetochore is reduced by treatment with Taxol. Alternatively, the SAC may be able to sense both, unattached and tensionless kinetochores, directly. In line with this idea, BubR1 is partially lost from the kinetochore when under tension but remains at high at attached, tensionless kinetochores. Bub1 and Bub3 in turn have been described as both attachment

and tension sensitive as their kinetochore localization decreases moderately upon attachment and strongly when tension is applied^[166, 167, 196, 612, 703, 723, 726-730].

How would localization of SAC proteins be rendered responsive to the attachment state? One possibility is an attachment or tension sensitive recruitment to kinetochores. Aurora B is a candidate factor for this regulated recruitment. Mps1 as one upstream SAC kinase may be able to sense unattached kinetochores independently, possibly by binding to NDC80C, because although its recruitment is accelerated by Aurora B, Aurora B is not absolutely required for its localization. Bub1, the second upstream SAC kinase, localizes to kinetochores independent of Aurora B in yeast but possibly dependent on Aurora B in animals. Because of the recruitment of Bub1 through Mps1 phosphorylation on Knl1 in yeast, Aurora B may have an indirect effect on Bub1 recruitment through Mps1 here but in animals requirement of Mps1 for Bub1 recruitment is still debated^[531, 601-603, 607, 655]. Localization requirements of the SAC proteins Bub3 and BubR1 are not fully clear. It is generally agreed upon that Bub1 and Bub3 are required to recruit BubR1 to the kinetochore, however, like for Bub1, a requirement for Mps1 in vertebrate BubR1 recruitment is debated. Furthermore, Bub3 may recruit Bub1 or conversely be either co-dependent or fully dependent on Bub1 for recruitment^[160, 191, 423, 522, 530, 609, 636, 637, 685, 689, 704, 731]. The recruitment dependency of Bub1 and BubR1 on Aurora B suggested by some authors could prove to be a tension sensitive mechanism rooted on the CPC. Supporting this, tension dependent phosphorylation of ScMad3 by ScAurora B is required for a tension dependent SAC arrest in budding yeast. However a substantial amount of authors argue against a requirement for Aurora B in Bub3 and BubR1 recruitment in animals^[636, 638, 639, 732, 733]. An alternative explanation would be a loss of these proteins in response to tension. BubR1 is stripped from the kinetochore by Dynein, Bub3 has been found to interact with dynein light chain 3 and both BubR1^{Mad3} and Bub3 have been found in complex with Spindly^[515, 516, 734]. Notably, in fission yeast but not animals, Bub3 is not required to establish a SAC arrest but has a role in silencing the SAC after chromosome alignment^[735]. A third mechanism rendering the SAC responsive to tension that is not based on localization has been suggested, following the observation that, under tension, NDC80C and Knl1 shift their relative position. Here it is thought that a signaling complex consisting of Bubs bound to Knl1 and other SAC proteins, such as Mad1, Mad2 and Mps1, bound to NDC80C is turned off as the two KMN components separate under tension^[736]. Although Bub1 is known to phosphorylate Mad1 and a complex of Bub1, Bub3 and Mad1 has been described, the binding partners of Mad1 and Mad2 at the kinetochore are far from clear^[155, 201]. While a yeast two-hybrid interaction between Mad1 and Ndc80 has been described, NDC80C is, at least, not its only recruitment factor in vivo because a loss of NDC80C does not lead to a failure of Mad1 and Mad2 to localize. Rather, in absence of NDC80C, Mad1 and Mad2 are not retained against Dynein-mediated stripping which initially

created the impression that it was lost from kinetochores^[523, 737]. A second possible recruiting factor for Mad1 and Mad2 is the RZZ complex as its absence leads to a loss of Mad2 from vertebrate kinetochores^[506, 738]. Because RZZ localization requires NDC80C and Mad2 localizes in absence of NDC80C, the RZZ complex again is either not a direct interaction partner or not the only one^[490]. A third possibility is Mad1's and Mad2's interaction with the nuclear pore subcomplexes (NPC). During interphase, Mad1 and 2 localize to NPCs, which in yeast requires the Nic96 complex containing Nic96, Nup53, Nup59, Nup157, Nup170, Nup188 as well as a nuclear basket complex consisting of Mlp1, Mlp2, Nup1, Nup2, Nup60. Mad1 and Mad2 are found associated with Nic96 complex members in co-immunoprecipitations. The nuclear export receptor Crm1, which in animals is required for kinetochore loading of the Nup107-160 complex, as well as RanGTP and a nuclear exclusion sequence on Mad1 are required to load Mad1 onto unattached yeast kinetochores. A Mad1 NES mutant however retains an active SAC, despite Mad1's inability to localize to kinetochores, underscoring that SAC protein localization does not absolutely correlate with SAC activation^[739-743]

Both Mad1 and Mad2 require Mps1 and Bub1 for their recruitment and Mps1 is required for O-Mad2/C-Mad2 turnover^[164, 191, 522, 523, 531, 609, 637, 702, 704]. While Mps1 localizes to unattached kinetochores and is required to recruit Mad1 and Mad2 it does not need to be at the kinetochore to accomplish this^[523, 601, 603]. When Mps1 is rendered cytoplasmic by Aurora B inhibition, Mad2 appears at KTs after a delay and the initial onset of cyclin B degradation is halted, producing a stable SAC arrest. Mps1 overexpression induces a SAC arrest despite correct attachment of all chromosomes and can do so in absence of kinetochores. Mps1 is activated by trans-autophosphorylation and leaves the kinetochore swiftly, dependent on its own kinase activity. Thus, in response to a lack of attachment, Aurora B concentrates Mps1 at kinetochores to expedite its activation, though it may autoactivate slowly at unattached kinetochores or in the cytoplasm^[603, 611, 744-746]. Based on this, recruitment and release of Mps1 has been suggested to supply the cytoplasm with active Mps1 in response to SAC activation, potentially providing a SAC signal upstream of MCC assembly^[202].

Recruitment of SAC proteins to the KMN network would suggest that it is, together with the KMN recruiting CCAN network, required for SAC signaling. However, while a loss of NDC80C and Knl1 in both yeast and animals abolishes the SAC, a loss of MIS12C only impairs the SAC and cells arrest if all kinetochores detach but fail to maintain arrest^[51, 493, 496, 594, 597, 675, 676, 747]. The requirement of CCAN proteins for SAC signaling has been extensively mapped in budding yeast^[479, 480, 675, 748]. Surprisingly, not a single ScCCAN protein, not even ScCENP-C, has been found to be required for a SAC arrest although the employed temperature sensitive alleles may be hypomorphic in this respect. The only known kinetochore proteins that abolish SAC signaling in budding yeast when lost are ScNDC80C,

ScKnl1 and the CBF3 complex. To observe a loss of SAC signaling in response to loss of Ndc80C components in budding yeast, one needs to either inactivate Spc24 or Spc25 or both Nuf2 and Ndc80. This may be either due to residual or redundant function of the remaining NDC80C components. It has, however, been reported that ScCENP-U mutants display a defect in maintaining a robust arrest^[591]. During general characterization of vertebrate CCAN proteins, no CCAN protein was found absolutely required for a SAC arrest, although a loss of CENP-C or Plk1 phosphosites on CENP-U impaired the SAC^[555, 556, 558, 576, 582]. Closer investigation demonstrated a SAC arrest to be impaired in CENP-O and CENP-I depletions. CENP-O displays a loss of SAC only under very stringent depletion while under CENP-I depletion, the SAC is unable to arrest mitosis during an unperturbed cell cycle but does so when all kinetochores are detached by Nocodazole treatment. It appears that after depletion of CENP-I, cells become polyploid during the first failed mitosis, accumulating sufficient chromosomes, and thereby kinetochores, to arrest robustly the subsequent mitosis^[521, 717].

2.7 Centromere inheritance in animals and budding yeast

When the budding yeast centromere was isolated and defined as a ~125bp genomic DNA element that was sufficient to direct kinetochore assembly, it was speculated that animal centromeres may similarly be genetically defined^[749]. 30 years later this appears highly unlikely as no animal centromere-defining sequence has been found, although low efficiency kinetochore assembly is observed on human type α -I satellite DNA^[750-753]. The genetically defined centromere of budding yeast appears to be a relatively recent evolutionary acquisition and an exception to the rule^[532]. In animals the location of a centromere is predominantly epigenetically defined. This is firstly evidenced by the occurrence of neocentromeres on chromosomal loci that have no significant similarity to the repetitive DNA sequences found at animal centromeres. While these neocentromeres are functional, inherited over multiple generations and recruit all proteins expected for an active centromere, including centromeric nucleosomes, CCAN proteins, KMN components and SAC proteins, the original centromere locus is silent and recruits none of these factors^[754-759]. A second well established system in which epigenetic effects on centromere activity are observed is fission yeast. Here, when the genomic centromere sequence is abbreviated, centromeres switch between active and inactive states and inherit the current state over a number of generations^[760].

Assembly of a kinetochore on a centromere that is defined by sequence is conceptually very simple. A DNA binding protein may recognize the centromeric sequence and recruit downstream kinetochore components. Budding yeast kinetochores assemble in such a manner. Its ~125bp centromeric consensus sequence is subdivided into 3 linearly arranged

elements, CDEI, CDEII and CDEIII^[761]. The 26bp CDEIII sequence is absolutely essential for kinetochore function and is recognized by CBF3, which directs downstream kinetochore assembly. The CBF3 complex consists of Ndc10, Cep3, Ctf13 and Skp1 and is a recent acquisition of a family of budding yeasts, including *S.cerevisiae*, which have evolved genetically defined point centromeres. CBF3 is the most upstream factor in kinetochore assembly and required for recruitment of all other kinetochore proteins including the centromeric nucleosome^[480, 568, 762-767]. While CDEIII is essential for kinetochore formation, it requires in addition at least a fragment of the AT rich CDEII element which is located between CDEI and CDEIII^[768]. A body of evidence indicates that CDEII is bound by the single centromeric nucleosome present in yeast kinetochores^[769-772]. The 8bp CDEI element is recognized by the homodimeric bHLH family transcription factor CBF1. Its exact role at the centromere is unclear but an effect on nucleosome positioning, DNA topology and a direct interaction between CBF1 and the CDEIII binding CBF3 complex have been demonstrated^[773-782]. The latter implies the CDEII element to form a loop around the centromeric nucleosome that is secured by interaction of CBF1 and CBF3.

Although CBF3 is critical for kinetochore assembly, thus far no interactions with structural components of the kinetochore have been described. Its role has recently become clearer with the identification of the HJURP/Scm3 protein family. HJURP/Scm3 family proteins are histone chaperones that facilitate loading of the centromeric nucleosome at the centromere^[783-787]. Scm3 and CBF3 interact and thereby CBF3 may facilitate sequence specific targeting and loading of centromeric nucleosomes during S-phase^[788]. Subsequently, structural kinetochore components would assemble on top of this nucleosome as it is the case in vertebrates, where the centromeric nucleosome is the most upstream factor for kinetochore assembly^[596]. Vertebrate CENP-C and CENP-N have been demonstrated to interact with the centromeric nucleosome and this may be the first step in CCAN assembly at the kinetochore^[587, 588]. The budding yeast centromeric nucleosome is required for recruitment of at least ScCENP-C, which is in turn required for localization of ScCENP-O^[592].

Epigenetic inheritance requires a mark other than DNA to define centromere location. The prime candidate to provide this mark is CENP-A, the centromeric histone found to replace canonical Histone H3 in centromeric nucleosomes^[789-792]. Animals and most yeast do not possess a CBF3 complex and here CENP-A is the most upstream factor in kinetochore protein recruitment. Kinetochore assembly on sperm chromatin vividly illustrates its presumed function as a mark. In frog and bovine spermatogenesis canonical nucleosomes are stripped from the genome and replaced with protamines. CENP-A however is quantitatively retained and after fertilization directs assembly of a kinetochore^[579, 793].

An epigenetic mark would require a mechanism to direct its own persistence and inheritance. In contrast to budding yeast, CENP-A levels at the vertebrate centromere decrease by 50%

following DNA replication and are subsequently replenished, replication independent, during early G1^[794-796]. Thus a mechanism for a cell cycle specific deposition of CENP-A exists. Identification of factors involved in deposition of CENP-A in model systems other than budding yeast suggest that it is a three step process that encompasses licensing, loading and maintenance of CENP-A in G1. Fission yeast Mis18 has two vertebrate orthologs, Mis18 α and Mis18 β . Mis18 α and Mis18 β together with Mis18BP1 form the vertebrate Mis18 complex (Mis18C)^[796-799]. Mis18BP1 is absent in fission yeast and only Mis18BP1 is present in *C.elegans*. Mis18C localizes to kinetochores at telophase, slightly before HJURP. Mis18C is believed to prime the centromere for subsequent loading of CENP-A by HJURP and force localizing of either HJURP or Mis18 α to ectopic sites can induce kinetochore assembly^[800, 801]. Two additional Histone chaperones may be involved in loading, RbAp46/48 which bind H4 and Nucleophosmin 1 which binds to all core histones^[784, 786, 799, 802]. The priming event may include histone modifications as a deacetylase inhibitor or a centromere tethered histone acetylase domain are able to rescue loss of vertebrate Mis18C but not HJURP^[797, 801]. Later factors in CENP-A deposition are the remodeling and spacing factor (Rsf) and MgcRacGAP. Rsf localizes to centromeres at mid G1, MgcRacGAP at late G1. A loss of Rsf1 appears to lead to a defect not in recruitment but in loading of CENP-A as it becomes more amenable to salt extraction. MgcRacGAP, a GTPase activating protein appears to act late in G1 and is required to maintain loaded CENP-A. It's likely target at the centromere is Cdc42 and a loss of Cdc42 mimiks the decrease of CENP-A when MgcRacGAP is depleted^[803, 804].

What is the role of the CCAN in epigenetic centromere inheritance? In addition to these priming, loading and maintenance factors, the vertebrate and fission yeast CCAN are required for CENP-A deposition. Vertebrate CENP-N and CENP-C bind directly to centromeric nucleosomes. CENP-A binding by CENP-N is required to load CENP-A. Additionally, vertebrate CENP-H/I/K and CENP-M as well as fission yeast CENP-I have been demonstrated to be necessary for CENP-A loading^[556, 587, 805]. Interestingly the CCAN in fission yeast defines a specialized chromatin domain that spreads over introduced sequences, between heterochromatin boundaries at both sides, in sum suggesting that the CCAN governs temporally and spatially restricted loading of CENP-A onto the centromere^[799, 806, 807]. Although budding yeast directs CENP-A loading to the centromere via CBF3 during S-phase, the ScCCAN may retain a vestigial function in CENP-A deposition. Cells that loose ScCENP-N are defective in activating a conditional centromere but capable of propagating previously activated centromeres over multiple generations^[568, 808, 809].

CENP-N binds to the CENP-A targeting domain(CATD). CENP-A is related to Histone H3 and when the CATD is grafted onto H3, this chimeric histone localizes to the centromere and directs kinetochore assembly in absence of CENP-A^[810-813]. Other proteins have been found to bind the CATD as well, including the HJURP/Scm3 family and Psh1, an E3 ubiquitin ligase

that targets ectopic CENP-A for degradation^[595, 814-818]. In contrast to CENP-A loading by HJURP, ubiquitination of CENP-A by Psh1 evicts CENP-A from ectopic chromosomal loci. Thus the centromeric locus may be defined by targeted loading of CENP-A via HJURP/Scm3 and via local protection of CENP-A from global degradation as recently suggested for *C.albicans*^[819]. The CCAN may collaborate with HJURP/Scm3, as centromere localization in fission yeast requires CENP-K and CENP-I^[786]. Furthermore in vertebrates CENP-C modulates Mis18BP1 recruitment to the centromere. More specifically it interacts directly with Mis18BP1 and is required to recruit Mis18BP1 to the centromere at telophase and to inhibit recruitment of Mis18BP1 to the centromere in interphase^[820]. Extending this to the known requirement of CENP-H/I/K for recruitment of CENP-C to interphase but not mitotic centromeres and the requirement of CENP-H/I/K for CENP-N localization, which in turn decreases by 80% during the course of mitosis up until metaphase, one may speculate about an indirect role of CENP-H/I/K in controlling CENP-A loading by regulating localization of the two CENP-A binding CCAN components, CENP-C and CENP-N^[570, 573]. It is interesting to note that organisms in which no CCAN components other than CENP-C have been identified, *D.melanogaster* and *C.elegans*, also possess no known HJURP/Scm3 homologues^[532, 783, 821, 822]. Although the budding yeast centromere is defined by DNA sequence, one epigenetic effect has been noted, the loading of Cohesin. The budding yeast centromere acts as an enhancer of Cohesin loading. This requires ScCENP-A, ScCENP-C, ScMIS12C, ScCENP-O/P, ScCENP-N/L and possibly ScCENP-H/I/K. Furthermore it requires the Smc2/4 Cohesin loader complex to localize to centromeres and localization of Smc2/4 is impaired in ScCENP-O mutants. ScCENP-A, ScCENP-C or Ndc10 mutants cause decreased Cohesin loading at newly activated centromeres, but not established centromeres^[57, 67, 68, 590, 722, 823, 824].

3. Results

3.1 In vivo characterization of the budding yeast CCAN

To investigate interactions among ScCCAN subcomplexes and between ScCCAN subcomplexes and other kinetochore components, I employed two parallel strategies. Firstly I constructed yeast strains in which one member of the ScCCAN was fused to a tandem affinity tag at its genomic locus. TAP-tag fusions were constructed for a representative member of each putative ScCCAN subcomplex as well as for all newly assigned proteins. Following strain construction and verification of correct integration of the tag, I purified each bait protein from 24l of exponentially growing liquid culture. Subsequently the affinity-purified samples were analyzed by our in-house mass-spectrometry facility in order to identify co-purifying kinetochore proteins and posttranslational modifications. Similar experiments have been performed previously, but only with single ScCCAN members and not systematically^[569, 592]. I reasoned that by comparison, one may observe differential association of kinetochore proteins with ScCCAN subcomplexes, which in turn would provide clues to their overall connectivity. Because I did not observe a convincing association of the putative CENP-T homologue with any kinetochore protein under standard conditions, this initial experimental approach was expanded and I performed a second set of purifications of all bait proteins under lower ionic strength. Thus, each of the 6 bait proteins was purified twice, in presence of either 100mM or 300mM NaCl. In a second approach, I expressed ScCCAN subcomplexes from a polycistronic bacterial vector in order to purify sufficient amounts of recombinant protein to perform direct binding assays. Because cloning into this vector is sequential, the possible orders in which one can perform the construction of a full vector with reasonable effort are limited. I chose the proteins to tag in vivo according to their compatibility with the cloning process for bacterial expression so that I would be able to tag and purify the same bait proteins in both approaches, yielding comparable data. A schematic description of the bait proteins and their position within the putative ScCCAN subcomplexes is given in Figure 1. Figure 2B shows a silver stained SDS-PAGE for each ScCCAN purification performed. 15µl of the three elutions performed for each purified native ScCCAN protein as well as 7.5µl of boiled beads after elution were applied to the Gel. Figure 2A shows a comparative SDS-PAGE of the entire remaining bead fraction, 77.5µl for each purification. While this is not representative for the samples analyzed by mass spectrometry, as these bead samples were collected after elution, it does allow comparison of remaining band patterns on the same scale. The inset shows the tentatively assigned band identities. The strongest band in each sample was assumed to be the bait protein while the remaining untagged proteins were assigned according to molecular weight in case of ScCENP-I, ScCENP-K and ScCENP-L and their relative migration distance in relation to ScCENP-U, inferred from recombinant protein in the case of ScCENP-Q, ScCENP-P and ScCENP-O.

Figure1. Purification rationale

Budding yeast CCAN:

Figure 1) This figure displays the putative grouping of budding yeast CCAN proteins into subcomplexes based on published interactions of both yeast and vertebrate CCAN proteins and assuming conservation of subcomplex architecture. The corresponding yeast gene is denoted in superscript, the emboldened protein names denote all constructed TAP-tag fusions.

Figure 2. SDS-PAGE of tandem affinity purifications

Figure 2A) This figure displays a SDS-PAGE of the contents remaining on beads after tandem affinity purification and elution. It allows comparison of the major bands found in each sample but is not representative for the samples analyzed by mass spectrometry. These are shown in Figure 2B.

B**High stringency:****Low stringency:**

Figure 2B) After purification, each sample was eluted three times in 60µl 0,1M Glycine pH 2. 15µl of each elution were loaded onto the gel while the remaining 45µl were analyzed by mass spectrometry. Following the third elution, 7,5 µl beads were boiled and the 4 samples, 3 elutions and the remaining bead bound protein were analyzed by SDS-PAGE to judge suitability for mass spectrometry and elution efficiency.

Protein identification data for all analyzed samples is summarized in Figure 3. Figure 3A displays structural kinetochore proteins that co-purify with the respective CCAN proteins. A few relationships are readily apparent. Firstly, the KMN network components do not co-purify as a single entity. Rather the ScMIS12C is found to associate with all established, but not the novel ScCCAN components while ScNDC80C and low levels of ScKnl1 are exclusively found associated with ScCENP-T. Secondly, as in previous publications, the ScCCAN components ScCENP-U, ScCENP-H and ScCENP-N purify as a tight complex, containing all of the established ScCCAN proteins, allowing no further conclusion about their subcomplex architecture from presence or absence alone. Thirdly the putative ScCENP-T is found in association with most established ScCCAN proteins but only under low purification stringency. These purifications also identified a candidate protein for the budding yeast homologue of CENP-W, the product of a small, uncharacterized open reading frame YDR374W-A, which we have subsequently termed Wip1. Furthermore the putative ScCENP-X co-purifies with a substantial number of ScCCAN proteins under low stringency, suggesting a weak or transient interaction with the established ScCCAN components. The results for the putative yeast CENP-S homologue are less clear as it only associates with ScCENP-U and ScCENP-T. Note that both, ScCENP-S and ScCENP-X associate with each other and are found in low stringency ScCENP-T purifications. Remarkably, ScCENP-C is found only in high, not low stringency ScCENP-T samples while the only other ScCCAN protein that co-purifies ScCENP-C, ScCENP-U does so regardless of the stringency applied. Lastly, while all three established ScCCAN components, ScCENP-U, ScCENP-N and ScCENP-H associate with all core histones and the CENP-A ubiquitin ligase Psh1, ScCENP-A itself is only found in ScCENP-U purifications.

Additional proteins of interest that copurify with ScCCAN components are summarized in Figure 3B. Note that exclusively the putative ScCENP-S homologue associates with three proteins involved in DNA repair Mph1, Msh2 and Msh3. Mph1 is a DEAH-box DNA helicase and a homologue of human FANCM, part of the Fanconi anemia complex^[825, 826]. FANCM/Mph1 has been suggested to promote replication fork regression and recombinatorial repair after the fork stalls due to replicational stress^[827-832]. Reasons for replication fork stalling are varied but include lack of nucleotides or interstrand crosslinks^[833]. Importantly however, FANCM associates with CENP-S/X (also known as MHF1&2) which promote FANCM DNA binding and replication fork regression^[834]. Thus, although only ScCENP-X displays association with the ScCCAN and only ScCENP-S associates with Mph1/FANCM we believe this corroborates conservation of CENP-S/X between human and yeast. The reason for the differential association of ScCENP-S/X in this experiment is not known but it is possible that multiple pools of CENP-S/X exist and that tagging either of the two discriminates between these two pools.

Of the nuclear pore complex proteins identified in these purifications, Nup60 is interesting as it is part of the nuclear basket complex that associates with Mad1. Additionally RanGTPase (Gsp1) and the exportin Crm1 were detected. However other NPC proteins were present in the ScCCAN purifications that are components of NPC subcomplexes that have not previously been implicated in Mad1/2 recruitment. Therefore it is likely that these proteins constitute contaminations rather than a specific association^[742]. Lastly a number of potentially regulatory kinases are found to co-purify with ScCCAN proteins. This includes the Dbf4/Cdc7 DDK kinase complex found to associate with ScCENP-H and ScCENP-N, Clb5-CDK1 found to associate with ScCENP-T and Cka1/Ckb1 of the casein kinase II complex found to associate with ScCENP-U and ScCENP-N.

Although all established ScCCAN proteins purified in a tight complex, precluding any inference to ScCCAN subcomplex architecture, the established ScCCAN bait proteins ScCENP-U, ScCENP-H and ScCENP-N did appear to enrich for peptides corresponding to proteins of the suggested subcomplexes. Label-free quantitative mass spectrometry has emerged as an alternative to SILAC, ITRAQ or similar label based quantification. While it is currently not possible to predict signal strength of a given protein based on its primary sequence, some of the parameters measured during protein identification correlate with protein concentration. Among these, the total number of acquired spectra, demonstrates a very good linear correlation with relative protein abundance ($r^2=0,9997$)^[835]. Although in absence of standards no absolute quantification is possible, a relative quantification in multiple samples, such as those resulting from my purifications, is. It needs to be said however that applying this method would, strictly speaking, firstly require validation with a protein complex of known assembly and secondly would have to be performed in replicates to determine the magnitude of error involved. Both are beyond the scope of this work and thus the following analysis serves only to visualize the relative abundance of peptide spectra for a given protein, which in turn may serve as a rough guide for potential relations within the ScCCAN that may be fruitful to investigate by more precise assays.

For a relative quantification of kinetochore proteins in the samples analyzed, the number of peptide spectra acquired per protein in a given sample was normalized to the total number of peptide spectra acquired for all proteins in that sample. Then, pooling the data from either high or low stringency purifications, the normalized peptide number of a given protein in one purification was divided by the sum of the normalized peptide numbers of a given protein in all three purifications, ScCENP-U, ScCENP-H and ScCENP-N. This yields an enrichment factor (EF) describing the enrichment for peptides of a given co-purifying protein when purifying one of the three baits. An exemplary calculation for the enrichment factor of a given bait protein "x" in the purification of ScCENP-U is given in equation 1.

Figure 3. Summary of protein identification

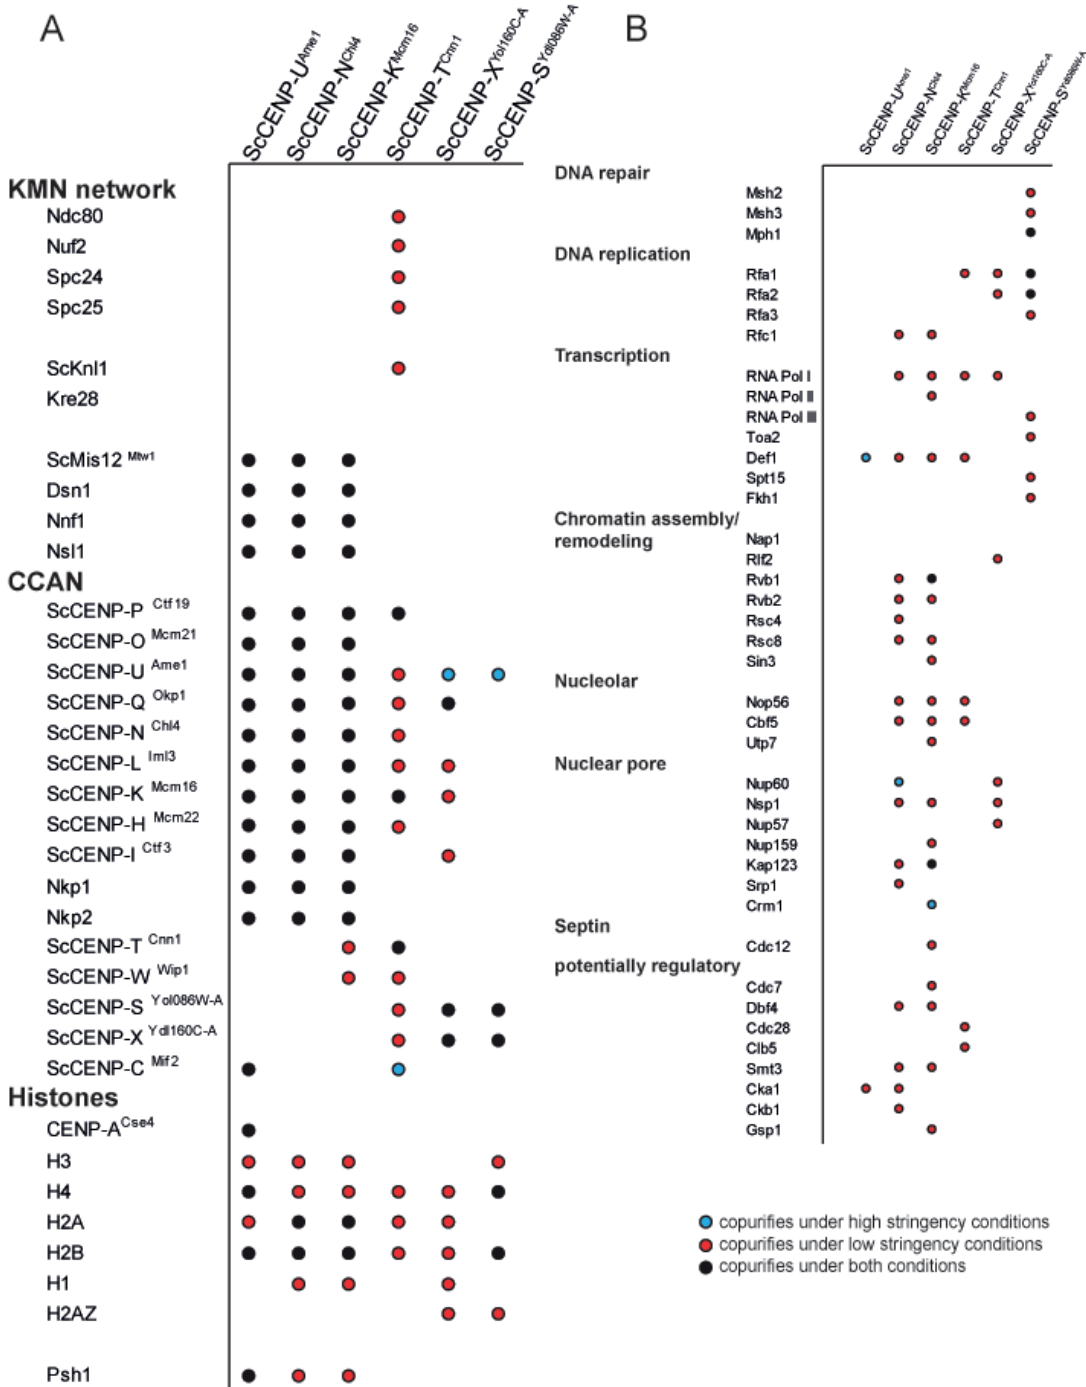

Figure 3A/B) Summary of proteins found to co-purify with ScCCAN bait proteins. The color code denotes identification in samples that were obtained after purification under high stringency (300mM NaCl), low stringency (100mM NaCl) or both. **Figure 3A** focuses on structural kinetochore proteins while **Figure 3B** focuses on proteins involved in replication, chromatin assembly as well as potentially regulatory proteins.

$$EF(x)_{ScCENP-U} = \frac{\frac{PS_{ScCENP-U}(x)}{PS_{ScCENP-U}(total)}}{\frac{PS_{ScCENP-U}(x)}{PS_{ScCENP-U}(total)} + \frac{PS_{ScCENP-N}(x)}{PS_{ScCENP-N}(total)} + \frac{PS_{ScCENP-H}(x)}{PS_{ScCENP-H}(total)}} \quad (1)$$

Equation 1) Exemplary calculation of the enrichment factor for protein X in a tandem affinity purification using ScCENP-U as bait. X is a given co-purifying protein, $EF(x)_{ScCENP-U}$ is the enrichment factor for X in a purification sample using ScCENP-U as a bait. $PS_{ScCENP-U}(x)$ is the number of recorded peptide spectra for X from a ScCENP-U purification sample while $PS_{ScCENP-U}(total)$ is the sum of all peptide spectra recorded for a ScCENP-U purification sample.

This approach assumes an average amount of a co-purifying protein to be present in purifications of the ScCCAN, regardless if ScCENP-U, ScCENP-H or ScCENP-N are used as a bait. Any increase above or decrease below this average amount reflects a stronger or weaker association with the bait protein in question. The enrichment factor thus describes peptide enrichment of a co-purifying protein by association of one of the bait proteins. To sum up individual contributions of bait proteins to enrichment, a coordinate system was generated using three unit vectors that represent an association with one of the three bait proteins as basis. To place a co-purifying protein in this coordinate system, each of the three enrichment factors was multiplied with the corresponding bait unit vector and the three resulting vectors were added together. The resulting coordinates for both stringency conditions are shown in Figure 4. The positions within these coordinate systems neither describe a spatial relation nor suggest direct interactions. They are merely a comparative measure for the relative increase of identified peptides, which is presumed to be due strength of association of an individual co-purifying protein with one of the three bait proteins. Note the similarity of both independent data sets. The components of ScCENP-N/L and ScCENP-H/I/K cluster closely. Similarly, all subunits of the established four protein ScMIS12C cluster together. There appears to be little association of ScMIS12C and ScCENP-N/L while ScMIS12C, especially ScNnf1 associates strongly with ScCENP-U and to a lesser extent with ScCENP-H.

Figure 4. Illustration of peptide spectra enrichment

Figure 4) A vector representation, illustrating the relative association of a co-purifying protein with one of the three bait proteins, ScCENP-U, -H and -N. Note that, as mentioned in the text, this serves only to illustrate increased peptide spectra specific to a bait protein and does not necessarily reflect a structural assembly or direct interaction. Each of the dots denotes the end of a vector beginning at the center of the coordinate system, generated by adding the three vectors that result from multiplying the bait unit vector with the corresponding enrichment factor. Small dots denote proteins that were detected co-purifying with only one bait protein and thus are found at the end of the respective bait unit vector. Circles denote proteins that were found in two purifications and are thus located on a vertex connecting the ends of the two bait protein unit vectors. Large dots denote proteins that were found to associate with all 3 bait proteins. Known and putative subcomplexes were color-coded as a visual aid. **Figure 4A** uses data from three independent purifications of ScCENP-U, ScCENP-H and ScCENP-N performed at high stringency (300mM NaCl). **Figure 4B** uses data from independent low stringency purifications (100mM NaCl) of ScCENP-U, ScCENP-H and ScCENP-N.

3.2 Identification of Wip1 as the budding yeast CENP-W homologue.

As mentioned in the preceding paragraph I identified the product of a small, uncharacterized open reading frame, YDR374W-A as co-purifying with ScCENP-T as well as ScCENP-H. At this time Dr. Alexander Schleiffer had proposed yeast homologues for CENP-T, CENP-S and CENP-X based on distant sequence homology to the vertebrate proteins. A potential yeast CENP-W homologue however eluded these efforts. Using YDR374W-A as a candidate Dr. Schleiffer demonstrated it to be a CENP-W related histone fold protein which we named Wip1 (W-like protein)^[11]. Figure 5 displays a multiple sequence alignment of Wip1 with CENP-W orthologues. Secondary structure prediction suggests three consecutive helices, characteristic of a histone fold. Helix 1 is divergent in budding yeast, which explains why purely bioinformatical methods failed to identify Wip1.

Figure 5. Multiple sequence alignment of Wip1 with CENP-W orthologues

Figure 5) Multiple sequence alignment of Wip1, the putative budding yeast CENP-W homologue by Dr. Alexander Schleiffer. Note the predicted three helices, characteristic for a histone fold. Also observe the low sequence conservation of Wip1 in helix 1 which impeded identification by bioinformatic means.

If Wip1 is indeed the budding yeast CENP-W ortholog, two predictions can be made. Firstly, that it should be a kinetochore protein. Secondly, because the two vertebrate histone fold proteins CENP-W and CENP-T form a dimeric complex and are interdependent for localization to the kinetochore, a similar relation should be observable in yeast^[576]. Figure 6 demonstrates both predictions to be true. A GFP tagged Wip1 expressed from its native locus localizes to the kinetochore throughout the cell cycle as evidenced by co-localization with the kinetochore marker Nuf2. Furthermore localization requires ScCENP-T as it is abolished in a ScCENP-T deletion strain. A recent publication suggests ScCENP-T copy number at the kinetochore to increase from 6 to 20 during anaphase. I have not noticed increase of the Wip1-GFP signal between different cell cycle stages, however I did not perform any quantification of fluorescence intensity^[836].

Figure 6A) GFP fused ScCENP-W^{Wip1} was found to co-localize with Nuf2 at the kinetochore throughout the cell cycle. **Figure 6B)** Localization of ScCENP-W^{Wip1} depends on ScCENP-T^{Cnn1} and is abolished when ScCENP-T^{Cnn1} is deleted.

3.3 Cloning of ScCCAN subcomplexes for bacterial expression

To generate recombinant proteins with which I could perform in vitro binding assays I chose to clone the established ScCCAN proteins into two different co-expression systems, preserving the putative subcomplex composition. I aimed to co-express all components of the putative ScCENP-Q/U/P/O, ScCENP-N/L or ScCENP-H/I/K complexes, each from an individual vector. The components of ScCENP-Q/U/P/O and those of ScCENP-H/I/K were cloned into individual polycistronic pST39 vectors with the tagged protein taking up the last cassette, allowing for an easy change of the tag type^[837]. Multiple tagged versions were generated, according to the schematic in Figure 7A-D. Expression required an intron in ScCENP-O to be removed. This was accomplished by reverse transcription of TRIzol[®] extracted total RNA and subsequent PCR amplification of the cDNA using ScCENP-O specific primers. The resulting construct was cloned into pET3aTr. Subcloning of ScCENP-O and ScCENP-H required removal of two EcoRI restriction sites in ScCENP-P and one SacI site in ScCENP-H (See materials and methods).

The components of the ScCENP-N/L complex were cloned into a pCOLADuet-1 dual expression vector according to Figure 7E-F^[838]. Kanamycin resistance of the pCOLADuet-1-ScCENP-N/L vector allows co-transfection and expression with either pST39-ScCENP-Q/U/P/O or pST39-ScCENP-H/I/K vectors. The final constructs with their respective tags are listed in Figure 7G. Two different tags on each complex allow CoIP experiments with any combination of complexes. Lastly I planned the cloning strategy in such a way that the construction of a composite vector containing all 9 proteins according to Figure 7H was possible. While the size of the vector approaches technical limits, the DAM1C has been cloned onto a single vector using a similar strategy and yielding a vector in a similar size range^[548]. This composite vector could however not be completed due to the limited time. For reasons unknown, the efficiency by which the pCOLADuet-1-CENP-L/N vector could be isolated by Miniprep was so low that it was only barely visible on an ethidium bromide gel. However this vector and all other described vectors were sequenced and found to contain the desired genes. Furthermore the CENP-L/N vector expresses efficiently as demonstrated later.

Figure 7. Cloning strategy for ScCCAN subcomplexes

3.4 Determining expression conditions

During initial bacterial expression it was noted that while ScCENP-P/O, ScCENP-Q/U, ScCENP-Q/U/P/O and ScCENP-L/N could be expressed, ScCENP-H/I/K could not. Furthermore bacterial cultures in which ScCENP-Q/U/P/O expression was induced over night

at 18°C, according to a standard protocol, would often cease growth. To investigate this and to find suitable expression conditions for ScCENP-H/I/K, I screened through different expression times and temperatures (Figure 8). For this screen, an exponentially grown pre-culture was split into smaller cultures. Expression was induced and the cultures were incubated at 4 different temperatures, 18°C, 24°C, 30°C and 37°C. At three timepoints, after 3h, 6h and 12h, samples were taken, sonicated and the soluble protein remaining in the supernatant after centrifugation was analyzed by western blotting. For the blots, ScCENP-O and ScCENP-U were probed with Anti-6xHis antibodies, ScCENP-N was probed with an Anti-FLAG antibody and CENP-H was probed with a Strep-Tactin HRP conjugate. Note that expression of ScCENP-Q/U/P/O and ScCENP-P/O decreases growth rate significantly and at higher rates appears to be toxic. A shorter expression of 5 hours at 24°C was adopted. Expression of ScCENP-Q/U or CENP-L/N did not have any adverse effects on growth and could be induced at 37°C for 6 hrs. Lastly no condition was found at which ScCENP-H/I/K were expressed efficiently. The blot in Figure 8D shows a weak signal from the Strep-Tactin HRP conjugate, appearing 12 hrs after induction of ScCENP-H/I/K-StrepII expression. This may be non-specific as in contrast to the other blots, which were exposed for seconds, this signal appeared only after a minute of exposure. Furthermore I attempted a small scale purification of 6xHis tagged ScCENP-H/I/K which did not specifically enrich for any protein. Lastly if the complex were expressed, ScCENP-I should produce a characteristic high molecular weight band of about 84kD, which was never observed (data not shown). Thus work on ScCENP-H/I/K was postponed.

Initial NiNTA bead batch purification of the ScCENP-Q/U/P/O complex suggested that it could be purified at high yield and high purity. Figure 9A shows a purification scheme for the ScCENP-Q/U/P/O complex and the inset shows the same sample run on a longer Gel as the central ScCENP-O and ScCENP-U bands often did not separate on a standard 10cm Gel. Band identity was established by cutting out the individual bands and identifying the corresponding protein by mass spectrometry. Although resolvable by large gels, these tended to smear and thus in many cases were not informative. Because this issue could not be resolved, only small gels will be shown. In these small gels, when ScCENP-O and ScCENP-U do not resolve, ScCENP-P acts as a proxy for the amount of ScCENP-O and ScCENP-Q acts a proxy for the amount of ScCENP-U. This is valid because when analyzing either, the ScCENP-Q/U/P/O complex or the two subcomplexes ScCENP-P/O and ScCENP-Q/U, there was always an equi-stoichiometric 1:1 relation between ScCENP-P and ScCENP-O as well as ScCENP-Q and ScCENP-U (compare Figure 18A).

Figure 8. Expression condition screen

Figure 8) Expression analysis for the constructed ScCCAN subcomplex expression vectors. Each putative complex was expressed at 4 different temperatures and samples were taken at three timepoints. OD₅₀₀ measurements are summarized by the graphs on the left while soluble protein from these samples is analyzed by western blots on the right. Results are displayed in **A)** for ScCENP-Q/U/P/O, in **B)** for ScCENP-P/O, in **C)** for ScCENP-Q/U, in **D)** for ScCENP-H/I/K and in **E)** for ScCENP-L/N.

3.5 Establishment of a purification protocol suitable for isolation of recombinant ScCENP-Q/U/P/O, ScCENP-Q/U, ScCENP-P/O and ScCENP-L/N

The ScCENP-Q/U/P/O complex after size exclusion chromatography appears equi-stoichiometric (Figure 9A). During size exclusion chromatography the entire ScCENP-Q/U/P/O peak migrated in the void volume, indicating either a large assembly or precipitated complex. Because no visible precipitation occurred in the sample and ScCENP-P, ScCENP-Q and ScCENP-U localize chromatin proximal, I reasoned that this effect could be caused by nonspecific binding to bacterial DNA^[469]. To investigate this I loaded purified ScCENP-Q/U/P/O onto an ethidium bromide stained agarose gel and indeed observed a smear of what presumably was DNA (Figure 9A). The ScNDC80C purified according to the same NiNTA standard protocol serves as a negative control, demonstrating that this is not an artifact of the purification process itself. Similarly a purified ScCENP-L/N complex co-purifies what presumably is DNA (Figure 9B).

To further investigate the co-purifying nucleic acid I performed a TRIzol[®] extraction of the purified ScCCAN-CENP-Q/U/P/O. Although one may assume that DNA is the contaminant, classical and modern work demonstrates RNA as a component of the vertebrate inner kinetochore plate during mitosis and a band connecting the two co-oriented kinetochores during meiosis^[839-841]. A role for RNA at the vertebrate kinetochore has been described. Human centromeric α -satellite DNA is highly transcribed by RNA-Pol2 and α -satellite RNA stabilizes CENP-C binding to DNA. Furthermore alpha satellite RNA is required for CENP-C, Borealin and INCENP but not Survivin to localize to the centromere. This is interesting in light of the fact that vertebrate CENP-I is required for CENP-C recruitment in interphase and that budding yeast loses ScBorealin and ScINCENP but not ScSurvivin from the kinetochore when ScCENP-U is lost^[842, 843]. Therefore it is not innately clear that the CENP-Q/U/P/O complex is DNA binding rather than RNA binding although the contamination by bacterial nucleic acid suggests that binding is rather unspecific.

A TRIzol[®] extraction allows to discriminate between DNA and RNA as RNA partitions to the aqueous phase while DNA can be recovered from the organic phase after extraction. To ensure that the extraction was successful, an additional step was applied, the digestions of extracted DNA or RNA by DNaseI or RNase A. Figure 10A shows an ethidium bromide stained agarose gel displaying the results of this experiment. The vector pET3aTr was used as control DNA, while control RNA was taken from an in situ hybridization kit available in the laboratory. It appears that the major fraction of the contaminating nucleic acid is found in the RNA-phase and contamination by carry over is unlikely as it is isolated from the top aqueous phase. Unfortunately subsequent digestion is not conclusive as our RNase A shows activity against the control DNA. Thus, I could not unequivocally identify the contaminant. Because

the contaminant is of bacterial origin and likely not representative for an actual interaction occurring in budding yeast I instead focused on removing it from the ScCENP-Q/U/P/O complex rather than further investigating it. It is however interesting to note that a different research group performing similar experiments found a bacterially expressed CENP-Q/O/P heterotrimer to be contaminated by nucleic acid and contamination could only be removed by RNase A, not DNase I or Benzonase^[844].

Following the results displayed in Figure 10A, I attempted to remove the contaminant by digestion. I was unsuccessful in using DNaseI and the higher pH and temperature required for a micrococcal nuclease digestion precipitated the complex. Digestion by RNase A had limited success and allowed purification of contaminant free ScCENP-Q/U/P/O, however the yield dropped significantly as much of the protein precipitated during the procedure and the remaining complex appeared inseparably bound to what is likely the bacterial DnaJ chaperone (data not shown). Thus a different purification protocol was needed. Figure 10B displays an initial attempt to use a high ionic strength buffer, 500mM NaCl, to dissociate complex and contaminant during size exclusion chromatography. While separation is evident, the resolution is insufficient to yield pure samples and one observes dissociation of the ScCENP-Q/U and ScCENP-O/P subcomplexes. After multiple different buffer additives and attempted ion exchange chromatography either failed to generate pure complex or dissociated the two subcomplexes, I performed a parallel screen, testing multiple ionic strength buffers in order to find conditions under which the complex would remain stable but the contaminant would be removed.

To find a suitable washing buffer I set up a large-scale batch purification from 24l of liquid culture in a standard low salt lysis buffer and split the ScCENP-Q/U/P/O bound Ni-NTA beads into equal fractions. These beads were then washed twice by incubation and agitation in a specific washing buffer. Each washing buffer had the same composition as the initial lysis buffer save for the salt concentration. A series of wash buffers was used, containing increasing concentrations of either KCl, NaCl, MgCl₂ or CaCl₂. I succeeded at removing the contaminant from ScCENP-Q/U/P/O 6xHis bound to NiNTA beads with both KCl and NaCl. While KCl was suitable to remove the contaminant and preserve subunit stoichiometry, NaCl did so at lower concentrations and therefore a 600mM NaCl was subsequently used for purification (Figure 11A). It is important to note that the high salt wash buffer was not added at the lysis step but only applied after two initial washes in low salt lysis buffer (150mM NaCl). Furthermore in later large-scale purifications each washing step was standardized and consisted of 10min agitation of the beads in wash buffer. It is not possible to give a standard number of washing steps. Rather, one needs to collect the wash buffer after washing and monitor 260nm and 280nm extinction at each washing step, continuing until completion, i.e. until protein and DNA signal in the wash buffer decrease to noise level.

Even low levels of remaining contaminant are sufficient to move most of the complex into the void volume during size exclusion chromatography.

Figure 9. Contamination of recombinant ScCCAN subcomplexes by bacterial DNA

Figure 9A) Expression and purification strategy for ScCENP-Q/U/P/O 6xHis by NiNTA affinity purification and size exclusion chromatography. The final complex migrated in the void volume during chromatography. To test for nonspecific DNA binding, a sample of the complex was analyzed on an ethidium bromide stained Agarose Gel. ScNDC80C served as control and in contrast to ScCENP-Q/U/P/O is not contaminated by DNA. **Figure 9B)** Similarly to the CENP-Q/U/P/O complex, FLAG-tag affinity purified ScCENP-L/N migrated in the void volume during size exclusion chromatography and was contaminated by DNA.

Figure 10. Analysis of the contaminant

Figure 10A) To analyze the contaminant found in recombinant ScCENP-Q/U/P/O complex, DNA and RNA from a sample of the complex were extracted with the Trizol® reagent. DNA and RNA fractions were further analyzed by digestion with DNaseI or RNase A, respectively, to confirm extraction results. Note that our RNase A was active against DNA as evidenced by degradation of the control DNA (pET3A). The majority of the contaminant remains in the RNA fraction. Note lane 6, CENP-Q/U/P/O that has not been extracted with TRizol® and remains in complex with the contaminant retains it in the Gel-pocket. **Figure 10B** demonstrates an initial attempt to separate complex and contaminant by increasing ionic strength in the buffer. ScCENP-Q/U/P/O was subjected to size exclusion chromatography in a running buffer containing either 150mM or 500mM NaCl. While the complex peak does separate from the contaminant peak in high salt, during chromatography the complex itself dissociates and peak separation is not sufficient to isolate pure samples.

Although salt washes removed the contaminant, the pure CENP-Q/U/P/O complex after elution was very unstable and tended to precipitate shortly after elution. Thus I set up a secondary systematic screen in the hope to find conditions that would stabilize the contaminant-free complex. The approach was similar to the initial screen. A large-scale purification from 24I was performed and washed as described. Following washing, beads were split into equal volumes and eluted with buffer that was equal to the lysis buffer save for the 300mM imidazole required for elution and one varied parameter, ionic strength, pH or additive. I screened a series of pH variations, a series of ionic strength variations and a number of ionic additives. 5mM of divalent cations known to be complexed with some proteins, Mg^{2+} , Zn^{2+} and Ca^{2+} were tested. Because divalent cations may have precipitating effect on proteins, one buffer containing 50mM of both EGTA and EDTA was tested. While EDTA has a preference for Mg^{2+} and EGTA has a preference for Ca^{2+} , both generally complex divalent cations and thus this buffer, with a relatively high concentration of chelators, would be expected to remove all divalent cations from solution. Lastly Heparin was tested. Heparin is highly negatively charged and thought to remove DNA from DNA binding proteins by competition for the often basic binding site. Figure 11B shows the results of the pH and additive screen, the ionic concentration screen is omitted because only a minor effect on complex stability was observed. Note that the ScCENP-U and ScCENP-O bands have not been separated on these gels. Thus complex integrity was judged by intensity of ScCENP-P relative to ScCENP-Q. Observe that in the bottom gel of Figure 11B addition of EGTA/EDTA affects stoichiometry negatively, as the ScCENP-P band is entirely absent. Addition of 5mM Ca^{2+} in contrast provides best preservation of stoichiometry although some ScCENP-O/P is lost and subsequently separates from ScCENP-Q/U/P/O during size exclusion chromatography. In the following large-scale purifications, the concentration of Ca^{2+} was reduced to 1mM to minimize possible adverse effects of this chaotropic ion. The top gel displays the effects of varying pH in the elution buffer. While not significant, it appears that a slightly lower pH between 6.6 and 7 is beneficial, although, because no Ca^{2+} was present in these elution buffers, complex stoichiometry is significantly disrupted.

Using the conditions established in this screen the first large scale purification was performed from 6l liquid culture. The purification scheme in Figure 12 demonstrates its success. The contaminant is present in the complex eluted from beads before the washing steps but absent after washing. Concentrated ScCENP-Q/U/P/O complex loaded onto a size exclusion chromatography column separates sufficiently to obtain pure samples (Figure 12B). The pure ScCENP-Q/U/P/O complex is followed by a complex that co-migrates with a high amount of putative chaperone and later by what appears to be disrupted dimeric complex, predominantly ScCENP-Q/U. The yield is relatively low, about 1,5mg of total protein per 6l culture, sufficient only for a few assays, but the complex behaves well during size exclusion chromatography as shown in Figure 14 A.

All three dimeric subcomplexes ScCENP-Q/U, ScCENP-O/P and ScCENP-L/N, when expressed individually, were found to be contaminated with bacterial DNA. I successfully applied this protocol to purify in addition the ScCENP-Q/U complex (Figure 13). The yield of a ScCENP-Q/U purification is significantly higher with about 11mg per 6l culture. Dr. Peter Hornung successfully used this protocol to purify both ScCENP-O/P and ScCENP-L/N complexes. One may deviate from the ScCENP-Q/U/P/O protocol by using salt concentrations of 1M and 1,5M for the purification of ScCENP-Q/U and ScCENP-P/O respectively, to expedite washing. Both dimeric complexes are extremely salt stable, the CENP-Q/U complex did not dissociate when NaCl concentration was gradually increased up to 5M, suggesting a hydrophobic interaction between ScCENP-Q and ScCENP-U (data not shown).

Figure 11. Systematic screen for suitable ScCENP-Q/U/P/O wash and elution buffers

Figure 11A) displays the results of the NaCl concentration series in a screen to find a suitable wash buffer that would remove the contaminant but retain complex stoichiometry. The contaminant is lost with increasing salt strength retaining complex integrity up to 600mM NaCl. Beyond 600mM NaCl, complex stoichiometry was significantly disrupted (not shown). **Figure 11B)** displays the results of the subsequent screen for an elution buffer that would stabilize the contaminant-free complex. Note the absence of ScCENP-P from the complex when EGTA/EDTA is supplemented (small arrow). Addition of 5mM Ca²⁺ in turn provided best conservation of ScCENP-P in the ScCENP-Q/U/P/O complex that was purified through a 6xHis tag on ScCENP-U.

Figure 12. Purification of ScCENP-Q/U/P/O

A. Batch purification

B. Size exclusion chromatography

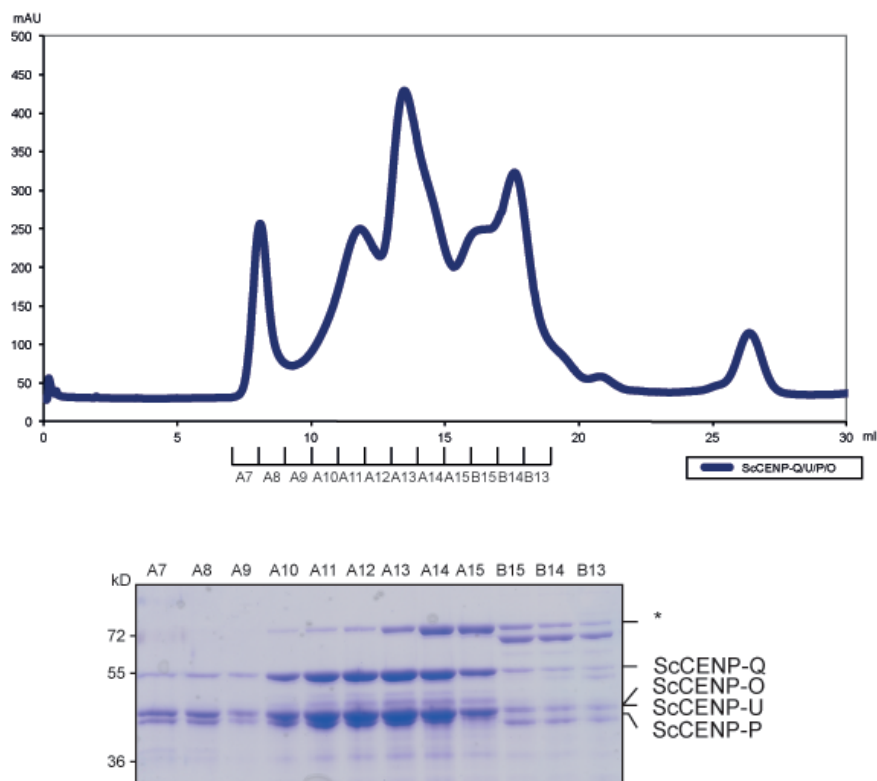

Figure 12A) Large scale batch purification of ScCENP-Q/U/P/O. Comparative SDS-PAGE and ethidium bromide agarose gels demonstrate that the contaminant is lost by washing and complex stoichiometry remains intact. **Figure 12B)** Size exclusion chromatography of ScCENP-Q/U/P/O. Note the pure complex in fraction A10-13 followed by a contaminating chaperone band (*) in fraction A14-15 and dimeric ScCENP-Q/U in A14-A15.

Figure 13. Purification strategy for ScCENP-Q/U

Figure 13) Purification scheme of recombinant ScCENP-Q/U. After initial adsorption of the complex onto beads, the complex was washed 5 times in 1M NaCl containing wash buffer. The complex was further purified by size exclusion chromatography. An ion exchange chromatography step following SEC did not yield a significant increase in purity.

3.6 Interactions of the ScCENP-Q/U/P/O complex.

With the recombinant ScCENP-Q/U/P/O complex in hand I was able to perform in vitro binding assays. Three candidates were investigated. Firstly the ScMIS12C, as it is unclear how it is recruited to kinetochores in yeast, but its localization is impaired in ScCENP-Q mutants^[600]. Secondly, binding to microtubules was tested, as a vertebrate CENP-Q interaction with microtubules had been shown^[451]. Thirdly, the interaction with DNA was tested, as the complex was contaminated with bacterial DNA/RNA. Starting out with the ScMIS12C, I tested for a potential interaction with the ScCENP-Q/U/P/O complex by a binding assay in which I mixed both complexes in solution and analyzed complex formation by size exclusion chromatography. The chromatogram in Figure 14A demonstrates co-elution of the two complexes after mixing and a notable shift of the elution profile to a lower volume which is accompanied by an increase of the Stokes radius as both complexes associate. This interaction was confirmed by Dr. Peter Hornung by both size exclusion chromatography and CoIP and has since been published^[488]. The corresponding SDS-PAGE analysis in Figure 14B shows the shift and the effect of binding on complex stoichiometry. Currently we are not certain why some ScCENP-O appears to remain in the higher elution volume. However in the topmost gel, lane A11, it appears that some ScCENP-O may exist free from the COMA complex in this sample. Some of our unpublished binding assays suggest that it is the CENP-Q/U complex, likely CENP-U, that binds to either ScMis12 or ScNnf1 which is supported by Figure 4. This would explain why free ScCENP-O is incompetent to bind ScMIS12C (Dr. Peter Hornung, personal communication).

Figure 14. In vitro reconstitution of an interaction between ScCENP-QUPO and ScMTW12C

Figure 14) In vitro reconstitution of an interaction between ScMIS12C and ScCENP-Q/U/P/O. **A)** Overlay of the chromatograms resulting from analytical size exclusion chromatography of ScCENP-Q/U/P/O, ScMIS12C and the ScMIS12C-ScCENP-Q/U/P/O complex formed by pre-incubation. **B)** Consecutive fractions eluted during analytical SEC. Note that some ScCENP-O retains a low elution volume and does not associate with the complex.

Having demonstrated interaction between ScCENP-Q/U/P/O and ScMIS12C I investigated the interaction of ScCENP-Q/U/P/O with microtubules. For this I initially employed a standard

microtubule co-sedimentation assay (MTBA) in which microtubules are assembled in vitro, stabilized by Taxol, incubated with the protein complex in question, then separated from the supernatant by centrifugation. The microtubule pellet and the remaining supernatant are then analyzed for the relative amount of sedimenting complex. The standard assay uses conditions that are detrimental to the solubility of ScCENP-Q/U/P/O, namely a low salt buffer and no Ca^{2+} . I was able to supplement 150mM NaCl but omit Ca^{2+} , which depolymerizes microtubules, and thereby reduce the fraction of ScCENP-Q/U/P/O that sedimented in absence of microtubules. Figure 15A displays an initial MTBA using standard conditions. Note the strong, microtubule independent sedimentation of ScCENP-Q/U/P/O. Figure 15B displays a microtubule binding assay in the presence of 150mM NaCl in the binding buffer. Some microtubule-independent sedimentation of ScCENP-Q/U/P/O remains but no microtubule concentration dependent increase in sedimentation is evident. Thus, ScCENP-Q/U/P/O does not bind microtubules in my hands.

Figure 15. ScCENP-Q/U/P/O microtubule binding assay

A

B

Figure 15) Microtubule binding assays for ScCENP-Q/U/P/O. **A)** The ScCENP-Q/U/P/O complex sediments on its own under standard MTBA buffer conditions. **B)** Supplementing 150mM NaCl reduces ScCENP-Q/U/P/O sedimentation. Under these conditions, no interaction with microtubules is observed, as there is no tubulin-dependent increase of sedimenting ScCENP-Q/U/P/O.

Lastly I attempted to demonstrate DNA binding activity of the ScCENP-Q/U/P/O complex. For this I adopted a simple electrophoretic mobility shift assay (EMSA) in which I used a yeast centromeric sequence that was incubated with ScCENP-Q/U/P/O for thirty minutes. Upon binding, I expected a decreased mobility of only the centromere-containing DNA in a Polyacrylamid Gel if ScCENP-Q/U/P/O bound the centromere with sequence specificity and decreased mobility for both centromeric and non-centromeric control DNA if binding was nonspecific.

Figure 16. EMSA for ScCENP-Q/U/P/O

Figure 16A) EMSA using recombinant ScCENP-Q/U/P/O, a CEN6-ARSH4 containing fragment excised from pRS313 and the corresponding CEN6-ARSH4 free fragment excised from the parent vector pRS303. **Figure 16B)** EMSA using CEN6 amplified from pRS313 and salmon sperm as a CEN-free control.

Figure 16A displays an initial attempt. Here a fragment containing CEN6-ARSH4 of pRS313 was excised using restriction enzymes *ScaI* and *AfeI*, yielding a CEN6 containing DNA fragment of 1231bp length. The same region was excised from the parent vector, pRS303,

lacking both yeast CEN6 and ARSH4, to yield a 708bp fragment devoid of a centromere. Both sequences were tested for binding to ScCENP-Q/U/P/O. Mobility of only the CEN6 containing sequence is decreased when incubated with ScCENP-Q/U/P/O complex. In an attempt to further refine this assay I used a smaller construct, a single CEN6 sequence amplified by PCR (Figure 16B). To increase the mobility shift, I added anti-Hisx6 antibodies to one ScCENP-Q/U/P/O-CEN6 binding reaction in the hope of supershifting the complex on the polyacrylamide gel. Results of these EMSAs were not conclusive. The ScCENP-Q/U/P/R samples used in these initial experiments were purified by RNase digestion, not by salt washes and retained some bacterial DNA. Rather than unambiguously decreasing DNA mobility, ScCENP-Q/U/P/O appeared prone to retain additional CEN6 DNA in the gel pocket. Note however that lane 4, which includes the anti-Hisx6 antibody, displays a band that is smeared upwards. Dr. Peter Hornung was more successful using agarose gels to demonstrate a mobility shift (not shown, unpublished)

3.7 Phosphorylation-site analysis of the budding yeast CCAN.

We decided to map phosphorylation sites on all ScCCAN proteins to be able to investigate potential phospho-regulation. To this end the samples I generated during my tandem affinity purifications of native yeast ScCCAN proteins were not only subjected to protein identification but also to identification of phosphorylation sites by mass spectrometry. Figure 17 displays the collection of all phosphosites detected in vivo. Among others, we detected multiple phosphosites conforming to the CDK1 minimum consensus sequence [S/T][P]. It has previously been established that ScCENP-T is a specific target of Clb5-CDK1^[95]. Vertebrate CENP-U and CENP-T have been demonstrated to contain multiple CDK-phosphorylated residues^[582]. ScCENP-U contains a cluster of phosphorylated CDK1 consensus sites close to its amino terminus (Figure 17B). Clusters of CDK1 consensus sites are predictive for in vivo phosphorylation and finding a phosphorylated cluster here identifies an interesting, possibly functionally regulated region of ScCENP-U^[845]. In order to confirm the results obtained from native kinetochore proteins I employed an in vitro phosphorylation assay. Both ScCENP-Q/U/P/O subcomplexes, ScCENP-Q/U and ScCENP-O/P were tested for phosphorylation by either Clb2-CDK1 or Clb5-CDK1. As demonstrated in Figure 18, ScCENP-U, ScCENP-Q and ScCENP-O are in vitro targets for CDK1. ScCENP-U displays a prominent mobility shift during SDS-PAGE after CDK1 phosphorylation (Figure 18A).

Figure 17A) Mapped in vivo phosphorylation sites on ScCCAN proteins. Red letters denote phosphorylated sites. Red-shaded letters mark phosphorylated CDK1 consensus sites. Pairs of blue letters denote that at least one residue of the pair is phosphorylated but it is uncertain which. The green serine within the sequence of ScCENP-U denotes a site conforming to a polo like kinase consensus sequence not found to be phosphorylated. **Figure 17B)** Schematic depiction of phosphorylation sites on proteins of the ScCENP-Q/U/P/O complex as well as on the ScCENP-T/W complex. Phosphorylation sites conforming to a minimal CDK1 consensus are marked in red, all other phosphorylation sites in black. The colored segments denote structural elements identified by Dr. Alexander Schleiffer. Blue represents a predicted coiled coil while green represents a histone fold. Light green marks a C-terminal domain unique to CENP-T orthologues.

ScCENP-Q/U and ScCENP-P/O were in vitro phosphorylated using ATP γ ³²P and either Clb2-CDK1 or Clb5-CDK1. The autoradiographs in Figure 18B demonstrate that ScCENP-U is strongly phosphorylated by Clb2-CDK1 but not by Clb5-CDK1. Similarly, ScCENP-O is strongly phosphorylated by Clb2-CDK1 but only weakly Clb5-CDK1. As Clb2-CDK1 displayed a higher activity towards both, ScCENP-Q/U and ScCENP-P/O, I performed two additional in vitro phosphorylation reactions of both complexes using Clb2-CDK1 and ATP. The residues phosphorylated in vitro were subsequently identified by mass spectrometry. As was the case in vivo, no in vitro phosphorylated residues were detected on ScCENP-P. Recombinant ScCENP-Q was in vitro phosphorylated by Clb2-CDK1 but none of the phosphorylated residues matched those identified on the native protein. In contrast the CDK1 consensus site on ScCENP-O S139 was phosphorylated both in vivo and in vitro. The CDK1 phosphorylated N-terminal cluster found on ScCENP-U in vivo was confirmed by in vitro phosphorylation. T31, S41, S45 and S53 were phosphorylated in both experiments. Phosphorylation of the adjacent S58 was only detected in vivo while phosphorylation of the CDK1 consensus at S101 was only detected in vitro.

The animal kinetochore undergoes extensive assembly and disassembly during the cell cycle. The CPC, the KMN network, Zwint-1, CENP-E, CENP-F, Bub1 and BubR1 localize to the kinetochore between late G2 and prophase while the RZZ complex, Spindly, Mad1&2 and Dynein/Dynactin localize to the kinetochore shortly before or after NEBD. SAC proteins and the CPC leave the kinetochore before anaphase onset while the KMN network leaves at telophase^[503, 515, 531, 577, 596, 612, 738, 846]. CCAN proteins remain at the centromere throughout most of the cell cycle but recent higher resolution assays demonstrate subtle cell cycle specific changes^[570, 632, 717, 795]. In contrast, budding yeast kinetochores appear competent to assemble at any point during the cell cycle as long as ScCENP-A has been deposited at the centromere during S-Phase. However more subtle changes of kinetochore assembly or, as reported for purified kinetochore particles, changes in microtubule affinity may take place over the cell cycle^[465, 788, 847]. The prime candidate for the regulation of cell cycle dependent kinetochore assembly would be a cyclin dependent kinase. Supporting the idea of a CDK regulated kinetochore assembly, it has recently been demonstrated that CDK1 phosphorylation- mimicking vertebrate CENP-T recruits NDC80C to ectopic foci while a CDK1 phosphorylation negative CENP-T does not^[577]. However to date no essential CDK phosphorylation at the kinetochore has been described. Confirming a CDK1 cluster on the essential ScCENP-U, together with its interaction with the ScMIS12C suggested its essential function may be regulated by CDK1.

In order to test this, I employed the anchor away technique in a yeast strain in which conditional nuclear depletion of ScCENP-U was possible. In short this technique relies on the

high affinity dimerization of human FKBP12 and the FRB domain of human mTOR that is induced in presence of rapamycin. FKBP12 is fused to the ribosomal RPL13A in the anchor away parent strain used, while a FRB domain can be fused to the protein targeted for depletion from the nucleus. Upon addition of rapamycin, RPL-13A-FKBP12 and FRB-ScCENP-U dimerize and the flux of ribosomal proteins out of the nucleus sequesters FRB-ScCENP-U into the cytoplasm. Because the nuclear envelope never breaks down, this technique is applicable to deplete a nuclear protein during budding yeast mitosis^[848]. The anchor away FRB-ScCENP-U strain was a kind donation of Dr. Christine Mieck. As demonstrated in Figure 19, this strain fails to grow when ScCENP-U depletion is induced on rapamycin containing YPD-plates while the parent strain is viable. To investigate the functional significance of the identified CDK1 cluster, ScCENP-U was cloned into pRS306. I included 284bp upstream sequence preceeding the start codon and 234bp downstream of the stop codon to preserve the native promoter and 3'UTR, so expression of episomal ScCENP-U would be regulated to levels close to those of genomic ScCENP-U. CDK1-phosphonegative ScCENP-U was generated by a Quikchange® site directed mutagenesis kit, mutating T31, S41, S45, S53 and S101 of pRS306-ScCENP-U to alanine. The FRB-ScCENP-U anchor away strain was then transformed with either pRS306-ScCENP-U or pRS306-ScCENP-U 5A linearized with AfeI and selection for the Ura⁺ marker allowed isolation of clones containing either ScCENP-U or ScCENP-U 5A integrated into the URA3 locus. If CDK1 phosphorylation of ScCENP-U regulated an essential process, one would expect ScCENP-U to rescue a depletion of genomic ScCENP-U while ScCENP-U 5A should not be able to do so.

As evident in Figure 19, both, ScCENP-U and ScCENP-U 5A are competent to rescue the lethality of a conditional ScCENP-U depletion. Three clones resulting from transformation with either pRS306-ScCENP-U or pRS306-ScCENP-U were tested. While this may be surprising, it is consistent with results in vertebrates. Here, changing 16 CDK1 phosphorylation sites of CENP-U to alanine did not have an observable phenotype^[582].

Figure 18A) In vitro phosphorylation of ScCENP-Q/U and ScCENP-P/O with either Clb2-CDK1 or Clb5-CDK1. Note the mobility shift of ScCENP-U upon phosphorylation. This figure also displays the 1:1 stoichiometry of ScCENP-Q/U and ScCENP-O/P and demonstrates that band identity ascribed earlier by mass spectrometric protein identification is correct. **Figure 18B)** Autoradiograms of ScCENP-Q/U and ScCENP-P/O phosphorylated by either Clb2-CDK1 or Clb5-CDK1 with ATP³²P. **Figure 18C)** Clb2-CDK1 in vitro phosphosites identified on ScCENP-O/P and ScCENP-Q/U. Phosphorylated residues identified both in vitro and in vivo are colored red, phosphorylated residues only found in vitro are colored pink. Phosphorylated minimum CDK1 sites are shaded red.

Figure 19. ScCENP-U CDK1 sites are not essential

Figure 19) A Rapamycin induced, conditional nuclear depletion of ScCENP-U fused to a FRB-domain in an anchor away strain is lethal but can be rescued by expression of ScCENP-U integrated into the URA3 locus. Mutating the 5 CDK1 phosphosites identified in vitro to alanine does not impair the ability of integrated ScCENP-U mutants to rescue viability.

4. Discussion

In this work I have investigated interactions of the budding yeast ScCCAN with other kinetochore components and thereby corroborated our claim that this supramolecular assembly located at the chromatin base of the kinetochore is a KMN network assembly platform conserved between yeast and vertebrates. The principal findings are firstly the conserved identity and function of CCAN subcomplexes. Secondly I have begun to delineate subcomplex architecture in the budding yeast CCAN and investigated interactions of the ScCENP-Q/U/P/O complex.

4.1 Conservation of CENP-T/W and CENP-S/X complexes in budding yeast

In my tandem affinity purifications, I found ScCENP-T^{Cnn1} to associate with ScNDC80C and ScKnl1. Furthermore I identified a candidate yeast CENP-W homologue, Wip1, confirmed it as a kinetochore protein and showed that its localization depends on ScCENP-T^{Cnn1}. This closely parallels the situation in vertebrates. Identification of ScCENP-W^{Wip1} allowed later successful co-expression and purification of a recombinant ScCENP-T/W dimer by Dr. Stefan Westermann, which was demonstrated to directly bind ScNDC80C via ScCENP-T's extended flexible N-terminus. While this work was ongoing, an interaction between

vertebrate CENP-T and NDC80C was demonstrated^[11, 577]. Taken together this strongly suggests a conserved function for ScCENP-T/W in ScNDC80C recruitment.

I failed to observe co-localization of GFP-tagged ScCENP-S/X with Nuf2 as a marker for the kinetochore. By tandem affinity purification however, ScCENP-X prominently associates with the ScCCAN while ScCENP-S associates with the FANCM related Mph1, interactions previously described for vertebrate CENP-S/X. I found both to co-purify with ScCENP-T, again paralleling the findings in vertebrates^[581, 834]. Therefore CENP-S/X are conserved in budding yeast and appear to associate with other centromere proteins. We do not know why I was unable to observe localization of either ScCENP-X-GFP or ScCENP-S-GFP to the kinetochore. A trivial explanation may be that the GFP fusion proteins are not functional. Alternatively we suspect that its localization may be very transient during S-phase when centromeres are replicated. Kinetochore may pose a replication block to a DNA polymerase encountering them. Indeed, the brief detachment of kinetochores during S-phase requires replication and is thus unlikely to be regulated by the outer kinetochore. Interestingly, during detachment, ScCENP-P is lost from the kinetochore suggesting that the encounter of a replication fork with a kinetochore induces its disassembly^[45]. It is conceivable that some ScCCAN proteins, including ScCENP-S/X, mediate disassembly of the ScCCAN during replication if they encounter an active replisome. FANCM/Mph1 promotes replication fork regression and recombination repair under replication stress, when the DNA polymerase stalls. It is possible that FANCM/Mph1 stabilizes replication forks encountering a kinetochore and thereby assists replication through the centromere. This would however not be an essential mechanism as neither ScCENP-S/X nor FANCM/Mph1 are essential.

4.2 Conservation of the CENP-Q/U/P/O/R complex and the CENP-L/M/N group in yeast

Distant sequence homology of CENP-Q/U/P/O/R and ScCENP-Q/U/P/O^{COMA} as well as CENP-L/M/N and ScCENP-N/L^{Chl4,Im13} suggests these two groups are also conserved in budding yeast. Indeed I was able to purify recombinant ScCENP-Q/U/P/O^{COMA}. As the existence of a vertebrate CENP-Q/U/P/O/R complex is established, this supports conservation of this complex as a defined molecular identity. We do, however, not know if the complex is functionally conserved. ScCENP-Q/U are essential, which might be explained by their interaction with ScMIS12C. Reports on the vertebrate CENP-Q/U/P/O/R conflict and most suggest that its loss leads to only a minor mitotic defect^[555, 556, 717]. Furthermore no effect on vertebrate MIS12C localization has been described upon loss of CENP-Q/U/P/O/R. Thus, binding of ScCENP-Q/U/P/O to ScMIS12 may be specific to yeast but it will be interesting to investigate this possible interaction in vertebrates. Time limited the characterization of the ScCENP-N/L^{Chl4,Im13} complex. All we can currently say is

that the two recombinant proteins, ScCENP-N and ScCENP-L, do form a stable complex even after bacterial DNA has been removed (Dr. Peter Hornung, personal communication). Complex formation for the vertebrate CENP-L/M/N has not yet been demonstrated. We lack a homologue for CENP-M in both budding and fission yeast (Table 1). It is interesting to note here that a loss of vertebrate CENP-M, in contrast to a loss of CENP-L or CENP-N, has a milder but still substantial effect on cell viability. Lastly, the existence of a complex formed by the ScCENP-H/I/K group of proteins still needs to be investigated in both budding yeast and human cells. For reasons unknown, I was unable to express recombinant ScCENP-H/I/K in bacteria. I speculate that either ScCENP-H/I/K may require other components of the ScCCAN to be co-expressed in order to fold correctly or that it is posttranslationally modified. Vertebrate CENP-H/I/K is SUMOylated during S-Phase and it has been suggested that this modification is required for stability^[715]. It may be therefore possible to express ScCENP-H/I/K in eukaryotic expression systems such as insect cells.

4.3 Interactions of the ScCENP-Q/U/P/O^{COMA} complex with ScMIS12C, microtubules and DNA

Two interactions between the ScCCAN complex and the KMN network could be demonstrated. A direct interaction between ScCENP-Q/U/P/O and MIS12C in this work and, following this work, a direct interaction between ScCENP-T and NDC80C by Dr. Stefan Westermann^[11, 488]. As MIS12C binds NDC80C, I suggest at that least two independent populations of NDC80C exist at the kinetochore, one recruited by ScCENP-T/W and one recruited by ScCENP-Q/U/P/O via the ScMIS12 complex. It is unclear if this interaction is conserved between budding yeast and man as depletion of vertebrate CENP-Q/U/P/O/R does in most cases not lead to severe defects. Alternatively animal MIS12 has been demonstrated to bind CENP-C, which has not been described for budding yeast^[598, 599]. It will be interesting to delineate if vertebrates and yeast possess three shared recruitment pathways for NDC80C or if budding yeast utilizes ScCENP-Q/U/P/O/R while vertebrates utilize CENP-C for MIS12C recruitment and both recruit additional NDC80C via CENP-T. It will also be necessary to resolve the position of Knl-1 within this network. One may suspect that Knl1 is recruited to MIS12C and not to ScCENP-T. However I find low amounts of ScKnl1 exclusively in ScCENP-T tandem affinity purifications. It has been demonstrated that a loss of the Ndc80 internal loop leads to a loss of a subpopulation of Knl1 from vertebrate kinetochores. In *C.elegans*, CeMIS12C has been suggested not to be required for CeNDC80C recruitment. In depletions of CeMIS12C, CeNDC80C is recruited to kinetochores, albeit delayed, dependent on CeKnl-1 and CeKnl-3, a protein essential for *C.elegans* kinetochore assembly that has no currently known homologues. Given that CENP-T is not conserved in *C.elegans*, this may have been due to incomplete depletion of

CeMis12C, yet, recruitment of CeNdc80C is dependent on CeKnl1. Furthermore in budding yeast, absence of either, ScNDC80C or ScKnl1, the respective other demonstrates decreased kinetochore localization. It is thus possible that ScNDC80C and ScKnl1 form a complex that is recruited by ScCENP-T independently of ScMIS12C or that ScKnl1 recruitment partially depends on the ScCCAN proteins present in this purification^[498, 849, 850]. Recent measurement of budding yeast kinetochore protein stoichiometry however does not support a ScMIS12 independent ScKnl1 population at the kinetochore as their copy number closely match. Yet ScNDC80C is present in excess over ScMIS12C, each kinetochore contains ~19 and ~15 copies respectively. Postulating the remaining 4 copies of NDC80C to be recruited by ScCENP-T/W would explain this discrepancy. Similarly, ScMIS12C is present in excess over both, ScCENP-C (4 copies) and ScCENP-P (6 copies). Dual recruitment of ScMIS12C by ScCENP-C and ScCENP-Q/U/P/O may explain how more ScMIS12 is recruited than could be accommodated by a single species of kinetochore receptors^[471, 851]. This model may however not sufficiently take into account the dynamics of structural ScCCAN and ScKMN network components as ScCENP-T has been reported to increase, from a copy number of 6 up to a copy number of 20 during anaphase^[836].

Vertebrate CENP-Q has previously been demonstrated to interact with microtubules^[451]. I could not observe microtubule binding of the ScCENP-Q/U/P/O complex. It is possible that the increased salt, 150mM, in the MTBA prohibits this interaction. It is also possible that microtubule binding of CENP-Q is vertebrate specific. Alternatively the observed microtubule binding could be an artifact of using an isolated protein that is normally part of an obligate CENP-Q/U complex in both yeast and vertebrate cells. ScCENP-Q/U, ScCENP-O/P, ScCENP-Q/U/P/O and ScCENP-N/L were all contaminated by bacterial nucleic acid after purification while ScNDC80C was not. It appears that each dimeric subcomplex, ScCENP-Q/U, ScCENP-O/P and ScCENP-N/L contains either DNA or RNA binding activity. I was unable to unambiguously identify the contaminant as either RNA or DNA but I suspect it may be both. I envision these complexes to bind randomly throughout the bacterial nucleoid and, on purification, to co-purify fragments of the nucleoid that are actively engaged in transcription to explain what is possibly contaminating bacterial RNA. I attempted to establish a polyacryl-amide gel based EMSA protocol that would allow me to unequivocally demonstrate ScCENP-Q/U/P/O interaction with DNA, with limited success. The complex appears to bind DNA but the results were not sufficiently reproducible and often the tester DNA would simply be retained in the pocket when mixed with ScCENP-Q/U/P/O. Dr. Peter Hornung had more success using an agarose gel based EMSA, likely because of the larger pore size of these gels. It is however important to note that we do detect an interaction of the ScCENP-Q/U/P/O complex with DNA but not microtubules. This suggests that it is not a nonspecific interaction due to complex charge as both microtubules and DNA are negatively

charged at physiological pH. It appears in Figure 16A that ScCENP-Q/U/P/O binds to the centromere containing fragment but not to the centromere free fragment but I have obtained no evidence that the binding would be sequence specific. Rather it is possible that ScCENP-Q/U/P/O has a preference for AT-rich sequences such as that found in the CDEII element. Consistent with this idea, some yeast CENP-U or -Q proteins are predicted to contain “AT-Hooks” (Dr. Schleiffer, personal communication)

4.4 Regulation of and by the budding yeast CCAN

We mapped phosphorylation sites of ScCCAN proteins in vivo and demonstrated that Clb2-CDK1 directly phosphorylates the ScCENP-Q/U/P/O complex in vitro. The most striking feature was a CDK1-phosphocluster that we found in the N-terminus of ScCENP-U. A 5A phospho-negative mutant however shows no impaired viability. I did not investigate the effect of a phospho-mimicking mutant. Thus it is still possible that not phosphorylation but de-phosphorylation of this cluster is essential. We suspect CDK1 to have a role in kinetochore assembly or regulation. Even though the budding yeast kinetochore appears to remain intact throughout the cell cycle, save for a short period when the centromere is replicated, there may be subtle changes in kinetochore assembly or a cell cycle dependent suppression/activation of some of its functions^[592]. As we find at least two KMN network anchor points in the budding yeast CCAN, it is possible that this phospho-cluster is redundant. We have not yet investigated more subtle phenotypes that may have arisen due to deletion of this cluster such as increased benymol sensitivity or slower progression through the cell cycle. Alternatively, loss of the cluster may only produce a pronounced phenotype when redundant KMN anchors such as ScCENP-T are deleted.

Beyond CDK1 regulation, there is another interesting kinase I identified in my tandem affinity purifications of ScCENP-N and ScCENP-H, namely the DDK kinase complex. This complex is implicated in a number of functions in addition to initiation of DNA replication, including the formation of the synaptonemal complex during meiosis, translesion DNA synthesis and loading of Cohesin during replication in *X.laevis*^[110, 114, 116, 852-855]. Association of DDK with CCAN proteins could be artifactual as it targets origins of replication and at least CEN12 is, in addition to a centromere, an active origin of replication^[856, 857]. However, I find no components of the origin recognition complex in my tandem affinity purifications. Another possibility is that DDK promotes cohesion loading at the centromere. As mentioned in the introduction, a number of ScCCAN proteins participate in the loading of Cohesin and ScCENP-O participates in recruitment of the cohesion loader complex Smc2/Smc4. *X.laevis* DDK is found in complex with Smc2/Smc4 and is required for its recruitment to origins of replication. A similar relation may hold true for budding yeast and the ScCCAN may enhance cohesion loading via DDK and Smc2/Smc4^[858].

In tandem affinity purifications of ScCENP-U, ScCENP-H and ScCENP-N I further find Psh1, the CENP-A ubiquitin ligase^[595]. Arguably it should be everywhere else along the chromosome to evict ectopic centromeric nucleosomes, but not at the centromere itself. ScCENP-A did only appear in purifications of ScCENP-U. An interaction between ScCENP-N or ScCENP-C and ScCENP-A has not yet been demonstrated. However an interaction between ScCENP-Q/U/P/O and ScCENP-A has. Specifically, ScCENP-P binds to a short region on the N-terminal tail of ScCENP-A, termed the end-domain. The end-domain contains a methylated arginine, R37. Methylation of R37 is necessary for recruitment of wild type levels of ScMIS12C and ScCENP-P but not to recruit wild type levels of ScCENP-A itself. Association of ScCENP-Q/U/P/O with both ScCENP-A and Psh1 tempts me to speculate that one of the functions of the CCAN may be to provide CENP-A binding sites that are protected from Psh1, possibly by negatively regulating it. As ScCENP-A R37 methylation is not required to localize normal ScCENP-A levels, protection of ScCENP-A would at least not require this modification. However, the end-domain is essential while neither ScCENP-P or R37 methylation are, suggesting additional functions of the complete domain^[859-862].

Lastly, I find neither, the CBF3 complex or the CPC which has been shown to bind to the CBF3 complex and partially require CENP-U/Q for kinetochore localization in my tandem affinity purifications. I attempted preliminary binding assays between the ScCENP-Q/U/P/O complex and a ScINCENP/ScAurora B dimer readily available in the laboratory but did not observe an interaction. An interaction between CPC and ScCENP-Q/U/P/O may however require Borealin and/or Survivin, which were not present in my CPC derivative. Especially since a loss of ScCENP-U leads to the absence of ScBorealin, ScINCENP and ScAurora B but not ScSurvivin from the kinetochore^[627]. Alternatively an interaction between the CPC and ScCENP-Q/U/P/O may require posttranslational modification as the localization of the CPC is controlled by phosphorylation^[863, 864]. Therefore an interaction between ScCENP-Q/U/P/O and the CPC needs to be reinvestigated.

4.5 Model and future directions

I have described two distinct pathways by which the budding yeast CCAN may recruit the KMN network and allows re-evaluation of older results. Firstly it explains conflicting observations when investigating recruitment dependencies. A purely hierarchical recruitment would be expected to lose all downstream components and functions, such as the KMN network and the SAC, when upstream components, such as CENP-C, are lost. Although we don't yet know if CENP-Q/U/P/O/R in vertebrates is able to recruit MIS12C and conversely if ScCENP-C is able to recruit ScMIS12C, there appear to be at least two independent anchor points for the KMN network in both.

With this in mind it is clear why some vertebrate KMN components strongly loose kinetochore localization on depletion of CENP-C while others do not. NDC80C simply is recruited by an additional pathway, including CENP-T/W and likely CENP-H/I/K. This also explains why the SAC is active when MIS12C is lost in vertebrates and yeast but abolished when NDC80C is lost. It would further explain why vertebrate cells that lose either, CENP-I or MIS12C, show an inability to stably arrest in the first mitosis when only a few kinetochores are unattached. The SAC may monitor attachment of NDC80C to MTs regardless of the kinetochore receptor it is recruited to. Reducing the amount of NDC80C by depletion of either, CENP-I or MIS12C, would decrease but not abolish NDC80C recruitment to the kinetochore. These impaired kinetochores may generate less MCC when unattached or not under tension due to the decreased amount of NDC80C and thus be unable to block anaphase when only one or a few kinetochores are mal-attached. Rather the SAC signal from these kinetochores may be sufficient for an arrest only when multiple kinetochores are mal-attached. Therefore these cells would be unable to arrest in the first cell cycle due to a weak signal from the few unattached signaling impaired kinetochores. However, as ploidy increases in subsequent cell cycles due to missegregation, so does the number of impaired unattached kinetochores and thereby their ability to arrest the cell^[51, 490, 493, 594, 597, 675, 747, 748, 865].

Why would two distinct recruitment pathways have evolved? Clearly it is simpler to just amplify recruitment by a single pathway, although evolution is not necessarily in search of the simplest approach. It is possible that the vertebrate NDC80C recruitment pathway via CENP-T supplements the recruitment pathway via CENP-C and MIS12. The outer plate of the kinetochore, which can be tentatively equated with NDC80C, is in many cases entirely absent when CENP-T is lost, while it is discontinuous in absence of CENP-C^[500, 576, 596]. Therefore the core kinetochore in vertebrates may consist of the centromeric nucleosome and a CENP-C-MIS12C-NDC80C recruitment pathway. This core kinetochore may exist in multiple copies and the space between CENP-A nucleosomes may be filled by CENP-T/W dimers, as suggested by super-resolution microscopy, recruiting additional NDC80 in order to form the stable inner and outer plate structures^[866]. In this case CENP-T/W would simply serve to “squeeze” as much NDC80C as possible onto a centromere in order to make attachments as stable as possible. A more enticing idea is that NDC80Cs recruited by either CENP-T or MIS12C are actually functionally divergent. In line with this idea, vertebrate NDC80C is required to recruit the RZZ complex and CENP-E. Similarly CENP-C is required to recruit these components but CENP-I is not^[490, 511, 596, 867]. A vertebrate cell may use different populations of NDC80C and Knl1, recruited by either CENP-T/W or MIS12C, to localize defined subsets of outer kinetochore proteins, MAPs and motors. In theory this could constitute functionally different linking structures connecting centromeric DNA and

microtubules. These linking structures may be subject to differential regulation by kinases, which may be a key to understand the interplay of Aurora B, Mps1, Plk1 and BubR1. Functionally differentiated linkers based on CENP-T/W and CENP-C could mediate distinct attachment phases, lateral or end-on and the conversion between both, as suggested in Figure 20B. While this is in principle also possible in budding yeast, the relatively mild defects observed when ScCENP-T is deleted suggests that a ScCENP-T based linker is less important compared to other linkers in the yeast kinetochore or a CENP-T based linker in vertebrates.

Figure 20A displays a model for the yeast kinetochore. ScNDC80C is recruited either by association with ScCENP-T or ScMIS12C. ScMIS12C in turn is recruited via ScCENP-Q/U/P/O. We do not yet know if budding yeast also recruits ScMIS12C via ScCENP-C. Furthermore we do not know the exact relation of ScCENP-Q/U/P/O and ScCENP-C. Although loss-of-function experiments suggest that ScCENP-C is required for ScCENP-Q/U/P/O recruitment, the recruitment dependency of the budding yeast CCAN remains confusing. As mentioned localization ScCENP-P and therefore likely the localization of the entire ScCENP-Q/U/P/O complex depends on ScCENP-C. Recruitment of the ScCENP-L/N complex in turn depends on ScCENP-O. Surprisingly ScCENP-T/W recruitment depends on ScCENP-N but not ScCENP-P. However loss of ScCENP-P dislodges ScCENP-O from the kinetochore^[11, 463, 567, 592]. Furthermore, ScNDC80 depletions lead to a complete loss of attachment phenotype, which can be mimicked by deleting ScCENP-T in combination with ScCENP-C, ScCENP-Q/U or ScMIS12, corroborating dual recruitment. The fact that loss of ScCENP-C or ScCENP-Q/U alone does not lead to complete detachment suggests that CENP-T/W is still present at the centromere^[11, 463]. Therefore it may localize independent of ScCENP-C and ScCENP-Q/U/P/O as is the case in vertebrates and fission yeast. Closer investigation into ScCCAN recruitment dependency may be able to resolve these issues and yield results transposable into the vertebrate system.

Figure 20B illustrates my speculation on the role of multiple subpopulations of NDC80C and Knl1 recruited by different kinetochore receptors using a vertebrate kinetochore as an example. The loss of the RZZ complex and Dynactin in absence of CENP-C or MIS12C suggests that these two components may be recruited exclusively to a KMN network anchored to the kinetochore by CENP-C while ScCENP-T/W recruited NDC80C does not participate in this process. Figure 20B also illustrates an inhibition of this CENP-C recruited KMN network by the RZZ complex during lateral attachment before it is stripped by Dynein. CENP-T/W anchored NDC80C may be free and assist lateral attachment during the motor based movement of kinetochores along the microtubule wall. Once at the MT +end, the CENP-C recruited KMN network is activated by Dynein mediated stripping of the RZZ complex which allows hand over to end-on attachment.

Anchoring two independently regulated populations of NDC80C at the kinetochore has potential benefits. It may allow asymmetric regulation of a specific set of attachment fibers during error correction and chromosome oscillation. As an example, if both kFibers are differentially destabilized during oscillation and error correction, CENP-H/I/K may facilitate this on the trailing kinetochore, acting only on a subpopulation of NDC80C, that is recruited by CENP-T/W, while Aurora B and MCAK may act on a different, CENP-C recruited subpopulation on the leading kinetochore. Alternatively I would like to suggest a role of the CENP-T/W recruited NDC80C subpopulation in increasing attachment stability of a bioriented chromosome in metaphase or a single segregating chromatid in anaphase. CENP-T/W recruited NDC80C could be activated in response to tension. Once a kinetochore attaches end-on to a kFiber via CENP-C recruited KMN network and is able to support tension, additional CENP-T/W recruited NDC80C may be activated, increasing attachment stability. Hyperstable kFibers in ScCENP-H/I/K depletions would corroborate both ideas if CENP-H/I/K indeed destabilizes kFibers by negatively regulating CENP-T/W recruited NDC80C.

My results suggest that kinetochore assembly is not absolutely hierarchical. While there are centromere proximal components that recruit centromere distal components, there are multiple pathways for the CCAN to recruit KMN components. Results from fission yeast demonstrate the ability of centromeric chromatin, defined by the CCAN, to spread along DNA between heterochromatin boundaries. I envision the CCAN to coat DNA as a copolymer that consists of defined repetitive elements, some of which mediate recruitment of microtubule binding proteins such as the KMN network while others organize the centromere in space, in animals crosslinking centromeric DNA into the inner plate structure. With this in mind, more detailed investigation into interactions between CCAN subunits and other kinetochore proteins and more exhaustive loss of function studies of single CCAN proteins will be necessary to define exactly which outer kinetochore proteins and microtubule associated factors are recruited by which CCAN subcomplex. Furthermore it will be necessary to define a temporally ordered sequence of CCAN assembly throughout the cell cycle in order to interpret recruitment dependencies. Because they appear to change during the cell cycle this may be the origin of some conflicting reports. The budding yeast CCAN will be instrumental for this as many relationships among proteins appear conserved, and biochemical reconstitutions of interactions are feasible.

Figure 20. Model of kinetochore architecture

A. Budding yeast:

B. Vertebrate:

Budding yeast:

Conserved:

Vertebrate:

Figure 20A) A model of budding yeast kinetochore architecture. ScNDC80C is recruited by both ScMIS12C and ScCENP-T/W. ScMIS12 additionally recruits ScKn1. There is currently no reason to believe that different populations of ScNDC80C interact differently with the DAM1C. ScMIS12C is recruited by ScCENP-Q/U/P/O and possibly ScCENP-C. ScCENP-C may recruit ScCENP-Q/U/P/O although this complex interacts with ScCENP-A. ScCENP-T/W is likely recruited by additional ScCCAN proteins, specifically ScCENP-N. CBF1 and CBF3 have no direct role in the structural assembly of the kinetochore but may establish it by loading of the ScCENP-A containing centromeric nucleosome and CBF3 mediated recruitment of the CPC may regulate attachment through the error correction mechanism (not depicted) **Figure 20B)** Model of vertebrate kinetochore architecture. Like in budding yeast, NDC80C is recruited by CENP-T/W and NDC80 and Kn1 are recruited by MIS12C. MIS12C is recruited by CENP-C, a recruitment by CENP-Q/U/P/O/R is not established. While in budding yeast the

centromeric nucleosome, CENP-C and CENP-N are required to recruit CENP-T, in vertebrates CENP-T is required to recruit the remaining CCAN proteins, of which CENP-H/I/K are required to load the centromeric nucleosome. This shift in recruitment dependency could be due to the evolution of sequence specific loading of the centromeric nucleosome by CBF3, obviating the need for the self-propagation of a centromeric chromatin domain defined by the CCAN. Subpopulations of NDC80 in vertebrates may be differentially regulated. The RZZ complex could localize to and inhibit only MIS12C recruited NDC80C while CENP-T/W recruited NDC80C is free to assist in lateral attachment assisting motor based movement of the kinetochore on the MT wall. Once the kinetochore reaches the +end of a MT, MIS12C recruited NDC80C is activated as Dynein removes the RZZ complex and depleted the kinetochore of motors, including itself and CENP-E.

5. Materials and methods

5.1 Strain and plasmid construction

Plasmid construction

All plasmids used, whether based on pET3aTr, pST39, pCOLADuet-1 or pRS306 were maintained in E.coli DH5 α and isolated using a Qiagen QIAprep spin Miniprep kit. For molecular cloning of genes, the respective fragments were amplified from yeast genomic DNA using a Finnzymes Phusion® high fidelity PCR kit and extended primers to add the desired restriction sites. Restriction enzyme digestion of both plasmid and insert were performed with Fermentas FastDigest® enzymes with the exception of digestions by MluI and BspEI for which NEB restriction enzymes were used. The restriction sites used for cloning into expression vectors are given in Figure 7, the sites used for cloning of Ame1 into pRS306 in the text (5'XbaI and 3'XhoI). Inserts and plasmids were purified by electrophoresis in an agarose gel, subsequent isolation of the correct bands and elution from the agarose gel using a Qiagen QIAquick Gel extraction Kit®. Purified insert and plasmid were subjected to analytical electrophoresis to judge concentration in the sample and subjected to ligation in approximate ratios of 3:1 and 10:1. Ligation was performed using a Fermentas T4 DNA ligase.

PCR protocol (Fermentas Phusion)

Reaction mix:

Overlap extension PCR to construct (ScCENP-H) Mcm16 inserts

To remove an internal *SacI* site in Mcm16 and allow for subcloning into pST39, an overlap extension PCR using mismatch primers was employed. Two overlapping fragments of Mcm16, N-terminal and C-terminal were amplified. oMM5/6 were used for the N-terminal fragment. oMM7 was used together with either, oMM8, oMM23 or oMM10 to generate one tag free, one 6xHis tagged and one Strep II tagged c-terminal fragment. The internal primers oMM6/7 are complementary and both contain a base change at position 300, C to G. To generate the full length constructs, second PCR reactions were prepared in which both N-terminal fragment and either of the C-terminal fragments were added as template. Primers were omitted in the first three cycles to allow annealing and elongation of the two fragments. Subsequently oMM5 and either, oMM8, oMM23 or oMM10 were added to the reaction to allow amplification of the fusion construct.

Restriction enzyme digestion protocol

Insert:

Fast Digest buffer	3µl
PCR product after purification	6µl
Restriction enzyme 1	1µl
Restriction enzyme 2	1µl
H ₂ O	19µl

Plasmid:

Fast Digest buffer	3µl
Plasmid after purification	15µl
Restriction enzyme 1	1µl
Restriction enzyme 2	1µl
H ₂ O	11µl

Digestions were carried out on 37°C for 60 minutes

Ligation protocol

Ligase buffer	2µl
Insert + vector, ratio 3:1 or 10:1, dissolved in H ₂ O	17µl
T4 Ligase	1µl

Ligation mixtures were incubated for 30 minutes at room temperature or at 16°C over night.

Quikchange® site directed mutagenesis

This site directed mutagenesis protocol utilizes mismatch dsDNA primers to amplify a linear derivate of an isolated template plasmid in a PCR reaction that contains the desired point mutation. The template is subsequently digested using DpnI endonuclease which is specific for methylated DNA. Following digestion, the linear derivate is transformed into bacteria where it is circularized and maintained as a circular plasmid. If the desired point mutations are in close proximity, one may employ single primers containing multiple mismatches. One may further use multiple primers in single reaction as long as their target sequences do not overlap. Quikchange® mutagenesis was employed to remove two EcoRI sites in ScCENP-O^{Ctf19} cloned into the pET3aTr vector to allow subsequent subcloning into pST39. Furthermore it was used to generate the ScCENP-U^{Ame1} 5A mutant in a pRS306 vector. Mutagenesis of ScCENP-O^{Ctf19} was achieved in a single reaction using oPH16 encoding both silent T to C mutations at positions 27 and 45. Construction of ScCENP-U^{Ame1} 5A required two reactions. In the first reaction mutations A to G at position 91 and mutations T to G at positions 133 and 301 were introduced using oMM90, oMM92 and oMM94. The 3A mutant was identified among a number of sequenced clones following transformation with the product of this first reaction. The vector was isolated and subjected to a second round of mutagenesis, utilizing oMM91 and oMM93 to introduce T to G mutations at positions 121 and 157. Successful mutagenesis for both ScCENP-O^{Ctf19} in pET3aTr and ScCENP-U^{Ame1} in pRS306 was confirmed by sequencing.

Quikchange protocol:

Reaction mix:

H ₂ O		to 25µl

DpnI digestion:

Add 1µl of DpnI supplied with the kit to the reaction mixture after PCR and incubate 1h at 37°C.

Transformation:

Standard bacterial transformation protocol as given below, using however the supplied ultra-competent XL1-Blue cells instead of DH5α.

Generation of yeast genomic integration constructs

Yeast strains containing genomic TAP fusion tags were constructed by transforming yeast cells with the respective integration construct. These constructs were generated by PCR amplification from a pKW804 template plasmid containing the respective tag-ORF using primers containing plasmid specific sequences and additional ~50bp extensions homologous to the targeted genomic region, allowing for integration. pKW804 encodes a modified TAP-tag in which a S-tag and a ZZ-tag are separated by a TEV cleavage site^[542]. The TAP-Tag construct contains a KanMX resistance cassette. The full list of plasmid and primer combinations is given below. Integration constructs were generated by application of the standard PCR protocol given above.

TAP-tag integration constructs:

Gene&Tag:	Primers:	Plasmid template:
ScCENP-U ^{Ame1} -TAP	oMM44; oMM45	pKW804
ScCENP-H ^{Mcm16} -TAP	oMM17; oMM26	pKW804
ScCENP-N ^{Chl4} -TAP	oMM13; oMM24	pKW804
ScCENP-S ^{YOL086W-A} -TAP	oMM51; oMM52	pKW804
ScCENP-X ^{YDL160C-A} -TAP	oMM55; oMM56	pKW804

Strain construction

Transformation protocol, E.coli

Chemically competent DH5 α were thawed on ice. 5 μ l of the ligation product was added to 100 μ l thawed DH5 α liquid culture and incubated 30 minutes on ice. This was followed by a 30 second heat shock at 42°C and a 2 minute incubation on ice before 400 μ l SOC medium was added and the cells were allowed to recover for 60 minutes at 37°C. Following recovery, cells were plated on selection medium.

Transformation protocol, budding yeast

Log phase cells were harvested, washed in MonoQ H₂O, then washed and resuspend in 1ml TE/LiAc (10mM Tris-HCl, 1mM EDTA, 100mM LiAc, pH7.5). 50 μ l of yeast suspension were mixed with 1 μ g transforming DNA and 50 μ g single stranded salmon sperm carrier DNA. 300 μ l of PEG 4000 solution was added (10mM Tris-HCl, 1mM EDTA, 100mM LiAc, 40% PEG 4000, pH7.5). Transformation mixes were incubated under agitation at 30°C for 30min and then heat shocked at 42°C for 15min. Following heat shock, cells were washed in MonoQ H₂O and plated on the appropriate medium. To select for resistance markers, cells were initially plated on YPD and replica plated onto antibiotic containing plates after 1-2 days.

5.2 Biochemistry

Tandem affinity purification protocol:

Harvest yeast cells from liquid culture at OD₆₀₀=1.2 and drop freeze in liquid N₂. Lyse by grinding pellets, immersed in liquid N₂, in a Warring blender into powder. (In low stringency purifications, frozen cell pellets were lysed in a freezer mill)

Thaw and dissolve 60g of powder in 60ml of 2xHyman buffer with added phosphatase inhibitors (+2,4ml 1M β -glycerol phosphate; +8ml phosphatase inhibitor cocktail)

Add protease inhibitors before powder has thawed (1.2ml PMSF, 1.2ml protease inhibitor cocktail, Calbiochem)

Incubate in warm water bath to expedite thawing

Add 12,5ml 10% TritonX-100, sonicate for 30s

Sediment insoluble fraction by centrifugation in SA-600 rotor at 10.000rpm for 25min

Aspirate supernatant and sediment remaining insoluble components by ultracentrifugation in a Ti-70 rotor at 45.000rpm for 30min

Pre-clear supernatant by passing it through a 12ml CL-6B Sepharose column, pre-equilibrated with 1xHyman buffer.

Wash 0,65ml IgG Sepharose slurry in a disposable column with 10ml TST, 1ml 0,5M NH₄OAc (pH 3,4), 5ml TST, 1ml 0,5M NH₄OAc (pH 3,4), 5ml TST, 5ml 1xHyman buffer or 5ml 1xHyman buffer +300mM KCl, depending on desired purification stringency.

For high stringency purification add sufficient 2,5M KCl to the pre-cleared supernatant to achieve a final concentration of 300mM. Omit this step in low stringency purifications.

Add washed IgG Sepharose beads to supernatant and rock at 4°C for 3hrs

Remove supernatant from IgG beads in a disposable column, wash with 15ml 1xHyman buffer for low stringency purification or 15ml 1xHyman buffer +300mM KCl for high stringency purification

Wash IgG beads with 25ml 1xHyman (+300mM KCl for high stringency purifications) +1mM DTT +0,1% Tween 20

Resuspend IgG beads in 1,5ml 1xHyman (+300mM KCl for high stringency purifications) +1mM DTT +0,1% Tween 20

Add 40µl of purified TEV protease (supplied in house) and keep rocking 4hrs at 4°C

Add 50µl of purified TEV protease and keep rocking over night at 4°C

Remove beads and collect supernatant in a disposable column. Wash with an additional 1ml of 1xHyman (+300mM KCl for high stringency purifications) +1mM DTT +0,1% Tween 20 and collect eluate.

Add 85µl S-protein agarose slurry (washed with 1xHyman buffer 3 times) to the pooled supernatant and eluate and rock at 4°C for 3h

Elute 3 times by incubation of the beads in 60µl 0,1M Glycine pH 2 for 30mins. Keep beads agitated.

Buffers and Reagents for tandem affinity purification:

1xHyman Buffer:

50mM Bis-Tris Propane (pH 7)

100mM KCl

5mM EDTA

5mM EGTA

10% Glycerol

TST:

50mM Tris-HCl (pH 7,4)

150mM NaCl

0,1% Tween 20

Phosphatase inhibitor cocktail 15x:

50ml H₂O

1,65g Sodium pyrophosphate

244mg Sodium azide

315mg Sodium fluoride

55mg Sodium orthovanadate

Expression:

All recombinant protein was expressed in Rosetta 2 cells. Expression was induced by addition of 0,2mM IPTG.

Standard protein purification from bacteria, 6xHis-tag

Harvest Bacteria, wash in PBS (freezing optional) and centrifuge 10min at 6000g

Resuspend pellet in cold lysis buffer (5-10 pellet Vol; 30 mM HEPES pH 7, with 150 mM NaCl and 30mM Imidazole). Add 1 tablet of Complete EDTA-free protease inhibitor per 50ml, 1/100 PMSF, Lysozyme 1/200 (100mg/ml stock) and DNase if too viscous

Sonicate 30s on ice, incubate 10 min

Centrifuge homogenous lysate 15 min at 15-17k rpm (SS-34 rotor)

Wash NiNTA resin three times in lysis buffer (approx. 1ml of resin per 10g of cell pellet dry weight were used) before adding it to the supernatant. Rock 1h at 4°C.

Remove supernatant and wash resin with lysis buffer until supernatant remains clear

Elute 3 times. Remove supernatant and add elution buffer (30 mM HEPES pH 7, with 150mM NaCl and 300mM Imidazole), rock 30min at 4°C before aspirating the eluate.

Modification of 6xHis purification protocol for ScCCAN complexes

Lyse cells in 30 mM HEPES pH 7, with 150 mM NaCl, 30mM Imidazole and additionally 1mM CaCl_2 if required by the complex (ScCENP-O/P, ScCENP-Q/U/P/O). Add 1 tablet of complete EDTA-free protease inhibitor per 50ml, 1/100 PMSF, Lysozyme 1/200 (100mg/ml stock) and DNase if too viscous.

Sonicate 30s on ice, incubate 10 min.

DNase is required for ScCENP-O/P, ScCENP-Q/U, ScCENP-Q/U/P/O and ScCENP-N/L complexes as expression produces a very viscous lysate that requires DNase digestion, possibly before and during sonication.

Centrifuge homogenous lysate 15 min at 15-17k rpm (SS-34 rotor)

Wash NiNTA resin three times in lysis buffer (approx. 1ml of resin per 10g of cell pellet dry weight were used) before adding it to the supernatant. Rock 1h at 4°C.

Perform two initial washing steps of the protein bound resin with the low salt lysis buffer.

For DNA binding ScCCAN complexes, perform all further washing steps with high salt wash buffers. Wash buffers are similar in composition to the lysis buffer, containing 30mM HEPES pH 7, 30mM Imidazole and 1mM CaCl_2 if required. Salt concentrations in the wash buffers depend on the target complex. I have used 600mM NaCl to wash DNA from the ScCENP-Q/U/P/O complex, 1M NaCl to wash DNA from the ScCENP-Q/U complex and up to 1.5M NaCl to wash DNA from the ScCENP-O/P complex. These higher salt concentrations are not necessary but decrease the number of required washing steps. As mentioned in the text, the number of required washing steps is variable. I monitor the decrease of absorption at 260

and 280 nm in the wash buffer after each wash step and continue washing until the values reach noise level.

After exhaustive washing, elute 3 times. Remove supernatant and add elution buffer (30 mM HEPES pH 7, with 150mM NaCl, 300mM Imidazole and 1mM CaCl_2 if required), rock 30min at 4°C before aspirating the eluate.

Protein purification from Bacteria, FLAG-tag

Harvest Bacteria, wash in PBS (freezing optional) and centrifuge 10min at 6000g

Resuspend pellet in cold lysis buffer (5-10 pellet Vol; 50 mM Tris HCl pH 7.4, with 150 mM NaCl), add 1 tablet of Complete EDTA-free protease inhibitor per 50ml, add 1/100 PMSF, Lysozyme 1/200 (100mg/ml stock) and DNase if too viscous

Sonicate 30s on ice, add 0,5% Triton X100 and incubate 10 min

Centrifuge homogenous lysate 15 min at 15-17k rpm (SS-34 rotor)

Rinse FLAG-resin in disposable column with TBS. Wash resin 3x with 0,1 M Glycine pH 3.5, then wash resin with 5 Vol. TBS

Add resin to supernatant, rotate 1h at 4°C, then sediment resin by centrifugation at 1000g and remove supernatant.

Wash resin with TBS until supernatant remains clear. To elute place resin in disposable column, drain supernatant and elute with TBS +100µg/ml FLAG-peptide. Elute 3-4 times.

Preparative size exclusion chromatography

Preparative size exclusion chromatography was performed to further purify recombinant ScCCAN complexes. Depending on the amount of protein, either a 120ml Superdex 200 HiLoad 16/60 or a 24ml Superose 6 10/300 GL column (GE Healthcare) were used. Running buffers were either 30mM HEPES pH 7 for NiNTA purified complexes or 50mM Tris HCl pH 7.4 for αFLAG antibody purified complexes. Either buffer contained 150mM NaCl and additionally 1mM CaCl_2 if a protein complex containing ScCENP-O/P was purified.

ScCENP-Q/U/P/O - ScMIS12C binding assay and analytical size exclusion chromatography

Samples of ScCENP-Q/U/P/O and ScMIS12C were mixed in a binding buffer containing 30mM HEPES pH 7, 150mM NaCl and 1mM CaCl_2 and left at 4°C for 30 minutes. Subsequently samples were subjected to analytical size exclusion chromatography in binding buffer on a 2.4 ml Superose 6 PC 3.2/30 column.

Microtubule binding assay

Microtubules were assembled in vitro from 60 μ M purified bovine brain tubulin in G-PEM buffer (80mM K-Pipes pH 6.8, 1mM EGTA, 1mM MgCl₂, 1mM GTP)+ 25% Glycerol. After 30min incubation at 35°C for MT assembly, 20 μ M Taxol was added to stabilize MTs. MTs were diluted in PEM (80mM K-Pipes pH 6.8, 1mM EGTA, 1mM MgCl₂, 1mM GTP) +10 μ M Taxol. Recombinant ScCENP-Q/U/P/O was dialyzed into PEM and 0.3 mg/ml of ScCENP-Q/U/P/O was added to variable concentrations of assembled tubulin (20 μ M-6 μ M). After 20min incubation on room temperature, MTs were sedimented by ultracentrifugation for 20min at 70.000rpm. Supernatant and pellets were separated and analyzed on gel. Improved ScCENP-Q/U/P/O MTBA's contained an additional 150mM NaCl in both G-PEM and PEM.

EMSA

50 μ l of ScCENP-Q/U/P/O complex samples were mixed with tester DNA or RNA and incubated 30minutes on 4°C. Subsequently, samples were loaded onto a nondenaturing 5% polyacrylamid gel, pH 7. After electrophoresis, gels were stained with ethidium bromide.

In vitro phosphorylation

Clb2-TAP and Clb5-TAP were purified according to the given TAP protocol. 3 μ l of kinase were incubated with 2 μ l of the ScCCAN subcomplex samples and 5 μ M ATP (γ -[P³²]ATP for radioassays) in CDK1 buffer (25mM HEPES pH 7.6, 100mM KCl, 2mM MgCl₂, 1mM DTT, 1mM EGTA, 5% glycerol, 20mM β -glycerolphosphate) for 30min at 25°C. The γ -[P³²]ATP-phosphorylated products were separated by SDS-PAGE, the gels dried and exposed to a autoradiography film. To map in vitro CDK1 phosphorylation sites ATP phosphorylated samples were handed to mass spectrometry for in solution digestion and analysis.

5.3 Mass spectrometry

Susanne Opravil, Richard Imre, Otto Hudecz

Information supplied by IMP/IMBA protein chemistry core facility

The nano-HPLC system used in all experiments was an UltiMate 3000 Dual Gradient HPLC system (Dionex), equipped with a Proxeon nanospray source (Proxeon), coupled to an LTQ Velos Orbitrap mass spectrometer (Thermo Fisher Scientific), operated in data-dependent mode using a full scan in the ion cyclotron resonance cell followed by tandem mass spectrometry (MS/MS) scans of the 12 most abundant ions in the linear ion trap. MS/MS

spectra were acquired in the multistage activation mode, where subsequent activation was performed on fragment ions resulting from the neutral loss of -98, -49 or -32.6 *m/z* for potential follow-up phosphorylation site analysis. Precursor ions selected for fragmentation were put on a dynamic exclusion list for 180 s. Monoisotopic precursor selection was enabled.

Analysis of MS data. For peptide identification, all MS/MS spectra were searched using Mascot 2.2.04 (Matrix Science) and Sequest (Thermo Scientific) against the yeast SGD protein sequence database (6,717 sequences; 3,020,761 residues). The following search parameters were used: carbamidomethylation or methyl methylthiomethyl sulphoxide respectively on cysteine was set as a fixed modification; oxidation on methionine was set as variable modification. Monoisotopic masses were searched within unrestricted protein masses for tryptic, chymotryptic and unspecific (subtilisin digest) peptides. The peptide mass tolerance was set to ± 5 ppm and the fragment mass tolerance to ± 0.5 Da. The maximal number of missed cleavages was set to 2. Using a Thermo Proteome Discoverer 1.3.0.339 (Thermo Scientific), the results of both search engines were combined and filtered to 1% false discovery rate using an integrated Percolator algorithm. Furthermore, high-quality criteria filters such as peptide rank 1 and minimum 2 peptides per protein were applied.

5.4 Live cell fluorescence microscopy

Unsynchronized cells expressing Nuf2-mCH and Wip1-GFP with or without a ScCENP-T deletion (yMM550, yMM551) were grown in synthetic medium and placed on a Concanavalin A coated cover slip. Cells representative of morphologically identifiable cell cycle stages (G1, S, M) were imaged by Deltavision deconvolution microscopy (AppliedPrecision) on an Olympus IX-71 microscope controlled by Softworx and equipped with a PlanApo 100x 1.4NA objective (Olympus) and a Coolsnap HQ camera (Photometrics) at 25°C.

Protein Sequence Database

yeast SGD (6717 sequences; 3020761 residues)

Peptide Filters	filter options
Peptide Rank	1
Peptide Confidence	High (1% FDR)
Protein Filters	
Minimum Peptides Per Protein	2

identified proteins

sequence coverage of the bait [%]

Unique Peptides

Displays the number of peptide sequences unique to a protein group

Peptides

Displays the number of distinct peptide sequences in the protein group

PSMs

Displays the total number of identified peptide sequences (peptide spectrum matches) for the protein, including those redundantly identified

Proteins

Displays the number of identified proteins in the protein group of a master protein

Coverage

Displays the percentage of the protein sequence covered by identified peptides

bait highlighted**ScCENP-U^{Ame1}, High stringency**

Abstract

Kinetochore are large multi-protein complexes that connect centromeres to spindle microtubules in all eukaryotes. Among the biochemically distinct kinetochore complexes, the conserved four-protein Mtw1 complex is a central part of the kinetochore in all organisms. Here we present the biochemical reconstitution and characterization of the budding yeast Mtw1 complex. Direct visualization by EM revealed an elongated, bi-lobed structure with a 25 nm long axis. The complex can be assembled from two stable heterodimers consisting of Mtw1p-Nnf1p and Dsn1p-Nsl1p and it interacts directly with the microtubule-binding Ndc80 kinetochore complex via the centromere-proximal Spc24/25 head domain. In addition we have reconstituted a partial Ctf19 complex and show that it directly associates with the Mtw1 complex in vitro. Ndc80 and Ctf19 complexes do not compete for binding to the Mtw1 complex, suggesting that Mtw1 can bridge the microtubule-binding components of the kinetochore to the inner centromere.

Keywords

Kinetochore; KMN network; chromosome segregation; force generation; microtubule; centromere

Introduction

The interaction between chromosomes and spindle microtubules requires the action of a complex multi-protein machine termed the kinetochore^{1, 2}. Kinetochore are responsible for microtubule-based force generation that drives sister chromatid separation in anaphase. They additionally contain an error-correction mechanism that ensures the bipolar attachments of sister chromatids to opposite spindle poles³ and they relay signals to the mitotic checkpoint

that prevents the cell from entering anaphase in the presence of unattached kinetochores 4. In budding yeast, the structural core of the kinetochore consists of at least seven biochemically distinct subcomplexes that are present in fixed copy numbers in mature budding yeast kinetochores 5 and assemble on centromeric DNA in a hierarchical manner 6. A current challenge in the field is to elucidate the architecture of the kinetochore by defining the binding interfaces between kinetochore complexes. Previous biochemical studies have focused on the reconstitution and functional analysis of two important parts of the budding yeast outer kinetochore: the Dam1 complex and the Ndc80 complex. Both of these complexes directly interact with microtubules and are required for force generation at yeast kinetochores 7-8. The Dam1 complex has the ability to oligomerize into rings *in vitro* 9-10, opening up the possibility that a Dam1 ring is a physiologically relevant coupling device for kinetochores on microtubule plus-ends in yeast. Recent experiments have demonstrated that Dam1 is a specialized plus-end tracking complex required for a persistent attachment of the Ndc80 complex to dynamic microtubule ends *in vitro* 11-12.

The four-protein 180kDa Ndc80 complex is a conserved component of all kinetochores. Biochemical isolations from extracts and *in vitro* reconstitution experiments using *C. elegans* Ndc80 subunits have demonstrated that the complex functions together with the conserved four-protein complex Mtw1 (also called Mis12 or MIND) and the protein KNL-1/Blinkin (Spc105p in budding yeast) as part of a larger network termed KMN (KNL-1 Mis12 Ndc80) 13. Analysis of temperature-sensitive mutants of MTW1 complex subunits in fission yeast and budding yeast, as well as depletion experiments in worms and human cells, have demonstrated that the complex is essential for kinetochore bi-orientation and chromosome segregation 14-15-16. Since biochemical reconstitution experiments have so far only been performed with *C. elegans* kinetochore proteins, it is an open question whether the architecture, topology and biochemical activities of the KMN network are conserved among evolutionary distinct eukaryotes. Furthermore, it is unknown how the KMN network is anchored to the inner kinetochore, a critical step in creating a microtubule attachment site specifically at the centromere. Here, we report the reconstitution and biochemical characterization of the budding yeast Mtw1 complex. Our analysis defines the architecture of this central kinetochore complex and is an important step towards a reconstitution of the full yeast kinetochore.

Results and Discussion

Reconstitution of the four-protein Mtw1 complex

To reconstitute the budding yeast Mtw1 complex, we employed a poly-cistronic expression strategy. Genes encoding all four subunits (DSN1, MTW1, NNF1 and NSL1) of the complex were placed under the control of a T7 promoter and expressed in BL21 DE3 cells. The purification strategy used a 6xhistidine tag on the Nnf1p subunit allowing initial purification with a Ni-NTA resin. After elution, the complex was further purified by size exclusion chromatography (Figure 1A). Analysis of the complex on Coomassie stained gels revealed that all four subunits of the complex were present in 1:1:1:1 stoichiometry. The complex eluted earlier than expected from a size exclusion chromatography with a Stokes radius of 74.3 Å. The sedimentation coefficient of the Mtw1 complex was determined by glycerol gradient centrifugation and estimated to be 6S (data not shown). Thus, the native molecular weight of the recombinant complex is 183 kDa, compared to the calculated molecular weight of 148 kDa, and the frictional coefficient f/f_0 is 2.0, predicting a complex that is moderately to highly elongated. These values are in close agreement to those obtained for the Mtw1 complex in yeast extracts 17 suggesting that the recombinant complex closely resembles its native counterpart. We noticed that the Dsn1p subunit of the complex was particularly prone to proteolytic degradation during purification (Figure 1A). Sequencing of the major proteolysis products revealed that the N-terminus of Dsn1p is easily cleaved. We

subsequently cloned an N-terminally shortened version of the Dsn1 subunit corresponding to the major proteolysis product, which lacks amino acids 1–171. Expression of Dsn1^{172–567} in combination with full-length Mtw1, Nnf1-6xHIS and Nsl1 allowed the purification of the entire four-protein Mtw1 complex (Figure 1B). We conclude that the N-terminal extension of Dsn1, which is unusually long in budding yeast compared to other eukaryotes and predicted to be unstructured, is dispensable for complex formation *in vitro*. To determine whether this N-terminal extension has an essential function *in vivo*, we expressed wild-type or N-terminally truncated DSN1^{172–576} on centromeric plasmids in a haploid DSN1 deletion strain that was kept viable by containing a wild-type copy of DSN1 on a CEN-based URA plasmid. Selection against the URA plasmid on 5-FOA plates demonstrated that Dsn1^{172–576} supported wild-type growth (Supplementary Figure 1). Thus, the N-terminal 172 amino acids of Dsn1 are not required for complex formation *in vitro* and do not have an essential function *in vivo*.

The Mtw1 complex can be assembled from two stable heterodimers

SEC analysis of epitope-tagged kinetochore proteins in yeast extracts has suggested that Dam1 and Ndc80 complexes are present only in their fully assembled state, although Mtw1 complexes of different compositions can be detected [17]. To identify such stable subcomplexes we expressed various combinations of Mtw1 complex subunits. We were able to express and purify two stable complexes: A heterodimer consisting of Mtw1p and Nnf1p (MN complex) (Figure 1D), and a heterodimer consisting of Dsn1p and Nsl1p (DN complex) (Figure 1C). We next asked whether the Mtw1 heterotetramer can be reconstituted by combining the two stable dimers. After mixing of MN and DN subcomplexes followed by size exclusion chromatography, we observed reconstitution of the full Mtw1 complex, which eluted at a position identical to the native complex (Figure 1E). Thus, the four-protein Mtw1 complex is composed of two stable heterodimers consisting of Mtw1p-Nnf1p and Dsn1p-Nsl1p, a result that is in agreement with binary two-hybrid interactions between these subunits [18].

EM analysis of the reconstituted Mtw1 complex

Negative stain single-particle electron microscopy was used to characterize the structural architecture of the Mtw1 complex. Despite our efforts to cross-link and purify the complex, the imaged fields of particles contained a heterogeneous mixture of aggregates and small fragments, as well as the monomeric, full size complex (Figure 2A). We manually picked the particle images that appeared to correspond to the monomeric, full-length complex based on their consistent size (indicated by white circles in Fig. 2A). After reference-free classification, we observed a distinct bi-lobed rod-like structure approximately 250 Å in length, with one of the lobes consistently appearing slightly larger than the other (Figure 2B and D). The larger lobe varied in size, likely reflecting the presence of degrons of the Dsn1p subunit and/or different views around the long axis of the complex.

The larger globular lobe has an approximate diameter of 71 Å, and the smaller lobe 47 Å. Assuming a spherical shape for each, this would correspond to an approximate mass of 150 kDa and 45 kDa, respectively, the sum of which (195 kDa) very closely matches the experimentally determined mass. The calculated mass of the smaller lobe matches well with the combined predicted masses of Mtw1p and Nnf1p (57 kDa) assuming that their coiled-coil domains project outwards from the lobe. The calculated mass of the larger lobe exceeds the combined masses of Dsn1p and Nsl1p (91 kDa), suggesting that this lobe deviates from spherical geometry (the smaller lobe is too small to accommodate the mass of this subcomplex). The thin density connecting the two globular lobes is approximately 90 Å long (Figure 2B), which matches the length of a predicted dimeric coiled-coil between the Mtw1p and Nnf1p subunits (Figure 2C). We also experimentally demonstrated that these two

proteins form a stable subcomplex, supporting the proposal that the coiled-coil regions of these two proteins probably dimerize in the context of the full complex. While this is the most parsimonious explanation for complex topology, we can't exclude the possibility that each globular head is occupied by more than two subunits.

In vivo the Mtw1 complex acts as a bridge between the microtubule-binding Ndc80 complex and the inner kinetochore 6. The Ndc80 complex is 57 nm in length 19, and the Mtw1 complex 25nm. Taken together, these dimensions suggest that the KMN network is long enough to span the full length of the outer kinetochore, consistent with high-resolution fluorescence microscopy studies 20.

Reconstitution of the interaction between Ndc80 and Mtw1 complexes

We next asked whether the recombinant Mtw1 complex can directly interact with the Ndc80 complex. To this end we purified the four-protein Ndc80 complex by expressing the Nuf2-Ndc80 and Spc24-Spc25 heterodimers individually and then reconstituted the entire complex using SEC (Figure 3A). When Mtw1 and Ndc80 complexes were mixed and subjected to gel filtration, the elution profile of the assembly was shifted with respect to the individual complexes. Coomassie stained gels revealed that the complexes co-eluted, and densitometry of the Coomassie-stained bands indicated a 1:1 stoichiometry of the Mtw1-Ndc80 binary complex (Figure 3B and C). The elution position indicated that the Ndc80-Mtw1 assembly is a dimer containing one copy of each complex. The Ndc80-Mtw1 stoichiometry obtained from this biochemical experiment is in agreement with quantitative fluorescence microscopy data indicating the presence of nearly identical numbers of Ndc80 (8 copies) and Mtw1 (6–7 copies) complexes per each budding yeast kinetochore 5. Another important implication is that budding yeast Ndc80 and Mtw1 complexes form a stable association that does not depend on the presence of the KNL-1 protein Spc105p. This is in contrast to the *in vitro* reconstituted *C. elegans* KMN network, where only a Mis12-Knl1 association is competent to interact with the Ndc80 complex 13. Thus, while the overall association of Ndc80 and Mtw1 complexes is critical for the function of all kinetochores, the molecular details of this association can vary significantly in different organisms. Despite extensive efforts we were unable to express sufficient amounts of full-length or partial Spc105p/KNL-1 fragments, leaving open the possibility that the affinity of the Mtw1 complex for the Ndc80 complex may be increased by the presence of Spc105p.

The two globular domains of the Ndc80 complex have different functions: The Ndc80-Nuf2 head displays microtubule-binding activity through the presence of two Calponin-Homology (CH) domains and a basic N-terminal tail 8; 21. The Spc24/25 head, on the other hand, is thought to reside centromere-proximal and connect the Ndc80 complex to the rest of the kinetochore. We tested which of the Ndc80 subcomplexes provides the binding site for the Mtw1 complex. Therefore we subjected the purified Spc24/25 head of the Ndc80 complex and the Mtw1 complex to size exclusion chromatography first individually and then in combination. Upon pre-incubation with Mtw1 complex, part of the isolated Spc24/25 head was found co-eluting with the Mtw1 complex (Figure 3D and E). The interaction with the head domain seemed to be less efficient when compared to the full Ndc80 complex, suggesting that high-affinity may require the full Ndc80 complex. We conclude that the Ndc80 complex directly binds to the Mtw1 complex via its centromere-proximal Spc24/25 head domain, a result that is in agreement with high resolution microscopy data that place Spc24/25 in the immediate vicinity of Mtw1 complex subunits 20.

Consistent with the results obtained for the *C. elegans* KMN network, the reconstituted Mtw1 complex did not bind directly to taxol-stabilized microtubules in co-sedimentation experiments (Supplementary Figure 2). Only upon inclusion of the purified Ndc80 complex, the Ndc80-Mtw1 assembly was found co-pelleting with microtubules. Furthermore, binding

of the Mtw1 complex did not significantly alter the microtubule-binding properties of the Ndc80 complex (Supplementary Figure 2).

A Ctf19 core complex directly associates with the Mtw1 complex

High-resolution co-localization data place the Mtw1 complex close to the centromere-kinetochore interface 20, but the inner centromere receptor for the complex has not been identified. Human Mis12 complex has been reported to co-purify and directly interact with the inner centromere protein HP1 via the hNSL1 subunit 22²³. The importance of this interaction for mitotic kinetochore function, however, is unclear and an HP1 homolog is absent from the *Saccharomyces cerevisiae* genome. Biochemical purifications of epitope-tagged Mtw1 subunits from yeast extracts 17²⁴ have suggested two candidate interaction partners at the inner centromere interface - the budding yeast CENP-C homolog Mif2p and the Ctf19 complex. Initial experiments failed to detect a direct interaction between recombinant Mif2p fragments and the Mtw1 complex (data not shown), prompting us to focus on the Ctf19 complex as a potential binding partner. The yeast Ctf19 complex is the functional homolog of the constitutive-centromere associated network (CCAN) of higher eukaryotes. The CCAN was originally identified as a set of polypeptides that co-purify with CENP-A containing nucleosomes 25²⁶. The budding yeast Ctf19 complex consists of at least 11 subunits, some of which are organized into more stable subcomplexes. We reconstituted a core Ctf19 complex consisting of the proteins Ctf19p, Okp1p, Mcm21p and Ame1p (also termed COMA 17) by co-expression in *E. coli*. A purification procedure utilizing the 6xHis-tagged Ame1p subunit allowed isolation of the four-protein complex to near homogeneity (Figure 4A). Mcm21, Ame1-6xHis and Ctf19 polypeptides could be resolved on a 20 cm long SDS-PAGE gel (Figure 4A, right panel), and individual bands were excised and analyzed by mass spectrometry. This allowed assignment of the subunits to the corresponding bands on the SDS-PAGE. The intensity of the Coomassie stained bands suggest the presence of all four subunits of the COMA complex in a 1:1:1:1 stoichiometry.

To analyze potential associations with other kinetochore complexes, different concentrations of FLAG-tagged COMA complex were immobilized on beads, incubated with recombinant Mtw1, Ndc80 and Dam1 kinetochore complexes, washed and subsequently eluted with FLAG peptide (Figure 4B). While we failed to detect a direct association of the purified COMA complex with recombinant Ndc80 and Dam1 complexes, the Mtw1 complex consistently co-eluted together with COMA in a concentration-dependent manner (Figure 4C).

To verify the direct interaction between Mtw1 and COMA complexes we performed a reciprocal experiment in which 6xHis-tagged Mtw1, Ndc80 and Dam1 complexes were each immobilized on Ni-NTA agarose, incubated with recombinant Ctf19-Flag core complex, washed and eluted with imidazole. Only in the presence of Mtw1 complex is co-elution of the COMA complex observed (Figure 4C). To more stringently test the physical interaction, we analyzed Mtw1 and COMA complexes by size exclusion chromatography and found that the complexes co-eluted (Figure 5). This result raises the possibility that COMA is involved in recruiting the Mtw1 complex to the inner centromere in budding yeast. A strong prediction from this hypothesis is that Ndc80 and COMA complexes should not compete for binding to the Mtw1 complex. We tested this by pre-incubating Mtw1- and Ndc80 complexes, allowing formation of the binary Mtw1-Ndc80 assembly, followed by incubation with COMA-Flag beads. Incubation with Ndc80 did not prevent the interaction between COMA and Mtw1 complexes and both complexes co-eluted from the beads (Figure 6A). This result indicates that Ndc80 and COMA complexes occupy different binding sites on the Mtw1 complex. When testing the Mtw1-Nnf1 (MN) and Dsn1-Nsl1 (DN) subcomplexes separately in pull-down experiments we found that the MN subcomplex interacted more efficiently with COMA (Figure 6, B and C). Interestingly, of all Mtw1

subunits, high-resolution co-localization data place Nnf1p closest to the inner centromere in both humans and *S. cerevisiae* 27. Since the size of the smaller lobe of the Mtw1 complex roughly fits the combined masses of Dsn1p and Nsl1p, we tentatively speculate that the larger lobe, predominantly consisting of Dsn1p and Nsl1p, interacts with Spc24/Sp25, while the smaller lobe makes contact to the inner centromere complex COMA. Further antibody decoration experiments and direct visualization by electron microscopy will have to test this hypothesis.

In summary we have characterized the basic architecture of the budding yeast Mtw1 complex. Very recently, two manuscripts have described the reconstitution of the yeast28 and human Mis12 complex29. Our independent results regarding the overall shape of the yeast Mtw1 complex as judged by electron microscopy, its assembly from two stable heterodimers and the high affinity interaction with the Ndc80 complex are in close agreement with the experiments by Maskell et al. A comparison to the human Mis12 complex reveals interesting similarities and differences: The overall architecture of the complex, its topology based on stable Mtw1-Nnf1 and Dsn1-Nsl1 heterodimers is conserved between yeast and human. However, the molecular mechanism by which a high-affinity interaction with the Ndc80 complex is achieved differs considerably between the two organisms. In particular, a yeast Dsn1-Nsl1 heterodimer alone is not competent to bind the Ndc80 complex (our unpublished observations). Yeast Nsl1 lacks a critical binding motif (PVIHL) and a c-terminal tail which is necessary for the interaction between human Nsl1 and the Ndc80 complex 29. Instead, the binding interface between Mtw1 and Ndc80 complexes seems to receive significant contributions from Mtw1 and/or Nnf1. These findings highlight the necessity to analyze kinetochores biochemically in evolutionary distinct organisms in order to reveal common architectural principles and local binding interfaces.

Our results extend the studies by Maskell et al., and Petrovic et al., to provide a potential inner centromere receptor for the Mtw1 complex. The precise molecular basis for the interaction with the yeast Ctf19/COMA complex remains to be investigated. A puzzling aspect is that there is a considerably lower copy number of Ctf19 complex subunits (1–2) versus Mtw1 complexes (6–7) per each budding yeast kinetochore as judged by fluorescence microscopy 5. Furthermore, only OKP1 and AME1 are essential genes in budding yeast 30. It will be important to dissect the molecular binding interface between Ctf19/COMA and Mtw1 complexes in detail and evaluate the disruption of this binding interface *in vivo*. There may be considerable flexibility in the way the KMN network is anchored to the inner centromere. Some organisms like *C. elegans* or *Drosophila melanogaster* for example, seem to lack proteins related to the CCAN network entirely 2. In these kinetochores, the Mtw1 complex may rely on direct interactions with CENP-C for recruitment to the inner centromere.

Materials and Methods

Cloning of polycistronic expression vectors for MTW1 and CTF19

Open reading frames corresponding to Mtw1 complex subunits were amplified from yeast genomic DNA, cloned and expressed using the polycistronic expression system pET3aTr/pST39 that has been described previously 31. Genes were subcloned from the monocistronic pET3aTr vector into the polycistronic cassettes (1–4) of pST39 in the following order for the Mtw1-complex: (1) MTW1, (2) NSL1, (3) NNF1-6xHis, (4) DSN1. The truncated version DSN1^{172–576} was cloned into pET28a(+) and expressed in combination with pST39 (MTW1-NSL1-NNF1-6xHis).

The Ctf19 COMA subcomplex was cloned in the following order into the pST39 plasmid: (1) CTF19, (2) MCM21, (3) OKP1 and (4) AME1-6xHis/FLAG. Because of the presence of an intron, MCM21 was amplified from yeast cDNA.

Protein Expression and Purification

The Mtw1 complex was expressed in BL21 DE3 (Novagen) for 4h at 37°C after induction at $OD_{600} = 0.6$ with 0.4 mM isopropyl- β -D-thiogalactopyranosid (IPTG). The coexpression with DSN¹⁷²⁻⁵⁷⁶ was performed overnight (o/n) in the presence of 0.2 mM IPTG. The Mtw1 subcomplexes MN and DN were cloned into cassette 1 and 2 of the pST39 vector and the expression conditions were 37°C for 4h (MN) and 18°C overnight (DN). The COMA subcomplex was expressed at 18°C overnight after induction with 0.2 mM IPTG.

Bacteria were lysed by sonication in the presence of protease inhibitors (Roche) and the fusion proteins were isolated using Ni-NTA agarose beads (Qiagen). Binding and subsequent washing was performed in 20 mM HEPES pH 7.0, 300 mM NaCl, 30 mM imidazole. The Mtw1 complex or its two subcomplexes was eluted from Ni-NTA beads with 20 mM Tris pH 8.5, 80 mM NaCl and 250 mM imidazole, subsequently, it was subjected to anion exchange chromatography using a MonoQ 5/50 GL column (GE Healthcare). The column was developed with 10 bed volumes of a linear gradient from 80 mM to 1M NaCl in 20 mM Tris pH 8.5 containing 5% glycerol. The DN-subcomplex was further purified using size exclusion chromatography on a Superose 6 10/30 column.

The COMA-6xHis subcomplex was either purified with Ni-NTA agarose beads or by Anti-FLAG M2 affinity gel (Sigma Aldrich). COMA-6xHis was eluted with 20 mM HEPES pH 7, 150 mM NaCl, 5% Glycerol, 250 mM Imidazol, and loaded onto a size exclusion chromatography (SEC) Superdex 200 HiLoad 16/60 column equilibrated in 20 mM HEPES pH 7, 150 mM NaCl, 5% Glycerol. COMA-FLAG was eluted from M2 affinity gel with 3x FLAG peptide in TBS and the complex was concentrated using ultrafiltration (Vivaspins, cut off 10000 MW) followed by buffer exchange into 20 mM HEPES, pH 7.0, 150 mM NaCl, 5% Glycerol using PD-10 columns (GE Healthcare). Protein concentration was determined with DC Protein Assay kit (Bio-Rad Laboratories).

The Ndc80 and Dam1 kinetochore complexes were expressed and purified as described previously [9, 11, 24].

Interaction studies

0.1 – 1 μ M kinetochore protein complex in 500 μ l binding buffer was immobilized on 20 μ l Anti-Flag M2 Affinity gel or 20 μ l Ni-NTA agarose beads. The interaction partner to be tested was used at 1 μ M in binding buffer (TBS or PBS containing 30 mM imidazole). After incubation for 1h at 4°C, beads were washed three times in either TBS with 0.1% (v/v) NP-40 or in PBS with 30 mM imidazole and complexes were specifically eluted with 3x FLAG peptide or 250 mM imidazole.

Electron Microscopy

Mtw1 complex was thawed and prepared for EM analysis by the GraFix method [32]. 150 μ g of the complex was layered on to a 5–40% glycerol gradient in 20mM HEPES pH 7.6, 100mM NaCl, 1mM EDTA, 1mM DTT, which also contained a 0.02 – 0.15% glutaraldehyde gradient, and ultracentrifuged at 55,000 rpm for 13 hours in a TLS55 rotor at 4°C. Fractions were analyzed by SDS-PAGE, and the fraction containing the monomeric cross-linked complex was applied to a glow-discharged C-flat grid (Protochips) augmented with a layer of thin carbon and stained with 2% uranyl formate.

Images were collected on a Gatan 4kx4k CCD camera using a Tecnai F20 electron microscope operating at 120kV and 30,000x magnification. Despite purification by glycerol gradient, the images contained a mixture of aggregates and fragments, as well as the monodispersed full complex. Approximately 5,000 particles that appeared to correspond to the full monomeric complex were picked manually with the BOXER program 33 and subjected to reference-free classification as described 34.

Coiled-coil predictions were performed with the MARCOIL program 35. The regions indicated with grey boxes in Figure 2C correspond to areas of greater than 50% coiled-coil probability, all of which contain regions of greater than 80% coiled-coil probability.

CENP-T proteins are conserved centromere receptors of the Ndc80 complex

Alexander Schleiffer¹, Michael Maier², Gabriele Litos², Fabienne Lampert², Peter Hornung², Karl Mechtler² and Stefan Westermann^{2,3}

Centromeres direct the assembly of kinetochores, microtubule-attachment sites that allow chromosome segregation on the mitotic spindle. Fundamental differences in size and organization between evolutionarily distant eukaryotic centromeres have in many cases obscured general principles of their function. Here we demonstrate that centromere-binding proteins are highly conserved between budding yeast and humans. We identify the histone-fold protein Cnn1^{CENP-T} as a direct centromere receptor of the microtubule-binding Ndc80 complex. The amino terminus of Cnn1 contains a conserved peptide motif that mediates stoichiometric binding to the Spc24–25 domain of the Ndc80 complex. Consistent with the critical role of this interaction, artificial tethering of the Ndc80 complex through Cnn1 allows mini-chromosomes to segregate in the absence of a natural centromere. Our results reveal the molecular function of CENP-T proteins and demonstrate how the Ndc80 complex is anchored to centromeres in a manner that couples chromosome movement to spindle dynamics.

Kinetochores are large assemblies of multiple-protein complexes exceeding 60 proteins in budding yeast and more than 100 components in humans^{1–3}. As essential cell-division organelles, kinetochores allow the mitotic spindle to drive chromosome segregation by productively coupling microtubule plus-end dynamics to the separation of sister chromatids. In addition, kinetochores contain error-correction and signalling mechanisms that relay the establishment of correct kinetochore bi-orientation on the spindle to the onset of anaphase^{4,5}. Kinetochores have the following general building plan: the KMN network (consisting of the four-protein Mtw1 complex, the four-protein Ndc80 complex and KNL-1 in complex with Zwint) is a supramolecular assembly that forms the architectural core of the kinetochore and contacts spindle microtubules directly^{6,7}. By means that are not well understood, the KMN network is anchored to centromeric chromatin that is characterized by the presence of a specialized nucleosome that contains the histone variant CENP-A replacing the canonical histone H3. The conserved DNA-binding protein CENP-C closely associates with and probably directly recognizes CENP-A nucleosomes^{8,9} to provide an essential step in kinetochore assembly. In addition, a group of at least 15 polypeptides, in humans termed the centromere constitutive-associated network (CCAN) co-purify specifically with CENP-A nucleosomes^{10,11}. Similar proteomic approaches have identified centromere proteins in budding yeast^{12,13} (collectively called the Ctf19 complex) and fission yeast¹⁴

(Sim4 complex). Although the evolutionary conservation of the KMN network has been well documented¹⁵, phylogenetic relationships between centromere proteins have remained uncertain. Centromere DNA is highly divergent between species, bearing no resemblance in length or sequence between evolutionarily distant yeasts such as *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* and between yeast and humans. The simplest centromeres are found in *S. cerevisiae*, comprising only 125 base pairs of DNA (point centromere) with three sequence elements that are conserved between the 16 chromosomes^{15,16}. The centromeres of *S. pombe* are regional, built on more complex DNA that contains repeated sequence elements and has the hallmarks of heterochromatin. Centromeric DNA in human cells spans over many megabases and contains α -satellite repeats that are, however, neither necessary nor sufficient to initiate kinetochore assembly¹⁷. These marked differences in centromere organization have led to the notion that budding yeast may employ many proteins dedicated to the sequence-determined point centromere and thus may have a fundamentally different kinetochore architecture when compared with higher eukaryotes.

Here we reveal a number of previously undetected homology relationships between yeast and human centromere proteins leading to the conclusion that structurally similar kinetochores assemble on small point and large regional centromeres. We show that the histone-fold protein Cnn1^{CENP-T} provides an evolutionarily conserved

direct link to the Ndc80 complex, the key microtubule-binding activity of the kinetochore.

RESULTS

Evolutionary conservation of centromere-proximal proteins between yeast and humans

To examine whether centromere-binding proteins of evolutionarily distant organisms share common ancestry, we performed a comprehensive bioinformatic analysis using sensitive remote homology searches in combination with secondary-structure predictions. Our analysis indicates a remarkable conservation of the centromere–kinetochore interface across eukaryotes (Table 1). We detected previously unrecognized homology relationships between the essential budding yeast proteins Ame1 and Okp1 and the human CCAN subunits CENP-U and CENP-Q, respectively (Supplementary Figs S1 and S2 and Methods). Importantly, this indicates that the budding yeast COMA (Ctf19–Okp1–Mcm21–Ame1) complex may have a biochemical counterpart in the human CENP-O/P/Q/U complex, which also forms a stable entity^{18,19}. In addition, we find that the yeast

Ctf19 complex subunit Mcm22 is orthologous to human CENP-K (Supplementary Fig. S3 and Methods).

Identification of fungal orthologues of the human kinetochore protein CENP-T

Recent studies have demonstrated a critical role for the DNA-binding activity of the human CENP-T/W complex in kinetochore function²⁰ and together with CENP-C, CENP-T plays an instructive role in kinetochore assembly²¹. Human CENP-T is 561 residues long, but besides a histone domain at the carboxy terminus^{20,22}, most of the protein consists of regions of compositional bias, rich in polar residues. On the sequence level, generally the histone fold is highly variable—pairwise identities between archaeal and eukaryotic histones range from 15 to 20%, but the structure is highly defined, consisting of three α -helices separated by two β -strand loops^{23–26}. A single BLASTP search identified orthologues in chordates and fungi with significant *E* values ($<4 \times 10^{-5}$), among those, the known *S. pombe* CENP-T homologue Cnp20 (SPBC800.13; ref. 27) and the uncharacterized protein YALI0A19162p in the Saccharomycetes *Yarrowia lipolytica*.

Table 1 Homology relationships between centromere proteins from human, *S. pombe* and *S. cerevisiae* based on sequence analysis.

<i>H. sapiens</i>	<i>S. pombe</i>	<i>S. cerevisiae</i>	CCAN module
CENP-C	Cnp3	Mif2	C
CENP-O	Mal2	Mcm21	O/P/Q/U/R
CENP-P	Fta2	Ctf19	
CENP-Q	Fta7	Okp1	
CENP-U	Mis17	Ame1	
CENP-R			
CENP-H	Fta3	Mcm16	H/I/K
CENP-I	Mis6	Ctf3	
CENP-K	Sim4	Mcm22	
CENP-T	SPBC800.13/Cnp20	Cnn1	CCAN-HF
CENP-W	SPAC17G8.15	YDR374W-A/Wip1	
CENP-S	SPBC2D10.16	YOL086W-A/Mhf1	
CENP-X	SPCC576.12c	YDL160C-A/Mhf2	
CENP-M			MNL
CENP-N	Mis15	Chl4	
CENP-L	Fta1	Iml3 (Mcm19)

	Cnl2	Nkp2	
	Fta5		
	Fta6		

The grouping reflects biochemically distinct subcomplexes. For a comprehensive overview of the CCAN subunits and their taxonomic distribution, see Supplementary Table S1.

Reciprocal BLASTP searches confirmed the orthologous relationship between fungal and mammalian CENP-T proteins. Iterative PSI-BLAST searches with the conserved C-terminal domain first collected CENP-T proteins, but in further iterations included histone H4 and other histone-fold proteins. To search for a *S. cerevisiae* homologue, we applied a series of sensitive hidden Markov model (HMM) profile searches within specified proteomes, where we first identified a candidate in *Pichia pastoris* (Pipas_chr3_0909, *E* value 1.5×10^{-14}), then in *Candida parapsilosis* (CPAG_01066, *E* value 3.2×10^{-12}) and then in *Saccharomyces kluyveri* (SAKL0F01012g, *E* value 2.5×10^{-10} ; Fig. 1a). In all proteomes, the second best hit was to histone H4 with highly significant *E* values as well (7.1×10^{-12} , 7.1×10^{-9} and 1.2×10^{-8} for *P. pastoris* Pipas_c034_0035, *C. parapsilosis* CPAG_04945 and *S. kluyveri* SAKL0C10714g, respectively). The *S. kluyveri* CENP-T candidate SAKL0F01012g was annotated to be weakly similar to *S. cerevisiae* Cnn1, and the homology was confirmed by BLASTP (*E* value 5×10^{-12}).

Although the sequence identity on the primary amino-acid level is low, CENP-T proteins share a conserved architecture. At the C terminus, there is the conserved CENP-T domain, consisting of a histone fold and two extra helices (Fig. 1b,c). The highly conserved central helix of the histone fold spans around 29 residues. In *S. cerevisiae* Cnn1, this helix is considerably shorter (20 residues), and less conserved in comparison with the adjacent non-histone-fold helices. Although no direct phylogenetic relationship between CENP-T and Cnn1 can be deduced, a common sequence architecture and experimental data, such as the biological significance of a conserved N-terminal motif (see below), lead to the conclusion that both proteins are indeed orthologous.

Proteomic analysis of the budding yeast CCAN

To gain insight into the molecular organization of the budding yeast CCAN network, we performed systematic tandem-affinity purifications

followed by mass spectrometry to identify associated proteins (Fig. 2a). For Ame1^{CENP-U}, Chl4^{CENP-N} and Mcm16^{CENP-H}, this approach yielded a similar interaction profile with each protein co-purifying all other members of the Ctf19 complex and all four subunits of the Mtw1 complex, demonstrating that the Mtw1 complex provides an important attachment point between CCAN and KMN components. Remarkably, purification of Cnn1^{CENP-T} resulted in a different set of co-purifying polypeptides: whereas most members of the Ctf19 complex could be detected, assigning Cnn1 as a CCAN component, Mtw1 complex subunits were absent from this purification and instead all four subunits of the Ndc80 complex were co-purified. This indicated that Cnn1^{CENP-T} might form a unique point of contact between the inner and outer kinetochore. In Mcm16^{CENP-H} and Cnn1^{CENP-T} purifications we additionally detected the product of an uncharacterized open reading frame, YDR374W-A, encoding an 89-amino-acid protein with a predicted high α -helical content. A GFP-fusion to YDR374W-A co-localized with the kinetochore marker Nuf2 and this localization was abolished in a *cnn1*-deletion mutant (Fig. 2b). Recombinant YDR374W-A expressed in bacteria formed a complex with the C terminus of Cnn1, which contains the predicted histone fold (Fig. 2c). Furthermore, chromatin immunoprecipitation (ChIP) in combination with quantitative real-time PCR showed both Cnn1 and YDR374W-A to be enriched at centromeric chromatin (Fig. 2d). Sensitive homology searches could not enlarge the YDR374W-A protein family outside the Saccharomycetes class, with the *Debaryomyces hansenii* protein DEHA2G10538g being the most distant homologue. However, DEHA2G10538g has also been identified in a CENP-W-derived HMM search (Methods). Taken together, these results indicate that YDR374W-A is the budding yeast homologue of human CENP-W and we will refer to this protein as Wip1 (W-like protein 1, Supplementary Fig. S4).

In mammals, two further histone-fold proteins are known to interact with the core CCAN complex: CENP-S and CENP-X (refs 20, 28), forming CENP-S/CENP-X (ref. 29) and CENP-T/CENP-W heterodimeric complexes or SXTW heterotetrameric complexes²². The yeast CENP-S and -X homologues Mhf1 and Mhf2 (refs 29,30) co-purified each other, Mhf2 exhibited further associations with a subset of CCAN subunits and Mhf1 interacted with the DEAH box helicase Mph1 and the DNA repair proteins Msh2 and 3, indicating that Mhf1 and Mhf2 might have dual functions at centromeres and in DNA repair (Supplementary Table S3).

To characterize the protein Wip1 further, we examined its localization in deletion mutants of other CCAN subunits. Whereas the typical bi-lobed localization to kinetochore clusters was unchanged in deletion mutants of *mcm16*^{CENP-H}, *iml3*^{CENP-L} and *mcm21*^{CENP-O}, it was abolished in a *chl4*^{CENP-N}-deletion mutant, demonstrating that in addition to Cnn1, the protein critically depends on this CCAN subunit for its localization to kinetochores (Fig. 3a). In a reciprocal experiment we investigated whether any other CCAN subunit depended on the presence of Wip1 for kinetochore localization. We found that the localization of Mcm16^{CENP-H}, Ctf19^{CENP-P} and Chl4^{CENP-N} was maintained in a *wip1*-deletion mutant (data not shown), but the intensity of the fluorescent signal of Cnn1 was severely reduced by about 80%, consistent with the observed physical interaction between Cnn1 and Wip1 (Fig. 3b). Cnn1 localization was disrupted to a similar extent in a *chl4*-deletion mutant (data not shown), as

Figure 2 Proteomic analysis of the yeast CCAN and identification of the subunit Wip1. **(a)** Summary of the systematic tandem-affinity purifications (TAPs) of CCAN components. '+' denotes that a protein was co-purified with the respective bait; 'high' and 'low' denote stringency conditions during purification of 300 mM or 100 mM KCl, respectively. **(b)** Live-cell microscopy of Wip1-GFP in wild-type cells or in a *cnn1*-deletion background. Scale bar, 5 μ m. **(c)** Wip1 forms a complex with the histone fold of Cnn1.

Analytical size-exclusion chromatography of Wip1 co-expressed with Cnn1 (residues 264–361) in bacteria after initial purification using Ni-NTA agarose. **(d)** ChIP with quantitative PCR was performed for Cse4–13xMyc, Mif2–13xMyc, Cnn1–13xMyc and Wip1–13xMyc using primers spanning a centromeric (CEN3) and a non-centromeric region (GAL2, chromosome XII). The no-antibody control/total-input control has been subtracted for each experiment. Data represent the mean of ≥ 2 independent experiments.

predicted from the observation that Wip1 depended on Chl4 for kinetochore localization.

Cnn1/CENP-T is a centromere receptor for the Ndc80 complex

Its unique protein interaction profile prompted us to investigate the role of Cnn1^{CENP-T} more closely. Physical interactions between CENP-T and KMN components have been reported²¹, but the specificity and molecular basis of these associations have remained uncharacterized. To rigorously probe potential interactions, we purified full-length Cnn1^{CENP-T} from yeast extracts and examined its association with reconstituted recombinant budding yeast Ndc80 and Mtw1 kinetochore complexes by size-exclusion chromatography. The appearance of a fast-eluting species indicated complex formation between the Ndc80 complex and Cnn1^{CENP-T} (Fig. 4a). The complex seemed stoichiometric on Coomassie-stained gels and formed under submicromolar input concentrations, indicating a high-affinity interaction. Under the same conditions, no complex formation was

observed between Cnn1–Flag and the Mtw1 complex (Supplementary Fig. S5a) or between Cnn1 and the purified Spc105/YDR532c complex (data not shown). We next examined whether the interaction of Cnn1 with the Ndc80 complex is compatible with simultaneous binding of the Mtw1 complex and thus would allow interaction with the KMN network. In three-component gel filtration experiments with an excess of Mtw1 complex, Ndc80–Mtw1 complex formation was readily observed as reported previously^{31–33}. Interestingly, under these conditions, Cnn1 failed to co-elute effectively with the Mtw1–Ndc80 supercomplex, indicating that the Mtw1 complex and Cnn1^{CENP-T} are competing binding partners of the Ndc80 complex (Supplementary Fig. S5b). Supporting this, Cnn1–Flag immobilized on beads efficiently pulled down the free recombinant Ndc80 complex, but the amount of interacting Ndc80 complex was reduced in a dose-dependent manner with increasing concentration of Mtw1 complex included in the reaction. Cnn1–Flag failed to pull down the Mtw1 complex, either alone or in the presence of the Ndc80

Figure 3 Localization dependencies of yeast CCAN histone-fold proteins. (a) Live-cell microscopy of Wip1-GFP in various CCAN-deletion mutants. Note the absence of kinetochore localization in the *chl4*-deletion mutant. (b) Live-cell microscopy of yeast strains expressing Cnn1-3GFP in a wild-type

or *wip1*-deletion background. Lower panel: Quantification of Cnn1-3GFP fluorescence intensity in a wild-type or *wip1*-deletion strain. The intensity of Cnn1-3GFP in a wild-type strain was normalized to 1; kinetochore clusters in 10 anaphase cells were quantified. Scale bar, 2 μ m.

complex (Fig. 4b,c). Taken together, these experiments indicate that Cnn1^{CENP-T} and the Mtw1 complex are competing binding partners for the Ndc80 complex.

To probe the interaction between the Ndc80 complex and Cnn1 in the cell, we performed co-immunoprecipitation experiments using myc-tagged Nuf2. Cnn1-Flag could be specifically co-immunoprecipitated from log-phase extracts, confirming an association between these proteins *in vivo* (Fig. 5a). Notably, when immunoprecipitations were performed from extracts that had been synchronized by release from an α -factor arrest, the interaction was detectable only in a time window of about 90–105 min after the release. Immunofluorescence microscopy indicated that these time points corresponded to the time of mitotic spindle elongation (Fig. 5b). In contrast, co-immunoprecipitation experiments indicated a relatively constant affinity between the Ndc80 complex and the Mtw1 complex over the cell cycle (Fig. 5c). We conclude that the interaction between Cnn1 and Ndc80 occurs in a cell-cycle-specific manner and is predominantly detectable in anaphase.

Identification of an Ndc80 receptor motif in the N terminus of Cnn1

Using the motif search program MEME, we could identify a short conserved motif in the otherwise unstructured N terminus of CENP-T proteins, predicted to fold into an α -helix with several conserved hydrophobic residues (Fig. 6a). We reasoned that this N-terminal motif might be involved in the interaction with the Ndc80 complex. Consistent with our hypothesis, a mutant Cnn1 protein lacking the 15-amino-acid conserved motif (Cnn1 ^{Δ 65–79}, Fig. 6b) failed to interact with the recombinant Ndc80 complex (Fig. 6c). We next established the binding site on the Ndc80 complex: the Ndc80 heterotetramer contains two functionally distinct ends, the microtubule-binding Ndc80–Nuf2 dimer and the Spc24–25 dimer, which is required for centromere

localization of the complex³⁴. Size-exclusion chromatography indicated the formation of a tight complex between the Spc24–25 dimer and Cnn1, which was abolished in the Cnn1 mutant lacking the conserved N-terminal motif (Fig. 6d). We also established that the Ndc80 complex can recruit Cnn1 to taxol-stabilized microtubules in co-sedimentation experiments (Supplementary Fig. S7). To determine whether the conserved motif is also sufficient for Ndc80 binding, we synthesized a 25-amino-acid peptide including the 15-residue binding motif. We characterized the association using isothermal titration calorimetry and found that this peptide binds in a 1:1 stoichiometry to the Spc24–25 heterodimer with an apparent dissociation constant of 3.2 μ M (Fig. 6e). This affinity seems to be lower than observed in gel filtration experiments with full-length Cnn1, indicating that additional parts of the N terminus may contribute to the high-affinity interaction with the Ndc80 complex. As the Spc24–25 domain has previously been identified as the binding site for the Mtw1 complex^{31–33}, this result can explain the observed competition for Ndc80-complex binding and implies that the Spc24–25 domain has at least two distinct, mutually exclusive binding partners within the yeast kinetochore, the N terminus of Cnn1^{CENP-T} and the Mtw1 complex.

Artificial tethering of the Ndc80 complex through Cnn1 promotes mini-chromosome segregation in the absence of a centromere

Budding yeast strains with a deletion of Cnn1^{CENP-T} and/or Wip1^{CENP-W} did not exhibit an obvious growth or chromosome segregation defect (data not shown), indicating that in principle the Mtw1-based Ndc80 recruitment pathway is sufficient to support viability in this organism. In addition, by fluorescence microscopy we could not detect a substantial reduction of Ndc80 signal intensity in a *cnn1*-deletion mutant (Supplementary Fig. S8). In contrast, the putative *S. pombe* CENP-T homologue Cnp20 is an

Figure 4 Cnn1^{CENP-T} is an exclusive and direct interaction partner of the Ndc80 complex. (a) Analytical size-exclusion chromatography of recombinant Cnn1-Flag (upper panel), reconstituted yeast Ndc80 complex (middle) or a combination of both (lower panel). Elution positions of standard

proteins are indicated at the top. (b) Pull-down experiment with recombinant Ndc80 and Mtw1 kinetochore complexes and Cnn1-Flag immobilized on beads. (c) Pull-down experiment with Cnn1-Flag, Ndc80 complex and increasing concentrations of the Mtw1 complex.

essential protein and mutants exhibit very severe chromosome segregation phenotypes²⁷.

To probe the biological function of Ndc80 recruitment by Cnn1^{CENP-T} in budding yeast we therefore employed a synthetic gain-of-function approach (Fig. 7a). As described previously, artificial tethering of proteins to a replication-competent mini-chromosome that lacks an authentic centromere can be used to determine whether candidate proteins are able to provide the function of an artificial kinetochore^{35,36}. Direct tethering of the Ndc80 complex through a C-terminal TetR fusion to the Spc24 subunit failed to induce a mitotic stabilization of mini-chromosomes³⁵. As a result of our biochemical experiments, we reasoned that it might be essential to recruit the Ndc80 complex through the elongated, flexible Cnn1 N terminus. We constructed a strain in which the histone-fold domain of Cnn1 was replaced with the TetR repressor and compared the stability of an acentric *tetO* mini-chromosome in this strain with that of a number of control strains (Fig. 7b). Notably, the Cnn1^{ΔHF}-TetR fusion, but not the Spc24-TetR fusion, strongly enhanced mini-chromosome stability over multiple generations. The stabilizing effect exceeded that of Ask1-TetR, a known force-transducing component of the budding yeast Dam1 kinetochore complex³⁷. Importantly, the artificial kinetochore function supplied by Cnn1^{ΔHF}-TetR was abolished in a mutant lacking amino acids 65–79 (Fig. 7c), demonstrating that it strictly depended on the ability of Cnn1 to interact with the Ndc80 complex. On the other hand, recruiting subunits of the Mtw1 complex (Mtw1-TetR and Nnf1-TetR) to the *tetO* array did not lead to plasmid stabilization.

In similar experiments, LacI fusions to CENP-T have been shown to recruit KMN components to ectopic chromosomal *lacO* arrays in human cells and they can partially replace the activity of an endogenous centromere in chicken DT40 cells²¹. Thus, the ability of Cnn1^{CENP-T} to anchor Ndc80 complexes to DNA in a manner that allows them to productively interact with the mitotic spindle seems to be a conserved feature of these proteins.

A Wip1-deletion allele exhibits severe synthetic phenotypes in combination with other kinetochore mutants

The experiments so far indicate that different receptors for Ndc80 complexes are present at yeast kinetochores. This could explain why Ndc80 loss-of-function mutants exhibit severe chromosome-detachment phenotypes³⁸ whereas mutants of Mtw1 complex subunits or Mif2^{CENP-C} do not³⁹. To address this issue, we combined temperature-sensitive *mif2* or *mtw1* mutants with *cnn1* or *wip1* deletions and investigated their phenotypes. *mif2 wip1* double mutants showed a severe growth defect (Fig. 7d) and similar synthetic interactions were detected with *okp1* and *mtw1* alleles (data not shown). Inspection of chromosome segregation by immunofluorescence microscopy showed that the *mif2 wip1* double mutant contained elongated mitotic spindles with a single mass of unsegregated DNA, phenotypically similar to the defects seen in an *ndc80-1* mutant at the restrictive temperature, but distinct from the *mif2-3* and *wip1* single mutants (Fig. 7e). Thus, simultaneously interfering with both Ndc80 recruitment modes leads to severe defects in chromosome segregation.

Figure 5 Cell-cycle-dependent interaction between Ndc80 and Cnn1^{CENP-T}. **(a)** Co-immunoprecipitation between Nuf2-13xMyc and Cnn1-6xFlag from yeast log-phase extracts. **(b)** Cell-cycle co-immunoprecipitation experiment (top panel): after release from an α -factor arrest, extracts were prepared at the indicated times and Nuf2 was immunoprecipitated using anti-myc beads. Cnn1 was detected by anti-Flag western blot. Lower panel: anti-tubulin immunofluorescence

microscopy of samples taken at the indicated time points from the cell-cycle experiment. Note the presence of long anaphase spindles in the 90 and 105 min time points. Scale bar, 5 μ m. **(c)** Corresponding experiment probing the interaction between the Ndc80 and the Mtw1 complex. Nuf2-13xMyc was immunoprecipitated and the association with Mtw1-6xFlag was detected by western blot. Uncropped images of western blots are shown in Supplementary Fig. S6.

DISCUSSION

Our investigations into budding yeast centromere proteins have uncovered general organization principles of kinetochores (Fig. 7f). The conserved role of CENP-T proteins is to act as direct, KMN-independent centromere receptors of the Ndc80 complex. This provides a molecular understanding for the requirement of the CENP-T N terminus for kinetochore assembly in human cells²¹ and can explain the observation that it undergoes a tension-dependent conformational change in response to microtubule attachments⁴⁰. The original identification of Cnn1 as an interaction partner of the Mtw1 complex¹⁹ was probably due to the use of a single-step purification protocol, which has been shown to co-purify a large set of kinetochore proteins⁴¹. Our results raise the question as to why kinetochores contain multiple different Ndc80 recruiters. In budding yeast, the interaction between Ndc80 and Cnn1 is detectable predominantly in anaphase, the mitotic phase in which cells have irreversibly committed to segregate their chromosomes. Consistent with this observation, the levels of Cnn1 at kinetochores seem to be increased in anaphase, as judged by live-cell microscopy⁴². Recruitment through CENP-T incorporates the Ndc80 complex into a flexible attachment filament that might be especially suited for force transduction to move chromosomes, a property that was reflected in our artificial kinetochore experiment⁴³. As part of the KMN network, on the other hand, Ndc80 complexes are

linked to signalling molecules of the mitotic checkpoint machinery⁴⁴ and thus play important roles in sensing the presence and quality of kinetochore-microtubule attachments. The observation that Cnn1 and the Mtw1 complex compete for Ndc80 binding and that the Cnn1-Ndc80 affinity is increased during anaphase is indicative of significant changes in kinetochore architecture that occur at the metaphase-anaphase transition. Future experiments will have to reveal how these structural rearrangements are established and what their precise functional consequence is. CENP-T proteins and CCAN subunits other than CENP-C seem to be absent from the kinetochores of *Caenorhabditis elegans* and *Drosophila melanogaster*. Consistent with the existence of different Ndc80 recruitment pathways, *mis12* mutants in these organisms exhibit a true kinetochore-null phenotype⁴⁵ because here Ndc80 is exclusively recruited as part of the KMN network. □

FP7/2007-2013)/ERC grant agreement no. 203499, and from the Austrian Science Fund FWF (S.W., SFB F34-B03).

AUTHOR CONTRIBUTIONS

A.S. performed bioinformatic sequence analysis. M.M. purified CCAN proteins and performed characterization of proteins. P.H. performed interaction studies. F.L. conducted ChIP and biochemical experiments. K.M. guided the mass spectrometry analysis. S.W. guided the study and performed biochemical and genetic experiments supported by G.L. All authors discussed results and analysed data. S.W. and A.S. wrote the manuscript.

ARTICLES

Figure 7 Artificial tethering of the Ndc80 complex through Cnn1^{CENP-T} allows mini-chromosomes to segregate in the absence of a centromere. (a) Scheme of the mini-chromosome stability assay. The segregation of a URA3-containing mini-chromosome containing a *tetO* array but lacking a centromere is assayed in different strain backgrounds. (b) Stability of URA3 mini-chromosomes in different strain backgrounds. Error bars denote s.e.m. $n = 3$. (c) Examples of plating assays for fusion strains Ask1-TetR, Spc24-TetR, Cnn1^{ΔHF}-TetR, Cnn1^{ΔHFΔ85-79}-TetR, Mtw1-TetR and Nnf1-TetR on YPD and doURA. (d) Double deficiency of the Ndc80 recruitment pathways: tetrad dissection of *wip1Δ mif2-3* double mutants. (e) Chromosome segregation defects in *wip1Δ mif2-3* double mutants. Left panel: Cells were processed for immunofluorescence microscopy two

hours after shift to the restrictive temperature of the temperature-sensitive mutants. DNA is stained with DAPI; microtubules are stained with an anti-tubulin antibody. Right panel: Phenotypic categories are indicated and the respective phenotypes were quantified for the individual strains. Scale bar, 5 μ m. (f) Two distinct receptors for Ndc80 molecules are present at yeast centromeres, one is the Mtw1 complex, which in turn may require the conserved protein Mif2/CENP-C for association with centromeric DNA. In a second pathway, Ndc80 molecules directly interact with the histone-fold complex Cnn1-Wip1 through a conserved receptor motif in the N-terminal extension of Cnn1. In a normal budding yeast cell cycle this linkage is not required for viability, but it becomes essential when Mtw1 subunits or Mif2 are functionally compromised.

METHODS

Homology searches and protein annotation. All searches were performed in the NCBI non-redundant protein database⁴⁷, or within specified proteomes, listed in Supplementary Table S4. Species and accession numbers are listed in Supplementary Table S2. We used NCBI BLASTP and PSI-BLAST version 2.2.24 (ref. 48), and HMMer v.3.0 (ref. 49) with significant *E* values below 0.01. Fold predictions were executed with HHpred in the PDB protein structure database^{50,51}. Domains were annotated with Pfam and Smart databases^{52,53}, coiled coils were predicted using COILS (window 21; ref. 54), low-complexity regions with SEG (window 12; ref. 55) and secondary structure with Jpred3⁵⁶. Sequences were aligned with MAFFT version 6 (L-INS-I method; ref. 56), and visualized and processed with Jalview (ref. 57) (Clustalx colouring scheme). To search for short motifs outside conserved domains, we used MEME (one occurrence per sequence, motif width 10–25; ref. 58).

Amel homology search. The budding yeast protein Amel1 is 324 residues in length and has a predicted coiled-coil region between amino acids 199 to 263. In homology searches, it is a common practice to disregard compositionally biased regions such as low-complexity, transmembrane or coiled-coil regions. When masking the coiled-coil region, an iterative PSI-BLAST search within the NCBI non-redundant protein database identified only Saccharomycetes strains closely related to *S. cerevisiae*, such as *Vanderwaltozyma polyspora*, *Zygosaccharomyces rouxii*, *Kluyveromyces lactis* or *Ashbya gossypii*, with significant *E* values $<5 \times 10^{-4}$ (round 1). The search converged in round 2 without incorporation of further hits. A multiple alignment of these orthologues revealed a conserved short region at the N terminus (rich in positively charged residues—corresponding to positions 2–22 in *S. cerevisiae* Amel) and a conserved, α -helical domain (residues 115–314), where the coiled-coil region is a central part of it. We included the coiled-coil region in further searches, allowing for the incorporation of unrelated coiled-coil proteins as false positive hits. A search with a more sensitive HMM profile using sequences comprising the conserved domain detected significant hits in the more distantly related *Penicillium marneffei* (*E* value 1.3×10^{-3}) and to other Pezizomycotina fungi, such as *Uncinocarpus reesii* and *Arthroderma gypseum* (*E* values 0.0029 and 0.0046, respectively). We used BLASTP searches to enlarge the sequence family within the Pezizomycotina fungi (*E* values $<1 \times 10^{-5}$). They all belong to a group of conserved hypothetical proteins, without known function. In the subsequent HMM search within the *S. pombe* proteome, only one significant hit was identified, namely Mis17 (*E* value 5.1×10^{-3} ; Supplementary Fig. S1).

Intriguingly, Mis17 has been identified as a centromere protein in genetic screens and is involved in the stable deposition of CENP-A to centromeres; thus, functionally it acts like a CCAN subunit⁵⁹. In addition to other Ascomycota, we enlarged our search to the proteome of the Basidiomycota *Ustilago maydis*. Using a HMM profile covering the α -helical Amel1/Mis17 domain, we identified one significant protein (UM03572, *E* value 0.00035). Applying the expanded model to the NCBI non-redundant protein database resulted in 11 newly identified proteins below the inclusion threshold (*E* value 0.01, apparent isoforms were not counted). Out of these, 5 proteins belong to the mammalian CENP-U gene family, with the CENP-U protein from *Bos taurus* as the best hit (*E* value 4.3×10^{-7}). CENP-U (also called CENP-50) is a CENP-A co-purifying protein⁶⁰ that forms a biochemically stable complex with CENP-O, -P and -Q (ref. 18). The six remaining proteins were unrelated coiled-coil proteins from Trypanosoma, Nematoda, Ascomycetes, Bacteria (2 proteins) and Archaea. Searching with the Amel1/Mis17 domain within the *Mus musculus* or *Homo sapiens* proteome results in CENP-U proteins as the only significant hits (*E* value 1.2×10^{-8} and 0.0051, respectively). In an alternative approach, a HMM–HMM comparison with the Amel1/Mis17 alignment identified a model built from mammalian CENP-U proteins as the next best hit (besides the known fungi ones) with a sub-significant *E* value (0.016, UniProt20 database; ref. 60). CENP-U orthologues can be easily collected from mammals to fish with BLASTP searches applying highly significant *E* values ($<1 \times 10^{-15}$). As is the case for Amel1 and Mis17, they all share a coiled-coil region at the C terminus that is part of a highly conserved domain and predicted to be α -helical.

Okp1 homology search. Okp1 is similar in architecture to Amel1, with a length of 406 residues and a coiled-coil region from 239 to 285. A BLASTP search with a coiled-coil masked sequence identified proteins in the closest Saccharomycetes organisms, such as *Lachancea thermotolerans*, *K. lactis* or *A. gossypii*, with significant *E* values ($<9 \times 10^{-8}$). As in Amel1, the conserved domain is located at the C-terminal region that is predicted to be α -helical and includes the coiled-coil region. The sequence conservation score is slightly higher than for Amel1 and so we could establish a linkage between Okp1 and the fission yeast Pta7 using a series of PSI-BLAST searches: the conserved region of the *Lachancea* Okp1 orthologue (including the coiled-coil region) hit one protein in *Sclerotinia sclerotiorum* with a significant *E* value (4×10^{-9}) in round 2, and the *Sclerotinia* Okp1 domain in turn found one protein in *Tuber melanosporum* (*E* value 5×10^{-21} , round 2), which finally led to the identification of *S. pombe* Pta7 (*E* value 8×10^{-4} , round 1). A HMM profile search with the fungi Okp1/Pta7 domain included 5 non-fungal proteins, all CENP-Q orthologues (inclusion value 0.01), such as the acorn worm *Saccoglossus*

kowalevskii (*E* value 4×10^{-4}) or the house mouse *Mus musculus* (*E* value 8×10^{-3} ; Supplementary Fig. S2).

Mcm22 and CENP-K are orthologues. *S. cerevisiae* Mcm22 is 239 residues long and has a predicted coiled coil from 113–134. A BLASTP search using the full-length Mcm22 (masking the coiled-coil region) identifies orthologues in the closest Saccharomycetes organisms, such as *Candida glabrata* (*E* value: 3×10^{-9}) or *A. gossypii* (*E* value: 5×10^{-11}). The conserved domain is spanning nearly the whole protein length (*S. cerevisiae* Mcm22: 7–233) and the coiled-coil predictions of the orthologues overlap with the one of *S. cerevisiae*. We constructed a HMM out of the conserved domain (the regions corresponding to the *S. cerevisiae* coiled coil were masked) and searched in the proteomes of *Candida dubliniensis*, *Pichia guilliermondii*, *Candida albicans* and *Aspergillus niger*, where in each case one protein was found below the inclusion value (*E* value <0.01 ; Cd36_87730, PGUT_03964, CAWT_03094, jgilAspn11[178612]). In the following iterative PSI-BLAST search within the NCBI non-redundant protein database, more Pezizomycotina proteins were collected in round 1 with significant *E* values ($<2 \times 10^{-8}$), among those *Gibberella zeae* and *Tuber melanosporum*. The subsequent HMM search identified proteins from *Strongylocentrotus purpuratus* (*E* value: 2.1×10^{-6}), *Gallus gallus* (0.0019), *Pan troglodytes* (0.0031), *Xenopus laevis* (0.0055) and six more animal proteins below the significant inclusion value (0.01). They all belong to the CENP-K family, where *S. pombe* Sim4 is included as well⁶² (Supplementary Fig. S3). In a reciprocal approach, the Pfam CENP-K HMM identified the *Gibberella zeae* and other Pezizomycotina orthologues, and a subsequent search with a HMM including the Pezizomycotina proteins hit *C. glabrata* Mcm22 (*E* values <0.01).

CENP-W homology search. In mammals, besides CENP-T, three further histone-fold proteins are known to interact with the core CCAN complex: CENP-S, CENP-W and CENP-X (refs 20,28), forming CENP-S/CENP-X (ref. 29) and CENP-T/CENP-W heterodimeric complexes. Unlike CENP-T, these three proteins are much shorter (81–138 residues), hardly extending the histone domain (CENP-S has an extension of around 30 amino acids at the C terminus rich in positively charged residues). CENP-X and CENP-S are well conserved and homologues in *S. pombe* and *S. cerevisiae* were identified with BLASTP. CENP-W family members can be detected in Pezizomycotina fungi, such as *A. niger*, and in *Schizosaccharomyces japonicus* with iterative PSI-BLAST searches, but the model iterated into histone-fold proteins, such as the transcription factors NC2 β or Hap3. To find Saccharomycetes homologues, a HMM model containing the CENP-W histone domain identified the orphan protein DEHA2G10538g in *Debaryomyces hansenii* with a highly significant *E* value (1.2×10^{-11}), followed by the NC2 β -like protein DEHA2E16126g (*E* value 7×10^{-67}), whereas we failed to detect any significant *S. cerevisiae* proteins.

In a biochemical isolation of CCAN-complex-binding proteins from budding yeast cell extracts, several hypothetical proteins were characterized by mass spectrometry, using Mcm16 and Cnn1 as bait (Supplementary Table S3). Among those, the protein YDR374W-A was of particular interest, owing to its short length (89 amino acids) and a high α -helical content. YDR374W-A is very weakly conserved and when applying sensitive HMM searches we found orthologues in *Z. rouxii*, *K. lactis* and *A. gossypii*. In the proteome of *Debaryomyces hansenii*, we identified one protein DEHA2G10538g with a significant *E* value (3.4×10^{-5}). Interestingly, *D. hansenii* DEHA2G10538g had been previously identified in the search for CENP-W candidates. Thus, it is very likely that budding yeast YDR374W-A is the orthologue of mammalian CENP-W (Supplementary Fig. S4).

Yeast strains and plasmids. Yeast strains are based on S288C and were generated by standard procedures. A list of used yeast strains and plasmids can be found in Supplementary Table S5.

Protein biochemistry. Ndc80 and Mtw1 complexes were expressed and purified as described previously^{15,61} with the following modifications: for the Mtw1 complex an N-terminal 6 \times His-tagged Dsn1 subunit was cloned into a pST39 expression plasmid harbouring the Nnn1, Nsl1 and Mtw1 subunits.

Overexpression and purification of proteins from yeast extracts were performed as described previously⁶² with the following modifications. Yeast pellets (60 g) were lysed with a freezer mill (Spex Centriprep) and the resulting yeast powder was stored at -80°C . For purification of Flag-tagged proteins, 10 g yeast powder was combined with 50 ml lysis buffer (25 mM HEPES at pH 8.0, 2 mM MgCl₂, 0.1% NP-40, 150 mM KCl, 15 (v/v) % glycerol, 1 mM dithiothreitol and protease inhibitors), left on ice for 30 min and centrifuged at 60,000g for 30 min at 4°C . The supernatant was further ultracentrifuged (100,000g, 45 min, 4°C), cleared by filtration through a 0.2 μm filter and collected. A 300 μl solution of anti-Flag M2 agarose beads was added and rotated for 3 h at 4°C . Beads were washed five times with wash buffer (lysis buffer with 0.5 M KCl, 1 mM ATP and 2 mM MgCl₂) and eluted three times with 1 mg ml⁻¹ 3 \times Flag peptide in buffer H. Proteins were snap-frozen in liquid N₂ and stored at -80°C .

Interaction studies. Interaction studies were performed by size-exclusion chromatography on Superose 6 PC3.2/30 columns. The indicated proteins or complexes

were used at 1 μ M concentration, mixed and left on ice for 30 min before injecting 50 μ l onto the column. Fractions of 100 μ l were collected, and proteins were precipitated using chloroform/methanol and subjected to SDS-PAGE.

Isothermal titration calorimetry. Thermodynamic values of the interaction between Cnn1-derived peptides and Spc24–25 were determined by ITC (MCS-ITC, Microcal). All experiments were conducted at 25 °C. A 1.8 ml solution of Spc24–25 (30 μ M) was placed in the temperature-controlled cell and titrated with Cnn1 peptide at 500 μ M in the syringe. The buffer used was 25 mM HEPES at pH 8 with 150 mM KCl. Data were analysed using ORIGIN following the instructions of the manufacturer.

Mass spectrometry. The nano-HPLC system used in all experiments was an UltiMate 3000 Dual Gradient HPLC system (Dionex), equipped with a Proxeon nanospray source (Proxeon), coupled to an LTQ Velos Orbitrap mass spectrometer (Thermo Fisher Scientific), operated in data-dependent mode using a full scan in the ion cyclotron resonance cell followed by tandem mass spectrometry (MS/MS) scans of the 12 most abundant ions in the linear ion trap. MS/MS spectra were acquired in the multistage activation mode, where subsequent activation was performed on fragment ions resulting from the neutral loss of -98 , -49 or -32.6 m/z for potential follow-up phosphorylation site analysis. Precursor ions selected for fragmentation were put on a dynamic exclusion list for 180 s. Monoisotopic precursor selection was enabled.

Analysis of MS data. For peptide identification, all MS/MS spectra were searched using Mascot 2.2.04 (Matrix Science) and Sequest (Thermo Scientific) against the yeast SGD protein sequence database (6,717 sequences; 3,020,761 residues). The following search parameters were used: carbamidomethylation or methyl methylthiomethyl sulphoxide respectively on cysteine was set as a fixed modification; oxidation on methionine was set as variable modification. Monoisotopic masses were searched within unrestricted protein masses for tryptic, chymotryptic and unspecific (subtilisin digest) peptides. The peptide mass tolerance was set to ± 5 ppm and the fragment mass tolerance to ± 0.5 Da. The maximal number of missed cleavages was set to 2. Using a Thermo Proteome Discoverer 1.3.0.339 (Thermo Scientific), the results of both search engines were combined and filtered to 1% false discovery rate using an integrated Percolator algorithm. Furthermore, high-quality criteria filters such as peptide rank 1 and minimum 2 peptides per protein were applied.

Artificial kinetochore experiments. Experiments to examine artificial kinetochore function were performed as described previously³⁸ with the following modifications. TetR-fusion proteins were integrated at the LEU2 locus and expressed as extra copies. Expression was verified by western blotting of whole-cell extracts with an anti-TetR antibody. Strains were transformed with mini-chromosomes, selected on drop-out uracil (doURA) and grown non-selectively for 24 h in YPD medium. An attenuation of 0.6 at 600 nm was adjusted and 70 μ l of a 1:1,000 dilution was plated

on YPD or doURA plates, leading to the formation of approximately 600 colonies on YPD. Experiments were performed in triplicates.

ChIP. Cultures were grown in YPD to mid-log phase. Cells were crosslinked for 30 min with formaldehyde (1%). Chromatin extract preparation and ChIP were performed as previously described³¹. Samples were analysed by quantitative PCR using the Biorad iQ5 real-time PCR system and software.

9. Curriculum vitae

Personal information

Name: Michael Josef Maier

Natianality: german

Date of Birth: 06.09.1983 in Cape Town, South Africa

Email: a0508282@unet.univie.ac.at

Education

2005-present: Studies of Molecular Biology

University of Vienna, Austria

2004-2005: Studies of Chemical Engineering,

Friedrich-Alexander University Erlangen

1993-2003: Staffelsee Gymnasium Murnau

10.Acknowledgements

In the last chapter of my thesis I want to thank everybody that has made this work possible. First and foremost I want to thank my parents who have given me the opportunity to study and who have supported me throughout this time.

Thank you Stefan, not only for giving me the opportunity to work on this exciting project but also for involving me after my work was complete. You have an exceptional lab and it was a pleasure to work with you and everybody else there.

Thank you, Peter. Just like I could not have wished for a better lab for my thesis, I could not have wished for a better supervisor. You gave me the freedom to be creative but kept me on track.

Thank you Chrissi, Evi, Fabi, Francesca, Gabi, Kati, Paulina, Tom, Vero. You gave me advice but probably more important, your amiable character buffered the frustrating days in the lab. One rarely meets a group of people like you.

I am very grateful for my friends. Although I tend to focus on work and neglect them more often than not, they were always there when I called and never stopped calling me.

And finally, thank you Marion, you gave me the strength to see this through.
