Abstract

The Budějovice Basin on the Bohemian Massif in the Southern part of the Czech Republic is a fault-bounded sedimentary basin delimited by NW-SE and NNE-SSW striking fault systems. The NW-striking Hluboká-Fault zone confines the basin to the NE, partly appearing as a morphological scarp in the landscape. Assessment of the kinematic history and timing of fault activity along this border fault as well as reconstruction of the tectonic evolution of the Budějovice Basin was the main objective of this master thesis.

Structural geological research concentrated on outcrops situated close to the Hluboká-Fault Zone. Field data include both ductile (foliation, folds and stretching lineation) and brittle structures (fault planes, deformation bands, tension gashes). Data were collected from outcrops located in crystalline basement rocks, Permian, Cretaceous and Miocene sediments of the Budějovice Basin in order to obtain information about the relative timing of the different fault movement events. Additional structural data were obtained from five interpreted 2D seismic profiles across the Hluboká-Fault and the parallel Zbudov-Fault.

Structural data are supplemented by computer aided 3D-modeling of the crystalline basement and the sedimentary basin fill to understand the tectonic evolution of the Budějovice Basin. Drilling reports from the Czech Geological Survey in Prague (Geofond), a high resolution DEM and geological maps of the region were used for modeling the geometry of the basin, as well as the distribution of Upper Cretaceous and Miocene sediments. The 3D Basin Model is based on subcrop information obtained from 679 wells.

Data indicate that the first movement of the NW-SE striking Hluboká-Fault System occurred at low to very low metamorphic conditions in late-Variscan times (deformation D_2). The fault strikes parallel to preexisting structural anisotropies in the crystalline basement (ductile foliation and folds, D_1). The ductile structures are overprinted by brittle faults. These include brittle normal faults and mineralized extension gashes indicative for SW-directed extension (D_3) and sub-vertical, dextral strike-slip faults striking parallel to the Hluboká-Fault (D_4). Structures of D_3 occur in Variscan phyllite, Permian sediments

and Cretaceous shale suggesting a post-Cretaceous Deformation age. Faults of D₄ occurring in strata of the Zliv Fm. give evidence that dextral strike-slip faulting post-dates the Miocene.

Interpretations of the 3D basin model show that the crystalline basement plunges towards the eastern border of the basin with a dip of approximately 5°. On the north-eastern and eastern border of the basin the Hluboká and Rudolfov Fault offset the crystalline Basement for up to about 340 m. Borehole and seismic data show that the Hluboká Fault fault steeply dips towards SW with up to 85°.

Information obtained from interpreted seismic sections and the 3D-basin model show Upper Cretaceous sediments as the main sedimentary infill of the Budějovice Basin, increasing in thickness from W to E. Interpreted seismic sections crossing the Hluboká Fault depict large, synformal fold geometries of constant thickness for Upper Cretaceous reflectors rising towards the northeastern basin margin. Seismic further displays an angular unconformity between Upper Cretaceous and overlying Miocene sediments. Neither Cretaceous nor Miocene growth strata have been observed in the seismic. The analyzed geological data therefore indicates that the main subsidence of the Budějovice Basin occurred due to post-Cretaceous tilting.

Zusammenfassung

Das Budweiser Becken im Süden der tschechischen Republik ist ein störungsgebundenes Sedimentbecken, das die Kristallineinheiten der Böhmisches Masse überlagert. Das Becken wird allseits von NW-SE- sowie NNE-SSW-streichenden Störungszonen begrenzt. Die NW-streichende Hluboká (Frauenberg) Störung begrenzt das Becken gegen NE und tritt in der Landschaft teilweise als markante Geländestufe in Erscheinung. Die Bewertung der Kinematik und die relative zeitliche Zuordnung der Störungsaktivität der Hluboká Störung sowie die Rekonstruktion der tektonischen Entwicklung des Budweiser Beckens bilden den Schwerpunkt dieser Masterarbeit.

Für die kinematische Bewertung wurden strukturgeologische Daten in Aufschlüssen entlang der Hluboká Störung-Zone aufgenommen. Die ausgewerteten Geländedaten umfassen sowohl duktile (Foliationen, Falten, Streckungslineare) als auch spröde Strukturen (Störungsflächen, Deformationsbänder, Zerrspalten). Das Alter der verschiedenen Deformationsereignisse wurde anhand von Strukturen aus Aufschlüssen in verschiedenen alten Formationen ermittelt. Daten liegen aus Aufschlüssen des kristallinen Untergrunds, der permischen, kretazischen und miozänen Sedimente des Budweiser Beckens vor. Weiters wurden fünf seismische Profile über die Hluboká Störung und die parallel dazu verlaufende Zbudov Störung ausgewertet.

Eine weitere Grundlage für die Rekonstruktion der tektonischen Entwicklung des Budweiser Beckens bildet die computergestützte 3D-Modellierung des kristallinen Untergrunds und der Sedimentfüllung des Beckens. Die Modellierung stützt sich auf Daten von 679 Bohrungen (Bohrungsberichte des Tschechischen Geologischen Dienstes – Geofond Prag), ein hochauflösendes DHM sowie die geologische Karten 1:25 000 der Region. Anhand der genannten Datengrundlage wurde die Beckenform sowie die Mächtigkeit der oberkretazischen und der miozänen Sedimente modelliert.

Die Ergebnisse der Strukturgeologischen Felddaten und der Dünnschliffanalysen zeigen, dass das Hluboká Störungssystem unter niedrigen bis sehr niedrigen metamorphen Bedingungen in spätvariszischer Zeit angelegt wurde (Deformation D_2). Die Störung streicht parallel zur variszischen Schieferung und duktilen Falten (D_1).

Die spätvariszischen Strukturen werden von spröden Störungen überprägt. Diese setzen sich aus spröden Abschiebungen und mineralisierten Zerrspalten (D_3) sowie subvertikalen, dextralen Blattverschiebungen (D_4), die parallel zur Hluboká Störung streichen, zusammen. Abschiebungen und Zerrspalten (D_3) zeigen SW-NE-gerichtete Dehnung an. Das Vorhandensein dieser Strukturen (D_3) in variszischem Phyllit, permischen Sedimenten und kretazischen Tonen weist auf post-kretazisches Deformationsalter hin. Das Auftreten dextraler Störungen in miozänen Sedimenten der Zliv Fm. läßt auf ein post-miozänes Deformationsalter von D_4 schließen.

Das 3D Beckenmodell zeigt, dass der kristalline Untergrund des Budweiser Beckens mit etwa ca. 5° nach Osten einfällt. Am nordöstlichen Beckenrand ist der Beckenuntergrund an der Hluboká Störung um ca. 340 m vertikal versetzt. Bohrungsdaten und Seismik dokumentieren, dass die Störung steil mit bis zu 85° nach SW einfällt. Den südöstlichen Beckenrand bildet die Rudolfov (Rudolfstadt) Störung, die mit etwa 50° zum Becken hin einfällt.

Seismikdaten und die Interpretation des 3D Beckenmodells zeigen, dass kretazische Sedimente den größten Anteil der Beckenfüllung bilden. Die Mächtigkeit dieser Serien nimmt von W nach E zu. Seismikprofile über die Hluboká Störung bilden eine großmaßstäbliche Synform der kretazischen Reflektoren am NE Beckenrand ab. Die Synform bildet mit den überlagernden, horizontal geschichteten miozänen Sedimenten eine markante Winkeldiskordanz. Die in der Seismik abgebildeten Reflexionsmuster bieten keinen Hinweis auf syntektonische Sedimente (Growth Strata) in der kretazischen und miozänen Beckenfüllung. Die ausgewerteten geologischen Daten weisen daher darauf hin, dass die Absenkung des Budweiser Beckens im Wesentlichen auf post-kretazisches Kippen zurückzuführen ist.

Acknowledgements

First of all I would like to express my gratitude to my supervisor Dr. Kurt Decker for supporting me with his knowledge during the first field trips to my research area and for constant help and patience in the process of writing this master thesis.

My appreciation especially goes to my project co-worker Dana Homolova for helping me with the interpretation of Czech literature and drilling reports and other problems related to the language barrier between Czech and German.

I also would like to thank Werner Chwatal from the Technical University of Vienna for processing of seismic data and help with interpretation of seismic profiles.

Numerous people throughout the Department for Geodynamics and Sedimentology helped me with words and deeds during the completion of this master thesis:

Magda Bottig and Ulli Exner helped me with various problems concerning the computer program GOCAD®.

My room colleagues Stephanie Neuhuber, Esther Hintersberger, Anton Tanzberger, Asma Nasir, Andreas Beidinger, Andras Zamolyi and Eun Young Lee who always had an open ear for questions that arose due to problems that needed to be solved.

Above all my university mates Johannes Steinbrener, Jasmin Kaiser, Philipp Stadler, Dominik Rehm, Bernhard Bretis and Alex Rath for their companionship and help during the time that we spend together at university and on field trips to many wonderful locations.

Finally I want to stress the importance of my father and my whole family for the time of my studies at the university. Through all those years they supported me in any imaginable way, giving me the opportunity to fully concentrate on my studies.

1. Introduction

The work at hand was done under the supervision of Dr. Kurt Decker at the Department of Geodynamics and Sedimentology at the University of Vienna as part of the Austrian Interfacing Project – AIP in collaboration with Czech geoscientists. This project aims at the classification of the near-regional faults (< 25 km) of the Temelin Nuclear Power Plant in the Czech Republic by using various approaches. These include: Geophysical measurements like Ground Penetrating Radar (GPR) and 2D seismic fault mapping, palaeoseismological trenching, age dating and correlation of quaternary terraces of the Vltava river in the Budějovice basin and intensive structural field work.

The main question hereby was, if faults in an area which is generally associated with low to moderate seismicity, were likely to cause major earthquakes in younger, quaternary times, which would proof that these faults have to be regarded as “active” (**Mallard, 1991**).

In this context the Budějovice Basin 15 km SSE of the Power Plant raised the main attention for our investigations. Especially the northeastern margin of the basin, highlighted by the linear topographic scarps of the Zbudov Fault and the Hluboká Fault - which is the most prominent fault scarp in the area - were of major interest.

In this framework my master thesis focussed on the poorly known kinematic history and timing of fault activity along the Hluboká and Zbudov Fault in pre-quaternary times including the tectonic and sedimentary evolution of the Budějovice Basin.

Geological research was not only carried out through fieldwork in outcrops in the vicinity of the Hluboká Fault Zone, but also through the interpretation of five seismic profiles, which were recorded in summer and fall 2009, crossing the Hluboká Fault and the parallel Zbudov Fault.

Beside structural field work and seismic fault mapping another approach included the acquisition of subcrop information based on drilling reports obtained from the Czech Geological Survey (Geofond) in Prague. Nearly 1000 drilling reports from wells situated in the lowlands and at the eastern margin of the Budějovice Basin were collected in order to create a computer aided 3D model of the basins bedrock. Additionally, the sedimentary basin fill was modeled according to the borehole informations obtained

from the drilling reports, in order to see if sedimentary layers are disrupted or offset by slip along the Hluboká and Zbudov Fault.

Taking the above mentioned background into account, the scientific questions and goals of this master are:

- 1) Resolving the kinematic history and timing of fault activity along the Hluboka Fault Zone.
- 2) Characterizing the spatial geometry of the Hluboká and Zbudov Fault through seismic fault mapping at the eastern and northeastern margin of the Budějovice Basin.
- 3) Combining information obtained from drilling reports and seismic 2D sections in order to create a computer aided 3D model, helping to resolve the tectonic and sedimentary evolution of the Budejovice Basin

2. Geological and geographical overview

The town of České Budějovice (Budweis), situated in the southern part of the Czech Republic, is the capital city of the South Bohemian Region. České Budějovice is situated in the southeastern part of the Budějovice Basin depression. The area of the Budejovice Basin is estimated to be roughly 900 km² in size. The oval-shaped basin is aligned on a NW-SE trending axis and extends from České Budějovice in the southeast to Vodňany in the northwest. Along with the larger Třeboň Basin around the city of Třeboň east of České Budějovice, the Budějovice Basin is part of the so-called South Bohemian Basins, covering an area of ca. 2300 km². They are divided by the Lišov Horst (Rudolfov Ridge) trending in N-S direction between the basin depressions (**Fig. 1**). The crystalline Basement and the margins of South Bohemian Basins are composed of mica schists, biotitic, sillimanite-biotitic to biotite-cordieritic paragneisses and leucocrate migmatites of the Moldanubian Unit as well as igneous rocks of the South Bohemian Pluton.

The metamorphites originated from the complex multiphase fold-thrust deformation of the Cadomian and the Variscan tectono-metamorphic cycle (**McCann, 2008; Váchal et al., 2010**).

The Budějovice Basin can be classified as a rather small and shallow sedimentary basin, with a length in NW-SE direction of approximately 48 km and a width in SW-NE direction of 19 km. The depocenter of the basin with a depth of about 400 m beneath the surface is located in the southeastern part of the basin. The basin is deeper than the Třeboň Basin with about 320 m thick sedimentary fill. Both basins have experienced a similar geological history, which is not only reflected in the sedimentary record, but also in the tectonic framework they were developed in (**Slánská; 1976**).

Probably developed as pull-apart basins on metamorphic basement of the Moldanubian terrane and South Bohemian Pluton (**McCann, 2008**), the South Bohemian Basins evolved at the intersection of the NW-striking Jáchymov (Joachimsthal) Fault zone and the NNE-striking Blanice-Kaplice-Rodl-Fault zone.

Fig. 1: Location of the South Bohemian Basins. Hluboká Fault at the northeastern margin of the Budejovice Basin indicated in red. Assumed faults (dotted lines) striking in ESE-WNW direction are interpreted as conjugated wrench faults to the Blanice-Kaplice-Rodl Fault Zone (see also **Fig. 4**), separating the basins in NNE-SSW direction. In contrast to the northern part of the Budějovice Basin which is delimited by marked morphological borders, the southern part is clearly controlled by a tectonic setting where border faults like the Hluboká Fault depict sharp contacts between the basin lowland and the surrounding crystalline basement. (modified after Vachova & Kvaček, 2009).

2.1. Previous geological investigations

Geological research in the area of the South Bohemian Basins mostly concentrated on the sedimentary deposits covering the crystalline basement. Detailed studies concerning the Late Palaeozoic,- Cretaceous and Tertiary sediments in southern Bohemia were carried out by **Falke, 1972,1975; Slánská, 1976; Holub and Tásler, 1978; Malkovský, 1987; Huber, 2003; Vachova, 2009**. The sedimentary deposits of the Upper Cretaceous Křivá-Formation in the South Bohemian Basins were of special interest to sedimentologists and palaeontologist due to their rich microflora. Whereas the sedimentological record and the greater tectonic setting of the Bohemian Massif in the southern part was well investigated (**Fritz & Neuhuber, 1993; Wallbrecher et al. 1993; Brandmayr et al., 1995, 1997; Büttner & Kruhl, 1997; Finger et al. 2007; Büttner, 2007**),the kinematic relationship of processes in central Bohemia around the South Bohemian Basins received less attention in scientific literature (**Šimůnek et al., 1995**).

2.2. Geologic evolution of the Bohemian Massif

Marking the easternmost part of the European Variscan belt, the Bohemian Massif with its rhombic shape can be subdivided into four units, which include from SE to NW: the Moravian, the Moldanubian, the Teplá-Barrandian and the Saxothuringian (**Fig.2**). All of which represent continental microplates being composed of Precambrian basement and Early Paleozoic sedimentary sequences which were consolidated due to the Variscan orogeny (**Hejl et al., 2003**).

Present reconstructions of the European Variscan belt assume a fan-like symmetry, characterized by two branches with opposite vergences (**Pitra et al., 1999**).

Whereas the northern branch including the Saxothuringian and Rhenohercynian depicts an overall northwestward vergence, the Moldanubian in the south is presented by generally southeastward vergence. Mostly unmetamorphosed, the Teplá-Barrandian terrane represents a discontinuous “median zone” separating those two orogenic branches in the Bohemian Massif (**Pitra et al., 1999**)

Fig. 2: a) Tectonic sketch of the Bohemian Massif. b) European Variscan massifs: BM, Bohemian Massif; AM, Armorican Massif; MC, Massif Central; A, Alps; M, Moldanubian Zone; B, Teplá-Barrandian; ST, Saxothuringian Zone; RH, Rhenohercynian Zone (Pitra et al., 1999)

High-temperature and medium-to high-pressure metamorphism during Devonian and Late Carboniferous times, associated to a continent-collisional setting by the subduction of the Paleo-Tethys underneath Laurasia, was followed by nappe stacking, crustal thickening and subsequent crustal collapse (Fritz & Neubauer, 1993; Büttner, 2007).

As a consequence of uplift and exhumation of the Moldanubian crust due to the Variscan northwest/southeast compression (Zulauf, 1997), the upper parts of the Variscan nappe pile were thrust southeastwards over the Moravian foreland. A process induced by the main Variscan Moravo-Moldanubian Phase (345-330 Ma), succeeded by the Bavarian Phase (330-315 Ma), characterized through reheating due to regional metamorphism (Finger et al., 2007).

The subsequent collapse of the Variscan crust was accompanied by the intrusion of late-to post-Variscan granitoids including the South Bohemian Pluton, which is dated to about 330-308 Ma (e.g. Weinsberger,- Eisgarner and Mauthausner Granites in lower Austria), **(Büttner, 2007)**.

Magmatic underplating as well as delamination of the lithospheric mantle is seen as the driving force for high-T/low-P metamorphism and the large scale plutonism in the southeastern Moldanubian zone **(Büttner & Kruhl, 1997)**.

Following the consolidation of the Bohemian Massif due to the Variscan orogeny in late Paleozoic times, tectonic activity in the lower Mesozoic remained sparse. Middle Triassic to Late Bathonian sediments are absent from the area of the Bohemian Massif, which probably formed a coherent land mass supplying clastics to the adjacent sedimentary basins **(Malkovsky, 1987)**.

Recurring tectonic activity associated with the Alpine orogeny reactivated Variscan structures in many cases due to its similar stress regime of generally north directed compression. Evidence for this process is given by brittle overprints of ductile, late-Variscan shear zones in southern Bohemia (e.g. Danube and Pfahl Shear Zone) **(Brandmayr et al., 1995, 1997)**.

The present-day NW-and N-directed compressional stress field throughout the European Variscan Massif reflects a combination of Alpine collision and Atlantic ridge-push forces which came into evidence during the early Miocene and intensified further during the late Pliocene–early Quaternary **(Ziegler & Dèzes, 2007)**.

2.3. Lithostratigraphic units of the Moldanubian Unit

The Moldanubian zone on Austrian and Czech territory between the Teplá-Barrandian unit in the northwest and the Moravian zone in the southeast is generally subdivided into three major geological units, comprising the Gföhl and Drosendorf metamorphic units, which represent pre-Variscan (Precambrian/Early Palaeozoic) crust, and the Variscan granitoids (**Fig. 3; Finger et al., 2007**)

The structural lower part of the Moldanubian nappe pile is represented by the parautochthonous Drosendorf Unit overlain by the allochthonous Gföhl Unit (Gföhl nappe complex). Furthermore the Drosendorf Unit is subdivided from bottom to top into a Monotonous series and a Variegated series, which is not commonly accepted, as some authors suggest the Monotonous series as a stand-alone unit (Ostrong Unit) underlying the Drosendorf nappe complex (e.g. **Fuchs, 1991; Büttner & Kruhl, 1997; Matura, 2003**).

Probably representing a part of Gondwana mainland, the Precambrian Monotonous series consists of uniform paragneisses with intercalations of quartzites, calcsilicates and amphibolites, separated from the Variegated series by a tectonic contact (**Büttner & Kruhl, 1997**). The younger, Paleozoic Variegated series comprises para- and orthogneisses, ultramafic rocks, micaschists, marbles, quartzites, graphitic rocks and amphibolites (**Hejl et al., 2003; Walter, 2007**).

At the top of the Moldanubian lithostratigraphic column, the allochthonous Gföhl nappe complex covers areas east of the South Bohemian Pluton and around České Budějovice in southern Bohemia. High-grade metamorphic conditions (up to granulite facies) define the Gföhl Unit (Gföhl gneiss and Gföhl granulite), consisting mainly of para- and orthogneisses, amphibolites, metagabbros, granulites and eclogites (**Walter, 2007**).

Following the formation and emplacement of these Moldanubian nappe units from Proterozoic to upper Paleozoic times, the widespread plutonic complexes of the Central and South Bohemian Batholith intruded syn-orogenic during the lower Carboniferous over a period of approximately 30-50 Ma (**Wessely, 2006; Büttner, 2007**).

2.4. Permocarboniferous sediments in southern Bohemia

Only a few remnants of Permocarboniferous sediments are still present in southern Bohemia, representing the oldest sedimentary successions in this region. Siltstones and shales of late Palaeozoic origin represent continental sediments of the NNE-SSW trending intramontane depressions of the Bohemian Massif. In the Southern Bohemian Region these sediments exclusively occur in the 12 km broad Blanice Graben between Český Brod in the north and České Budějovice in the south (**Fig 4.**). The graben can be divided into three parts: a) northern part with outcrops near Český Brod and Kostelec nad Č. Lesy which represent the largest areal distribution of late Paleozoic sediments, b) central part with occurrences in the vicinity of Vlašim and Tábor, and c) southern part with outcrops near České Budějovice (including the Lhotice coal district) (**Chlupáč & Vrána, 1994**).

These Permocarboniferous sediments represent the periodic transport from the denuded part of the massif. Proluvial, deluvial, fluvial, lacustrine, swamp and rarely eolian sediments were distinguished in the late Palaeozoic basins by **Holub & Tasler (1978)**. During periods of higher humidity in the Permian, pyroclastics and coal seams were deposited and red to reddish-brown sediments (red-bed type sediments) during arid periods. The Deposition of sediments started in the Upper Carboniferous (Gzhelian) and lasted till the Lower Permian (**Falke, 1972, 1975; Malkovský, 1987; Chlupáč & Vrána, 1994**).

To the northeast of České Budějovice, the Permocarboniferous occurs isolated in the asymmetrical Lhotice Basin of 18 km² between Lhotice and Jelmo (**Fig. 5**). With a depocenter of ca. 250 m, the Lhotice Basin is bounded by faults running in NNE-SSW direction of the Blanice Graben system and cross faults. Drillings near Vráto east of České Budějovice give evidence that Permocarboniferous sediments reach below the Cretaceous sediments of the Budejovice Basin. The Lhotice Basin is interpreted as a pull-apart basin, which emerged in the late Paleozoic due to the left lateral movement of the Blanice-Kaplice-Rodl Fault System (**Falke, 1972**).

The grabens and half-grabens associated with the Blanice-Kaplice-Rodl Fault System appear to be post-Variscan structures developed upon a slightly undulating surface of

the early Bohemian Massif which had been deeply eroded to the granitic layer, forming much of the graben basement (**Jindrich, 1971**).

Fig. 4: Outline geological map of the southern Bohemian Massif showing the Blanice-Kaplice-Rodl-Fault zone. Lhotice Basin indicated in red. Vertical lines correspond to the exposed part of the Moldanubian Block (modified after **Kosler, 2001**).

Fig: 5: **a)** Watersupply trench in Usilne in Permocarboniferous red shale and siltstone. **b)** Outcrop CP_011 southwest of Usilne exposing red siltstone and sandstone. Tension gashes indicate NE-SW directed extension. **c)** Geological cross-section through the southern part of the Permo-Carboniferous of the Blanice graben near České Budějovice between (Lhotice and Jelmo). 1 – Upper Cretaceous and Quaternary, 2 – reddish and variegated mudstones and sandstones (middle Lower Permian), 3 – reddish and variegated sandstones and mudstones with interbeds of micritic limestone (middle Lower Permian), 4 – grey complex, in the upper part faintly variegated, with 1-2 anthracite seams (Lower Permian), 5 – grey arkosic sandstones and conglomerates with silty and clayey intercalations and 1 anthracite seam (Upper Gzhelian) 6 – granitic rocks 7 – metamorphics (gneiss and migmatite of the Moldanubicum) (modified after Falke, 1972).

2.5. Mesozoic and Cenozoic sedimentation

Following the consolidation of the Bohemian Massif and subsequent Permocarboniferous sedimentation (see chapter 2.4.) the time span from late Permian to early Triassic remained tectonically quiet. From middle Triassic to middle Jurassic the Bohemian Massif was uplifted due to an unknown mechanism (**Malkovsky, 1987**). During the Upper Jurassic, from Callovian to Tithonian, the NW–SE-trending Saxonian strait transected this high, thus linking the North German Basin with the Tethys shelves. However, this seaway was interrupted during the Early Cretaceous in response to wrench deformations, attributed to the build-up of pre- and syn-collisional compression in the foreland of the evolving Karpathian–East-Alpine orogen (**Ziegler & Dèzes, 2007**). In the latest Jurassic and earliest Cretaceous, climatic conditions caused the lowering of the sea level. Combined with the uplift of the Bohemian Massif, these processes induced the closure of the Saxonian strait. The Permocarboniferous fault system was reactivated and convergent dextral wrench movements induced the deep truncation of Jurassic and Triassic strata. Thereby, up to 1500 m of sediments were eroded prior to the deposition of Middle to Upper Cretaceous Albian and Cenomanian sands (**Ziegler, 1990**). These Pre-Upper Cretaceous fluvial-lacustrine sediments, referred to as České Budějovice Formation consist of conglomerates, sandstones and shalestones. Marking the bottom of the stratigraphic column, the České Budějovice Formation covers the deeply weathered crystalline basin floor, or buries – only locally within the basin – relicts of Upper Paleozoic and Permo-Carboniferous sediments (**Huber, 2003**), (**Fig. 6**).

The main sedimentation started in the Upper Cretaceous with clastic, freshwater sediments of the Klikov-Formation. Due to the SE-directed drainage system in the Upper Cretaceous, the Klikov-Formation covered an area expanding into Austrian territory, where it is also known as “Gmündner Schichten”. The sedimentary deposits of the Klikov-Formation represent the periodic transport from the denuded part of the Bohemian Massif. The presence of marine microplankton in the lower part of some cycles indicates shallow-marine influence, while the upper parts of the cycles are interpreted of fluviolacustrine origin (**McCann, 2008**).

Fig. 6: Stratigraphy of the Budějovice Basin (modified after Šimůnek et al., 1995)

Slánská 1976 described cyclothems reflecting relative stages of Uplift and Subsidence of the Basin in the Sedimentary succession of the Klikov Formation. The ideal cyclothem consists from bottom to top of light grey sandstone beds, red beds and grey beds. Light grey sandstone beds (A), forming the basal member of the cyclothem, are made up of coarse to medium grained conglomeratic sandstones, poorly sorted and sometimes cemented by siderite and limonite (**Fig. 7**). The middle part of a cyclothem consists of reddish-brown, poorly sorted sediments, principally conglomeratic muddy, fine to medium sandstones or conglomeratic, sandy mudstones and sandy claystones (B). Dark-grey sandstones (C) with variable amounts of carbonized plant debris and greenish grey claystones partly used in the local ceramic industry are forming the top member of each cyclothem (**Fig. 8; Fig. 9**), (**Slanska, 1976**).

Fig. 7: Sandpit near Hrdejovice (Outcrop CP_010) showing the basal member (A) of a cyclothem of the Klikov-Formation consisting of poorly sorted coarse to medium grained conglomeratic sandstones, partly cemented by siderite and limonite.

Fig. 8: Claypit north of Munice (Outcrop CP_002). The Reddish, greenish and grey claystones are typical for the top member (C) of the Klikov-Formation.

Fig. 9: Schematic profile of a common cyclothem of the Klikov-Formation (Slanska, 1976). For abbreviations see Text above.

The Neogene filling of the basin is to be considered with respect to the drainage pattern during the middle Miocene, when a predominant part of Bohemia was drained into the Alpine-Karpathian foredeep to the SE. In the Pliocene the streams drained north- and southwards from the upheaving area of central Bohemia. The Paleogene Lipnice Formation, succeeding the Klikov Formation after a hiatus of approximately 30 Ma, is preserved only in relics, composed of fluvatile and lacustrine silicified sandstones. The following Zliv Formation marks the oldest Miocene unit, composed of silicified conglomerates and sandstones (**Fig. 10**). Ranging in thickness up to 80 m, the overlying Mydlovary Formation as the thickest and most extensive complex of Miocene sediments is composed of clays, diatomaceous earth and coal. The Badenian Transgression from the Alpine-Carpathian Foreland had a major influence on the deposition of the Mydlovary Formation. From the Tethys in the southeast, the sea advanced through the river valleys deep into the interior of the Bohemian Massif, resulting in the deposition of diatomites and temporary change to brackish conditions. The fresh-water Moldavite-bearing Domanin Formation, succeeding the Mydlovary Formation and overlying it partly, consists of psammites and psephites. Stratigraphically this complex corresponds probably to the earliest Sarmatian.

Fig. 10: Zliv-Formation near Mydlovary (Outcrop CP_013). Conglomerate with well-rounded Qtz-components (ca. 0,5 -2 cm in diameter) in sandy matrix.

The Pliocene Ledenice Formation, lying unconformably on the Mydlovary Formation as the youngest Miocene unit, is build up by fresh-water, generally lacustrine sediments (**Fig.11**), (**Suk, 1984; Chlupáč & Vrána, 1994**). Senonian to Pliocene sedimentation

during the Alpine orogeny has previously been interpreted to be related to the episodic reactivation of Variscan NNE-and NW-striking faults zones mostly by vertical movements (Váchal et al., 2010).

Formation	ČESKO-BUDĚJOVICE FORMATION	KLIKOV FORMATION	LIPNICE FORMATION	ZLIV FORMATION	MYDLOVARY FORMATION	LEDENICE FORMATION
Age	Pre-Upper Cretaceous	Upper Cretaceous	Oligocene	Miocene(?Helvetian ?Carpathian)	Miocene (?Tortonian -?Pontian)	Pliocene
Main rock types	Conglomerates, sandstones, shales	Conglomerates, sandstones, mudstones, sandy and/or silty claystones	Gravels, sands, conglomerates (siliceous cement), sandstones, quartzite (quartz-limonite cement)	Conglomerates, sandstones (clayey quartz cement), sandy clays (silicified), volcanic conglomerate	Gravels, sands, sandstones, clays, claystones, diatomite, lignite, marl, tuffs, tuffites	Sands, sandy clays, diatomite
Cyclic sedimentation	Present	Pronounced	Absent	Absent	Absent	Absent
Main components of sand fractions	Quartz, orthoclase, plagioclase, muscovite, biotite, chlorite, calcite, plant fragments	Quartz, orthoclase, microcline, plagioclase, biotite, muscovite, chlorite, plant fragments	Quartz, minor feldspars (altered)	Quartz, pyroclastic material (volcanic glass), plant fragments, tests of diatoms	Quartz, feldspars, biotite, pyroclastic material	Quartz, tests of diatoms
Main components of clay	Mica, smectite, chlorite, kaolinite, limonite, silica	Kaolinite, illite, limonite, hematite, organic matter	Kaolinite, limonite, hematite, silica	Kaolinite, smectite, limonite, silica, organic matter	Kaolinite, smectite, illite, limonite, silica, calcite, organic matter	Kaolinite, illite, limonite
Siderite	-	Major amount	-	Accessory amount	Accessory am.	-
Calcite	Concretions, euhedral grains	-	-	-	Micrite (major amount in the Třeboň Basin)	-
Others	Anatase, biotite	Mineral of the crandallite group	-	-	Quartzine	-
Heavy minerals	Apatite, garnet, zircon, tourmaline, rutile	Zircon, tourmaline, rutile, kyanite, opaques, andalusite, staurolite, monazite, spinel. In places: corundum (VRÁNA, 1991)	Zircon, tourmaline, rutile, kyanite, opaques, monazite, andalusite, staurolite, spinel	Zircon, tourmaline, rutile, kyanite, opaques, andalusite, garnet, clinozoisite, monazite, staurolite, sillimanite, spinel, sphene	Zircon, tourmaline, rutile, zoisite, kyanite, garnet, sillimanite, epidote, amphibole, etc.	-
Crystallinity of kaolinite	Poorly-ordered pseudomonoclinic	Well-ordered triclinic	Well-ordered triclinic to poorly-ordered pseudomonoclinic	Poorly-ordered pseudomonoclinic	Poorly-ordered pseudomonoclinic	Poorly-ordered pseudomonoclinic
Cement	Quartzose, carbonaceous	Ferruginous (limonite, hematite, siderite), barite	Ferruginous, quartzose	Ferruginous, siliceous (opal), quartzose	Quartzose, ferruginous, calcareous	Quartzose
Bedding type and other characteristic features	Cleavage, slickensided fractures, weak metamorphism	Massive, cross-bedding, graded bedding, horizontal	Horizontal	Undistinctive	Cross-bedding, horizontal	Horizontal
Environment and conditions of deposition	Lacustrine	Fluvial, lacustrine, alluvial fans, flood plains, river-channels, lakes	Lacustrine	Fluvio-lacustrine	Fluvio-lacustrine, river channels, overbank floods, backswamps, lakes	

Fig. 11: Lithostratigraphic units of the Budějovice Basin (Huber, 2003). The moldavite-bearing Domanin-Formation of upper Badenian/Sarmatian Age, overlying the Mydlovary Formation and underlying the Ledenice-Formation is not considered by the cited author.

2.6. The kinematic evolution of the southern Bohemian Massif

Previous geological studies concerning structural geology and especially paleostress determinations mostly concentrated on the northern, eastern and western parts of the Bohemian Massif (e.g. **Peterek et al., 1997; Adamovic & Coubal, 1999; Haviř, 2000, 2005; Pešková et al., 2010**).

In the southeastern section of the Bohemian Massif detailed investigations were done along the Moldanubian-Moravian thrust boundary zone (**Fritz & Neubauer, 1993; Fritz, 1996; Fritz et al., 1996** and references cited therein). The previously mentioned large-scale set of conjugate shear zones in southern Bohemia was widely discussed in **Wallbrecher et al., 1993** and **Brandmayr et al., 1995; 1997** (see Chapter 2.5).

In general, geological research with emphasis on structural geology was mostly restricted to the border areas of the Bohemian Massif with little attention paid to the central region with the South Bohemian Basins.

For the discontinuous and polyphase geological history of the Moldanubian sector in southern Bohemia (**Finger et al., 2007**) three deformation phases have been described so far for the tectonometamorphic/geodynamic evolution in scientific literature (e.g. **Büttner & Kruhl 1997; Büttner 2007; Zulauf et al., 1997, Zulauf 2001**).

Nappe stacking of the parautochthonous Drosendorf unit and the allochthonous Gföhl unit and their subsequent north-northeast directed thrusting onto the Ostrong unit under upper amphibolite to granulite facies conditions corresponds to the oldest deformational phase D_1 (**Büttner & Kruhl, 1997; Büttner 2007**). Defined by fabrics of the Drosendorf unit indicative for top-to-north and top-to-northeast kinematics, D_1 was subsequently followed by ductile flow in east-west direction (D_2). N-to NE compression (D_1) was converted into E-W compression (D_2) by clockwise rotation of the stressfield following the oblique collision of the Moldanubian indenter against the Bruno-Vistulian foreland (**Fritz, 1991; Fritz & Neubauer, 1993**). Generally associated with nappe stacking and thrust kinematics, D_1 and D_2 were mostly studied at the Moravo-Moldanubian border

zone in the southeastern section of the Bohemian Massif, making it difficult to assess to what degree these deformation events affected the centre of the Moldanubian Block.

The third deformation event D_3 clearly postdates Moldanubian nappe stacking and melt emplacement. It is characterized by Late-Variscan NNW-SSE directed compression and lower-greenschist to subgreenschist facies folding and thrusting in the centre of the Bohemian Massif (**Zulauf, 2001**). At the southwestern margin of the Moldanubian Unit, D_3 is manifested through strike-slip shearing and the formation of the dextral NW-striking Danube and Pfahl shear zones during Carboniferous to Permian times with possible brittle reactivation during the Alpine event (**Büttner, 2007**).

2.7. The Late-Variscan fault pattern in southern Bohemia

The major fault pattern in southern Bohemia is dominated by two major fault systems (**Fig. 12**) striking in NW-SE and NNE-SSW to NE-SW direction, respectively. The main structural framework of the Bohemian Massif is particularly dominated by NW-SE trending basement blocks following a broad zone of essentially NW-striking faults paralleling the direction of the Tornquist-Teisseyre Line, which forms the boundary between the stable Fennoscandian East European craton and the fragmented platform of Western Europe (**Malkovsky, 1987; Matte et al., 1990; Ziegler, 1990**).

The eastern part of southern Bohemia is dominated by NNE-SSW to NE-SW striking faults. From east to west those are the Diendorf-, Vitis-, Karlstift and Rodl-Kaplice-Blanice shear zone. In the western part of southern Bohemia, the Danube shear zone and the Pfahl shear zone represent the NW-SE striking fault systems. These faults moved with dextral (NW-SE) and sinistral (NNE-SSW to NE-SW) shear sense in the Paleozoic. This spatial tectonic framework is traditionally interpreted as a conjugated set of wrench faults by N-S directed compression during the Variscan orogeny, probably caused by indentation of an underlying crustal block moving to the north (**Wessely, 2006**).

Fig. 12: Lithotectonic units and shear zones of the Southern Bohemian Massif. The continuation of the Rodl shear zone into the Blanice Graben and the Diendorf shear zone into the Boskovice Graben to the north are traced along the Permian deposits. The South Bohemian Basins with their mainly Mesozoic sedimentary fill are shown south of Tabor. Being part of the Jáchymov shear zone, the Hluboká Fault confines the Budějovice Basin to the NE (indicated in red) (modified after Brandmayr et al., 1997).

Dating of initial fault activity has been done by several authors (Brandmayr et al., 1995, 1997; Wallbrecher et al., 1993). $^{40}\text{Ar}/^{39}\text{Ar}$ muscovite cooling ages from mylonites of 287 Ma for the NW-SE-striking dextral systems and ca. 288-281 Ma for the NNE-SSW-striking sinistral fault systems indicate Lower-Permian deformation (Brandmayr et al., 1995). Dating upon microgranodiorite dykes emplaced along the Blanice-Kaplice-Rodl-Fault zone yielded intrusion ages of 270 Ma corresponding to this age of fault movements (Kosler et al., 2001)

Rb-Sr dating of muscovites from the southern part of the Rodl-Kaplice-Blanice-Fault Zone yielded ages of approximately 190 Ma, indicating partial Alpine rejuvenation of this ductile fault system (**Wallbrecher et al., 1993**).

An upper age limit for shear zone formation is given by Intrusion ages of 330 to 300 Ma for Late-Variscan granites as all shear zones crosscut various granite bodies (**Brandmayr et al., 1997**).

Two of the NNE-SSW striking shear zones (Rodl and Diendorf shear zone) extend further to the north merging with the NNE-striking Boskovice and Blanice Graben forming the Rodl-Kaplice-Blanice Fault zone and the Diendorf-Boskovice Fault zone. Extending from the east of Prague to Linz in Upper Austria, the Blanice-Kaplice-Rodl Fault zone is associated with a component of sinistral displacement of about 17 km (**Kosler, 2001**). A sinistral slip movement of at least 25 km is associated with the Diendorf-Boskovice Fault zone dissecting the Bruno-Vistulian Block from the Moravian Zone (**Mandl, 1999; Hejl et al., 2003**).

Shear zones are interpreted as corresponding kinematically to E/W oriented extension associated with N-S to NNW-SSE directed convergence.

3. Study Area

The area of interest is situated around the northeastern margin of the Budějovice Basin where the Hluboká Fault is featured as a linear topographic scarp with a height of up to about 80 m, extending over 15 km from Rudolfov in the Southeast to Mydlovary in the Northwest. Structural data were collected from 30 outcrops near the Hluboká and Zbudov fault scarp located in Moldanubian crystalline basement as well as Permocarboniferous, - Cretaceous and Miocene sedimentary deposits (**Fig. 13; Tab. 1**). The strategy of collecting structural data from rocks of different age should allow age dating of different deformation events with the “paleostress stratigraphy” method (**Kleinspehn et al., 1989**).

The inclination of the lowland area is directed south-eastwards with average elevations ranging from 395 m in the northwest to 375 m in the southeast, towards a basin with numerous lakes (**Vachal et al., 2010**).

From the southern edge of the basin two streams - Vltava and Malse - enter the lowlands and merge together in České Budějovice, leaving the basin at the northeastern margin near Hluboka nad Vltavou.

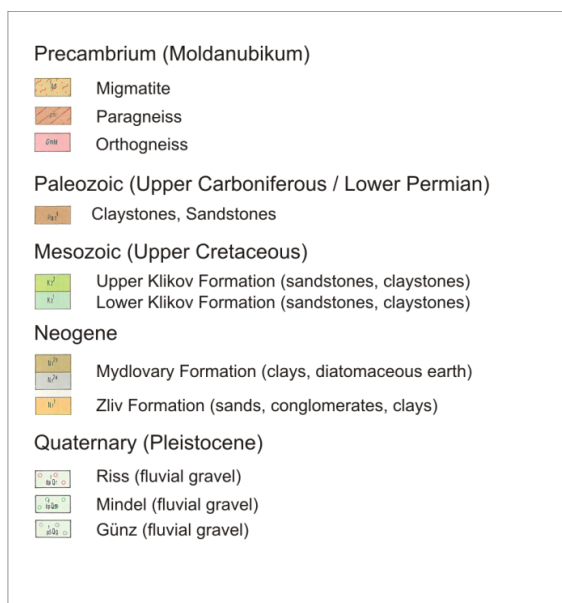

Fig.13: Left side and next page: Legend and geological map of study area with outcrops situated along the Hluboká Fault Zone.

Table 1: Complete outcrop list

3.1. Structural data

Only a few of the investigated outcrops will be addressed in this chapter, due to the fact that most outcrops were extensively weathered lacking good structural data and particularly, fault slip data. In some cases only foliation and lithology could be recorded. Collected structural data are displayed in Schmidt equal area plots of the lower-hemisphere. For a better graphic discrimination between ductile and brittle features, ductile features like foliations, folds, ductile stretching lineations and crenulations are colored in red in contrast to brittle features indicated in black. Complete, polygenetic datasets were manually separated into cogenetic subsets potentially characterizing the same tectonic regime (**Fig. 14**).

Fig. 14: Separation of polyphase datasets into cogenetic subsets (from Peterek et al., 1997)

Throughout the investigation area at the northeastern margin of the Budějovice Basin foliation of the Moldanubian basement strikes NW-SE, dipping steeply to SW towards the basin, suggesting that the orientation of the Hluboká Fault is predefined by Variscan structural anisotropies.

3.1.1. CP_001

Outcrop CP_001 is located southwest of Hosin in the crystalline basement at the starting point of the Hosin seismic 2D section (see chapter 4.2.). Even though deeply weathered a shear zone about 20 m in size striking parallel to the Hluboká Fault in NW-SE direction could be detected (**Fig. 15**). Measured faults could be separated into three different fault types, characterized by brittle NW-SE striking strike-slip faults with lunate fractures and syntectonic Riedel shears indicating right lateral displacement; SW-dipping, ductile normal faults and NE-dipping, brittle normal faults (**Fig. 16**).

Lower greenschistfacies conditions are estimated for SW-dipping normal faults, which show ductile, synkinematic quartz depicting stretching lineations.

Fig. 15: Brittle fault zone in Bt-Ms-Paragneis with slightly W-dipping, sub-horizontal foliation (outcrop CP_001, Variscan, Moldanubian crystalline; viewing direction: SW).

Fig.16: Sorted datasets displaying SW-directed, ductile extension (a), NE-directed, brittle extension (b), NW-striking, dextral strike-slip faulting (c), and calculated Pt-axes for dextral strike-slip faulting indicating subhorizontal NNW-directed shortening (d). (Outcrop CP_001, apparent strike of Hluboká Fault indicated by red lines).

3.1.2. CP_002

Outcrop CP_002 is located in a large claypit near Munice close to the presumed continuation of the Hluboká Fault to the NW. Grey, silty marls intercalated with red shale, 3 cm thick siltstone beds and 5-10 cm thick yellow-brownish middle sand layers are present, depicting the top section of the Upper Cretaceous Klikov Formation (**Fig. 17**; see also chapter 2). Abundant polished slickensides in shale show evidence for normal displacement mostly induced by gravitationally driven compaction. Nevertheless, two datasets indicating SW-NE directed extension by the presence of normal faults and NW-trending strike-slip faults could be recorded (**Fig.18**).

Fig. 17: Horizontally bedded clays, siltstones and middle sands of the Upper Klikov-Fm (outcrop CP_002).

Fig. 18: NE-SW dipping normal faults (a) and two datasets indicating strike slip faulting (b), paralleling the strike of the Hluboká Fault, could be separated from the complete dataset (c), (outcrop CP_002).

3.1.3. CP_003

Located in the centre of Hluboká nad Vltavou and build up by micaschists, CP_003 is dominated by NW-striking, dextral strike-slip faults, paralleling the direction of ductile structures like chlorite stretching lineations and fold axes. A dataset of two slickensides indicates top-to-NE-directed normal faulting under greenschist facies conditions by the presence of chlorite stretching lineation. Several NE-SW striking faults are oriented parallel to a map scale fault, which probably displaces the Hluboká Fault for about 500m in southwestern direction and forming a passage way for the Vltava river (**Fig. 19; Fig. 20**).

Fig. 19: Dextral strike-slip faults paralleling the strike of ductile stretching lineations (Istr, plotted as \diamond) (a), NE-striking, sub-vertical faults associated with the possible displacement of the Hluboká Fault in southwestern direction (b), Greenschist facies, NE-dipping normal faults with Chl-mineralization (c), (outcrop CP_003).

Fig. 20: Geological map displaying the location of CP_003 between the offset of the Hluboká Fault across the strike.

3.1.4. CP_004

CP_004 is located about 400 m SE of the Usilne seismic section (see chapter 4.1.) where the Hluboká Fault splits up into several splay faults, which are all associated with prominent morphological scarps. At the top of one of those scarps (Cherveny Vrch) the outcrop resides in the centre of a small, NW-trending tectonic window composed of amphibolites and aplites surrounded by Permocarboniferous deposits of the Lhotice Basin (see chapter 2.4.). Evidence for W-WSW directed extension is given by normal faults roughly trending N-S. Three fault planes striking NW-SE indicate oblique strike-slip shearing in this outcrop as well (**Fig. 21**).

Fig. 21: Datasets reflecting W-WSW-directed extension (a) and NW-striking, oblique strike slip faults (b), (outcrop CP_004).

3.1.5. CP_005

Situated at the southeastern end of the investigation area near Rudolfov in Variscan crystalline basement close to CP_012 (**Fig. 13**), CP_005 exposes amphibolites and an aplitic intrusive dyke. Both lithologies are delimited from each other by a ductile fault striking WNW-ESE (**Fig. 22/a**). Dextral offset of about 1 cm was observed at this shear zone. The outcrop also exposes two, apparently younger NE-SW-striking normal faults striking perpendicular to the dextral shear zone. Structures depict ductile faulting for these faults as well (**Fig. 22/b**). Furthermore, ductile stretching lineations in a shear band defined by elongated quartz and muscovite indicate greenschist facies metamorphic conditions associated with the late Variscan cooling phase of the Moldanubian units (**Fig. 22/b & Fig. 23**).

Fig. 22: Late variscan, ductile strike-slip faulting (a) and SW-directed normal faulting (b), (outcrop CP_005).

Fig.23: Aplitic intrusion with quartz (a) and shear band with ductile stretching lineations defined by quartz and muscovite (b), (outcrop CP_005, Variscan, Moldanubian crystalline).

3.1.6. CP_006

Located in Bt-Mu-Gneiss of the crystalline basement, three fault sets were discovered displaying brittle and ductile deformation in this outcrop. Ductile structures include muscovite stretching lineations suggesting NW-SE-directed extension (**Fig 24/a**). Idiomorphic quartz crystals grown into open tension gashes at a SW-dipping normal fault indicate late-Variscan SW-directed extension. Brittle deformation structures include SW-dipping normal faults (**Fig. 24/b**) and oblique dextral strike-slip faults striking NE-SW (**Fig. 24/c**). The former ones define a structure of two overstepping normal faults in some way resembling a breached relay ramp and marking the most striking feature in this outcrop (**Fig. 25**).

Fig. 24: Ductile normal faults related to NW-SE directed extension (a), SW-dipping, brittle normal faults (b) and oblique, dextral NE-directed strike-slip faults (c), (outcrop CP_006).

Fig. 25: Outcrop CP_006 (a) and sketch map of overstepping normal faults (b; **Fig. 24/b**). Lunate fractures give evidence for normal displacement (Variscan, Moldanubian crystalline).

3.1.7. CP_009

Located about 200 m further uphill to the NE of CP_006, this outcrop exposes a large SW-dipping brittle normal fault. The centre of the fault consists of a cataclasite-clay gouge band characterized by angular rock fragments in a light-grey shale matrix. Furthermore, the fault core hosts a mylonite composed mainly of quartz and associated with greenschist-facies metamorphic conditions (**Fig. 26**, see also chapter 3.2.)

Lineations and shear sense indicators were found in the cataclastic fault zone and in the mylonite, indicating two phases of fault activity. An older phase of ductile deformation is represented by the mylonite and gives evidence for normal faulting in northwestern direction. Information obtained from the cataclastic zone denotes subsequently brittle reactivation of ductile structures (shear bands) by normal faulting in southwestern direction (**Fig. 27/a**).

A feature worth mentioning beside the shear zone at this location is the presence of sub-vertical joints paralleling the strike of the Hluboká Fault. Unfortunately, their kinematics remained unresolved due to the absence of mineralizations and striations that would have been needed to assess their past tectonic activity.

Fig. 26: Shear zone at outcrop CP_009 in crystalline basement (a), cataclasite-clay gouge band (b) and mylonite (c), (outcrop CP_009, leucocratic Migmatite).

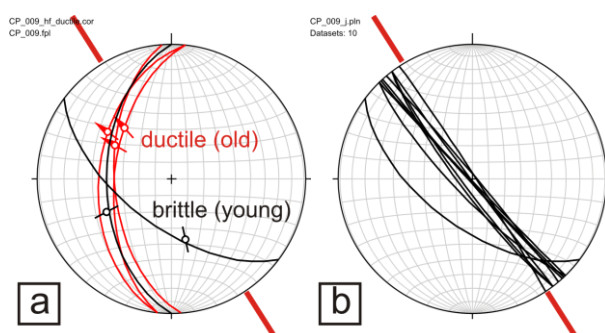

Fig.27: Ductile NW-directed and brittle SE-directed normal faulting (a). Sub-vertical joints striking NW-SE (b), (outcrop CP_009).

3.1.8. CP_010

CP_010 is located in a large sandpit in the forest northeast of Hrdejovice. Its sedimentary succession is dominated by poorly sorted, white-to white-grey, coarse grained sands and few conglomerate layers with components up to 4 cm in size. Components are exclusively angular to sub-rounded and well-rounded quartz grains are partly cemented by siderite and limonite. Sedimentary structures including large-scale cross-bedding indicate the formation under fluvial conditions, in this case depicting the lower part of the Upper Cretaceous Klikov-Formation (see chapter 2.).

Observed structural features include deformation bands and joints, both clearly discriminated from the surrounding white-grey sands by their dark red colors (**Fig. 28**). Joints are oriented at an angle of approximately 20° with respect to the strike of the

Hluboká Fault (**Fig. 29/a**). The geometry of the deformation bands is further compatible with the orientations of syn- and antithetic Riedel shears in a NW-striking, dextral shear zone. “Synthetic” deformation bands are paralleling the joints described above. Both sets are most likely associated with N-S directed compression (**Fig. 29/b**).

Fig. 28: Deformation bands in course grained conglomeratic sand (**a & b**) and sandstone block cemented by siderite/limonite (**c**), (outcrop CP_010, Lower Klikov Fm.).)

Fig. 29: Joints paralleling the strike of the Hluboká Fault (**a**). Conjugated set of deformation bands probably related to N-S directed compression (**b**), (outcrop CP_010).

3.1.9. CP_011

The only outcrop analysed from the Permocarboneous shale-siltstone is located in the southwestern section of the Lhotice Basin (see chapter 2.4.). It contains structural features including calcite filled tension gashes, abundant normal faults with fibrous calcite slickensides and dextral strike-slip faults (**Fig. 30**).

SW-NE and SSW-NNE-directed extension is indicated by the orientation of tension gashes and normal faults, respectively (**Fig. 31/a & b**). The WNW-striking dextral faults are sub-parallel to the Hluboká Fault in this area (**Fig. 31/c**).

Fig. 30: Fibrous slickensides on a normal fault (a) and calcite filled tension gashes in Permocarboneous siltstones (b), (outcrop CP_011).

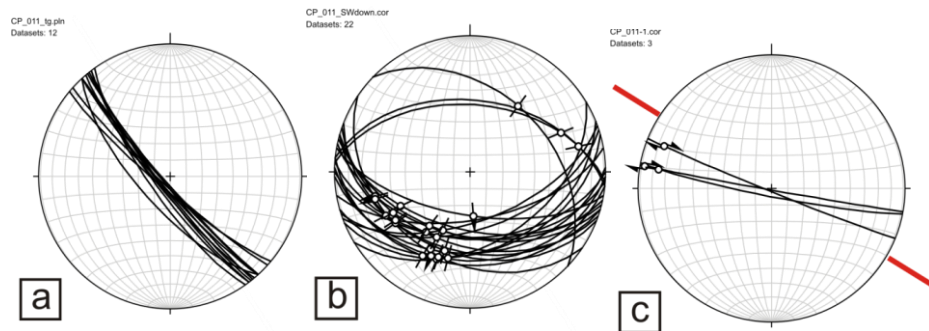

Fig. 31: Tension gashes (a), normal faults (b; also observed in outcrop Cp_012, Fig. 33/a) and dextral strike-slip faults (c), (outcrop CP_011).

3.1.10. CP_012

Located closely to the east of CP_005, the most striking feature in this outcrop is the presence of ductile and brittle-ductile faults. Mineralizations of quartz and chlorite along faults are significant for low metamorphic conditions ranging from greenschist facies to the brittle-ductile transition zone. Structural features in general include ductile strike-slip faults with dextral sense of shear striking NW- SE and E-W respectively, SE-dipping ductile faults with vertical striations and SW-dipping normal faults (also observed in CP_011, **Fig. 31/b**) partly overprinted by quartz slickenlines (**Fig. 32 & Fig 33**)

Two generations of quartz and chlorite stretching lineations further indicate an older stage of SW-directed extension subsequently followed by SSW-directed normal faulting.

Fig. 32: Older stretching lineation (greenschistfacies) overprinted by younger quartz-slickenline (a), synkinematic quartz and chlorite on the slickenside of a brittle-ductile fault (b), (outcrop CP_012, Variscan, Moldanubian crystalline)

Fig. 33: SW-and SE-dipping ductile normal faults (a & b) and ductile, dextral strike-slip faults related to NW-directed compression (c), (outcrop CP_012).

3.1.11. CP_013

CP_013 is located near Mydlovary at the northwestern end of the investigation area. The small pit exposes conglomerate composed of well-rounded quartz components (0.5-2 cm) in a sandy matrix. Throughout the whole study area, CP_013 marks the only spot along the Hluboká and Zbudov Fault where structural data could be obtained from sediments of the Lower Miocene Zliv-Formation.

Recorded structures include steep vertical, NW-striking fault planes hosting a 2 cm thick cataclasite coated in red shale. Riedel shears denote right-lateral displacement, indicating dextral strike-slip faulting for the adjacent Zbudov Fault as well (**Fig. 34**)

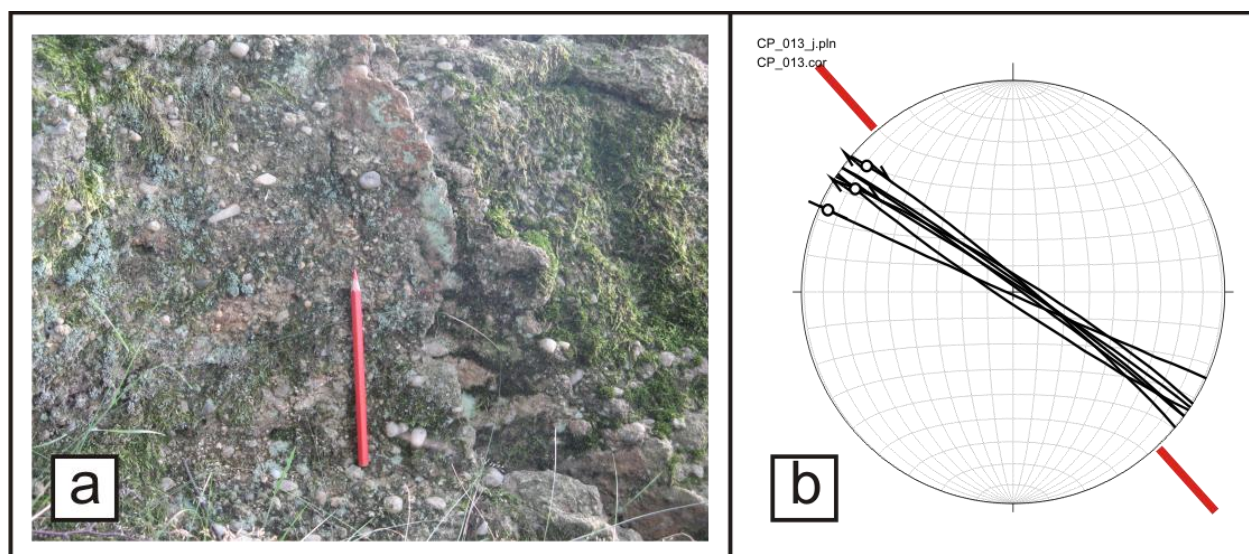

Fig. 34: Dextral strike-slip fault in Miocene conglomerate coated by reddish cataclasite (**a**). Dataset indicates strike-slip faulting in Miocene times as well (**b**), (outcrop CP_013; Zliv Fm., apparent strike of Zbudov Fault indicated by red lines).

3.2. Thin Section interpretation

Samples for thin sections were taken from 4 different outcrops (CP_001, CP_006, CP_007, CP_009), which are all situated in the Variscan crystalline basement southeast of Hluboká nad Vltavou near the village of Hosin. Orientated samples were cut in the XZ-plane of the mesoscopic structural framework, in which the XY-plane refers to the foliation or fault plane and X to the direction of the stretching lineation of the mylonites and slickensides, respectively. Micro-images of the thin sections were taken with a LEICA DM 4500 Microscope with a DCF 420 camera under bipolarized light.

Quartz, alkali feldspars and plagioclase are by far the most abundant mineral phases in all studied thin sections, followed by biotite, muscovite and chlorite in small amounts. Undulose extinction of quartz and partly of feldspar was observed in all thin sections. Dissolution of feldspar and subsequent formation of white mica as well as transition from muscovite to chlorite can be observed in nearly all samples.

However, except from thin sections taken from a mylonite in outcrop CP_009 (**Fig. 35**; see also chapter 3.1.7.), most samples were lacking good information concerning structural features and microtectonics.

Micro-images taken from this mylonite (outcrop CP_009, fault plane (276/45), lineation (306/40), normal fault) depict quartz as the predominant phase forming mylonitic trails bordered by partly broken feldspar grains (**Fig. 35/a**), providing a strong argument that high grade metamorphism above greenschist facies was not present. Although quartz grains in this shear zones depict shape preferred orientation, microscopic investigations under the wave plate revealed no alignment of quartz c-axes and accompanied crystal preferred orientation that would yield information about dextral or sinistral shearing. Nevertheless, top-to-NW shearing is indicated by slightly clockwise rotated feldspar clasts (**Fig. 35/b**).

Broken feldspar grains, which were observed throughout all thin sections from CP_009, strongly indicate a low temperature mylonite (300-450°C), (**Fig. 35/c & d**). Brittle behavior of feldspar, which was verified in all thin sections, as well as observations made in the field like synkinematic grown chlorite minerals along shear zones strongly

suggest the formation under greenschist facies metamorphic conditions including NW and NE-striking normal faults as well as dextral, NW-striking strike-slip fault within the Hluboká Fault Zone.

Comparing the Hluboká Fault Zone with the parallel striking Pfahl and Danube shear zones at the southwestern border of the Bohemian Massif suggests that all three fault systems experienced a similar evolution concerning their microstructural and tectonic characteristics (**Brandmayr et al., 1995, 1997; Wallbrecher et al., 1993**).

Fig.35: Oriented thin sections taken from mylonite in CP_009. **a)** Mylonitic zone with related muscovite migration along quartz-trails bordered by broken feldspar grains. **b)** Clockwise rotated feldspar-clast indicating top to NW normal faulting (see also **Fig. 27/a**). **c)** Brittle behavior of feldspar indicating a low temperature mylonite. **d)** Feldspar grains broken along high-grade quartz-veins.

3.3. Deformation history

The deformation history described below is based on the analysis of low-grade ductile and brittle deformation features, mostly faults and shear zones with shear sense indicators. The main problem therein is the age determination of brittle faulting events. In general it can be stated, that structures linked with a particular deformation phase are considered younger than the rocks deformed. Nevertheless, the investigation of the deformation history in the Bohemian Massif remains complicated due to the recurrence of similarly oriented paleostress fields throughout geologic history.

Taking into account all information obtained from structural field work including ductile and brittle deformation features as well as thin section analysis, four deformational phases have been reconstructed affecting all kinds of formations ranging from Variscan crystalline basement units to Lower Miocene deposits (**Fig. 40 & Fig. 41**).

Deformation D1: Variscan folding

Throughout the Variscan crystalline basement, ductile features including crenulation lineations, boudins, ductile stretching lineations, folds and foliations depict a paleostress field of NE-SW to NNE-SSW-directed shortening and NW-SE-directed stretching respectively, in this context referred to as D_1 .

Foliation planes of crystalline basement units generally striking NW-SE parallel a large-scale, sub-horizontal fold axis (Fa 155/03), strongly suggesting that the regional fault strike of the Hluboká Fault is predefined by Variscan structures (**Fig. 36/a**).

Mesoscopic, NNW-trending fold axes measured in the field as well as ductile stretching and crenulation lineations contribute to the assumption of a paleostress field related to NE-SW to NNE-SSW-directed shortening (**Fig. 36/b**).

Associated mineralizations of ductile structures are indicative for greenschist facies metamorphic conditions, suggesting that D_1 -deformation reflects the cooling stage of the Moldanubian crustal units during the late-phase of the Variscan orogeny.

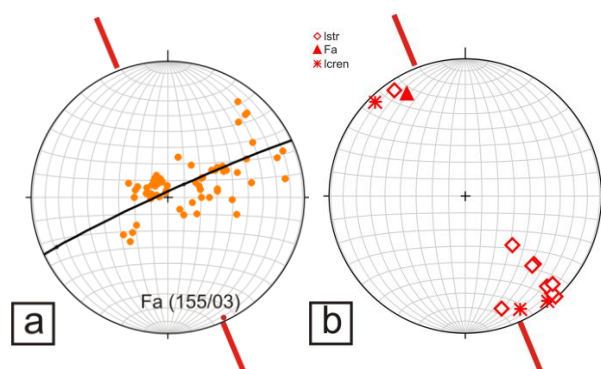

Fig. 36: Poles to Foliation pointing out NNW-SSE-trending Variscan fold axis (orientation of Fa: 155/03) paralleling the strike of the Hluboká Fault (a). Recorded crenulation lineations, ductile stretching lineations and fold axes (b). Summary plots from all outcrops in Variscan crystalline basement.

Deformation D2: Late-Variscan ductile normal-and strike-slip faulting

Structures linked to the second deformation stage include three kinds of ductile and brittle-ductile faults related to different kinematic regimes. D₂-features are characterized by NW-SE-striking normal faults (**D_{2A}**; **Fig. 37/a**), NE-SW-striking normal faults (**D_{2B}**; **Fig. 37/b**) and dextral strike-slip faults striking between NW-SE and E-W in Variscan crystalline basement (**D_{2C}**; **Fig. 37/c**), with the latter one probably linked to the first movement of the Hluboká Fault in Late-Variscan times

NW-and NE-striking ductile normal faults clearly postdate deformation phase D₁ by cutting older folds and foliations. In general, D₂ marks the transition from ductile to brittle deformation of the Variscan crystalline basement units. Brittle deformation of Permian sediments of the Lhotice Basin may have also occurred during D₂.

Fig. 37: Faults associated with deformation D_2 . D_{2A} : NW and SE-dipping normal faults (a). D_{2B} : NE-SW-dipping normal faults (b). D_{2C} : dextral strike-slip faults striking between NW-SE and E-W in the southeastern section of the investigation area (c, see also **Fig. 13**, CP_005 & CP_012). Stereoplots combine data from different outcrops in crystalline basement.

Deformation D3: Brittle normal faulting

Brittle normal faults in crystalline basement rocks, Permian and Cretaceous sediments as well as calcite filled tension gashes observed in Permian shale deposits are significant for D_3 . All structures are related to an extensional stress field with SW-NE-directed extension (**Fig. 38**). Ductile normal faults referring to D_2 are partly overprinted by D_3 -structures (e.g. CP_006, CP_009) leading to a relative age correlation of these deformation events. D_3 -deformation features were not observed in Lower Miocene deposits, suggesting that D_3 terminated during the Upper Cretaceous or Paleogene.

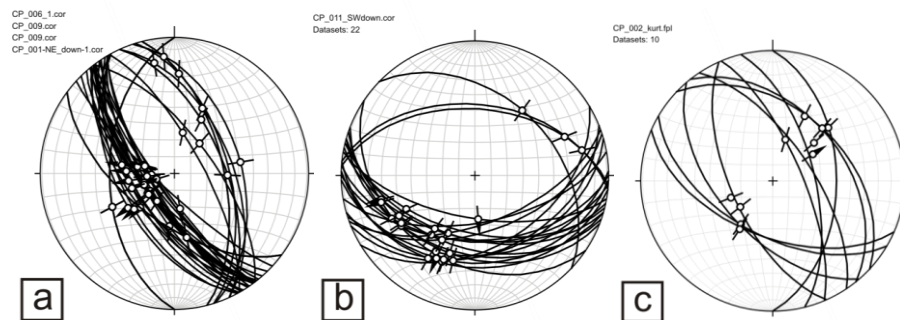

Fig. 38: Brittle normal faults in crystalline basement (a), Permian shale (b) and Upper Cretaceous sediments (c). Stereoplots combine data from different outcrops.

Deformation D4: Brittle strike-slip faulting

NW-striking, dextral strike-slip faults apparently related to the Hluboká represent the most abundant structures in the whole investigation area. Such faults have been observed in all units (Variscan basement; Permian, Cretaceous and Miocene sediments) suggesting a post-Miocene age for D₄ (**Fig. 39**). The overall characteristics of D₄-features in basement rocks are significant for brittle deformation. Unfortunately, cross-cutting relations as seen with D₁ and D₂ have not been observed with D₄, leaving the fact that D₃ features were not present in Lower Miocene deposits as the only criteria for D₄ post-dating D₃.

Fig. 39: Stereoplots depicting abundant dextral strike-slip faulting in crystalline basement (a), Permian shale (b), Upper Cretaceous (c) and Miocene sediments (d). Stereoplots combine data from different outcrops.

Fig. 40: Map view of investigation area. D₁ dataset combining foliation, crenulation, ductile stretching lineation and fold axes from different outcrops. D₂ and D₃ and D₄ datasets with related outcrops.

	Deformation Phase and Age	Related structures	Deformed Formations	Kinematics
Brittle	D4 Post-Miocene 	- Dextral strike-slip faults	- Variscan Basement - Permian shale - Upper Cretaceous (Klikov Fm.) - Miocene conglomerate (ZlivFm.)	
	D3 Post-Cretaceous 	- Tension gashes - SW & SSW dipping normal faults	- Variscan Basement - Permian shale - Upper Cretaceous (Klikov. Fm.)	
Ductile	D2 Late-Variscan D _{2A}  D _{2B}  D _{2C} 	D _{2A} - SE & NW dipping normal faults D _{2B} - SW & NE dipping normal faults D _{2C} - NW-SE to E-W-striking dextral strike-slip faults	- Variscan Basement	D _{2A}  D _{2B}  D _{2C} 
	D1 (Late)-Variscan 	- Foliation - Folds with NW-trending fold-axes - Boudins - Crenulation - Stretching lineation	- Variscan Basement

4. Interpretation of 2D Seismic Profiles

Five seismic profiles have been recorded by the company Pöyry Engineering from June to September 2009 in order to assess the slip history and spatial geometry of the Hluboká Fault and the adjacent Zbudov Fault in the basin lowlands. All seismic sections roughly trend in NE-SW to ENE-WSW direction, with three of them covering the Hluboká Fault near the villages of Úsilné, Hosín and Munice from SE to NW. The profiles are spaced at distances of approximately 4.3 km. Two seismic profiles near Dasny and Mydlovary intersect the Zbudov Fault at a distance of approximately 8.3 km (**Fig. 42**). Each of the recorded sections has a length of 1.2 km summing up to a total length of 6 km of available reflection seismic.

A vacuum enhanced hammer (Vakimpac) was used as seismic energy source yielding an excitation frequency of 100-120 MHz for the seismic impulse (resolution limit: < 10 ms TWT ~ 2.5 – 3 m). Seismic processing and the conversion of seismic profiles from time to depth units were done exclusively by Werner Chwatal of the Technical University of Vienna. Seismic check shots for the Budejovice Basin were not available and calibration of seismic reflectors through well control was not useful due to mostly shallow drillings. However, comparison of the depth of crystalline basement rocks in wells near Hosin with depth converted seismic, prove that depth conversion leads to reasonable results (for post-stack/pre-migration data see attachment part 3: Seismic data).

The top of the crystalline Basement and Permian rocks underlying the Cretaceous basin fill are depicted in all seismic sections. They are marked as a band of three parallel reflectors characterized by high reflectivity situated in depths from about 400m (section Usilne) to 100m (section Mydlovary) below surface. Vertical offset of these reflectors along the northeastern basin margin to depths of about 400m is depicted in all sections covering the Hluboká Fault Zone.

Cretaceous sediments are characterized by reflectors of low and medium amplitudes, gently dipping SW at the northeastern basin margin and flattening towards the center of the basin. Miocene sediments in all seismic sections are depicted as sub-horizontal reflectors of medium to high amplitudes showing onlaps onto crystalline basement as

seen in section Munice. In all sections covering the northeastern basin margin, interpreted faults coincide with the linear topographic scarp of the Hluboká Fault.

Fig.42: Location of 2D seismic profiles crossing the Hluboká Fault (Section P_US_Usilne, P_HO_Hosin, P_MU_Munice) and Zbudov Fault (P_DA_Dasny & P_MD_Mydlovary). Blue dots indicate drillings projected into seismic profiles.

4.1. Profile Usilne (P_US_Usilne)

Section P_US_Usilne depicts one master fault (1) and a couple of branch faults (2 & 3), partly accompanied by topographic expressions at the surface (**Fig. 43 & Table 2**). The master fault, representing the main branch of the Hluboká Fault, reaches the surface at geophone 184, offsetting the pre-Cretaceous basement to depths of about 400 m. At the surface the master fault coincides with a morphological scarp and forms the contact between Permian shale and siltstones of the Lhotice Basin in the northeast and Upper Cretaceous sediments of the Klikov Formation in the southwest. The presence of the master fault at this location was validated in the course of the first palaeoseismological trench at Usilne within the framework of CIP (**Špaček et al., 2011**).

In southwestern direction, three faults have been interpreted in this section branching off from the master fault and reaching the surface at geophone 197, 211 and 256, with the latter one coinciding with a second morphological scarp. Slight evidence for the presence of a fault at geophone 197 at the toe of the first morphological scarp also comes from field observations in outcrop CP_004 (Chervený Vrch) about 400 m further southeast, showing a NW-striking fault (see chapter 3.1.4.).

Interpreted faults are also indicated by three marked steps in the diving wave velocity profile, with the first one delimiting high velocity Permian rocks and medium velocity Upper Cretaceous sediments and the latter ones confining an area of lower velocity in between, probably depicting an offset block of Upper Cretaceous sediments.

The southwestern section of P_US_Usilne is characterized by subhorizontal, slightly concave reflectors of Upper Cretaceous sediments gently dipping into southwestern direction and reflectors of high amplitudes depicting the pre-Cretaceous basement. It is not clear if top basement reflectors in this part of the basin depict the Variscan crystalline or Permian rocks forming the basin floor.

Upper Cretaceous sediments show constant thickness of about 370 m in the southwestern section. Growth strata geometries have not been observed, suggesting post-Cretaceous offset along the master fault.

The overall listric master fault geometry as well as offsets of Upper Cretaceous sediments along the branch faults might be connected with a releasing horsetail splay bending to the right and merging with the Rudolfov Fault (**Fig. 42**).

Fig. 43: Seismic profile P_US_Usilne. From top to bottom: Topographic profile; interpreted, migrated seismic depth section; uninterpreted seismic section and diving wave velocity profile. Top of pre-Cretaceous basement marked as dashed, yellow line. Reference level for seismic processing was picked at 415 m above sealevel.

	Wellname	Report Nr.	Depth	Projected from	Crystalline	Permian shale	Upper Cretaceous
A	1/40	V046625/046665	25 m	80 m NW			4,4 m
B	US 1	V070452	345 m	1180 m NW	330 m		4,5 m
C	JBV69	P059532	42 m	42 m SE		1,9 m	
D	JB72	P059532	13 m	13 m SE		3 m	

Table 2: Wells from Czech Geological Survey (Geofond Prague) displayed in **Fig. 43**.

4.2. Profile Hosin (P_HO_Hosin)

Profile Hosin depicts two sub-vertical, slightly SW-dipping faults at the toe of the morphological scarp at geophone 216 **(2)** and the second one located about 200 m further uphill **(1)**, intercepting the crystalline basement reflectors at geophone 166 (**Fig. 44 & Table 3**). The steep dip of the main fault at geophone 216, which offsets the crystalline basement for about 300 m vertically, is constrained by the termination of basement reflectors northeast and southwest of the fault. Both faults are supported by the diving wave velocity profile, which shows two marked steps of the top of the high-velocity basement adjacent to the interpreted faults.

The image in the southwestern part of P_HO Hosin strongly resembles P_US_Usilne with horizontal reflectors of constant thickness, mostly associated with Upper Cretaceous sediments overlying the crystalline basement depicted as a prominent band of three parallel reflectors. An additional fault was assumed about 80 m southwest of the main fault slightly disrupting shallow reflectors of Upper Cretaceous sediments **(3)**.

In general, the geometry of the sub-vertical fault **(2)** indicates strike-slip faulting with a high component of normal displacement.

	Wellname	Report Nr.	Depth	Projected from	Crystalline	Upper Cretaceous	Miocene
A	V904	P020833	8,5 m	900 m NW		5,8 m	
B	OH6	P012368	5 m	447 m NW			4,2 m
C	HL1	P018881	331 m	505 m NW	315,8 m	14,8	

Table 3: Wells from Czech Geological Survey (Geofond Prague) displayed in **Fig. 44**.

Fig. 44: Seismic profile P_HO Hosin. From top to bottom: Topographic profile; interpreted, migrated seismic depth section; uninterpreted seismic section and diving wave velocity profile. Top of pre-Cretaceous basement marked as dashed, yellow line. Reference level for seismic processing was picked at 415 m above sealevel.

4.3. Profile Munice (P_MU_Munice)

Section P_MU_Munice displays some similarities with P_HO_Hosin by the presence of two sub-vertical, slightly SW-dipping faults at geophone 172 (1) and 226 (2), also indicated by the top basement geometry in the diving wave velocity profile (**Fig. 45 & Table 4**). The fault interpreted in the northeastern part of the section coincides with the toe of a morphological scarp. The master fault accommodating the main vertical offset of the crystalline basement of 280 m is, however, not expressed by surface topography. Slight changes in topography can also be seen at geophone 251, coinciding with a suspected fault in the seismic section (3).

The image in the SW part of the section strongly resembles to what has been observed in section Hosin and Usilne showing concave reflectors of Upper Cretaceous sediments rising towards the margin of the basin, resulting in a large, synformal fold geometry with Cretaceous strata of approximately constant thickness. The upper part of the section displays sub-horizontal reflectors with onlaps onto the crystalline basement, consequently interpreted as sediments of the Mydlovary Formation of middle Miocene age (Karpatian - Lower Badenian) and separated from the underlying sediments by an angular unconformity. Offset of Miocene reflectors overlying fault 2 are not evident, leading to the assumption that activity of this fault terminated between the Upper Cretaceous and Miocene.

Growth strata geometries have neither been observed in Cretaceous nor Miocene sediments adjacent to the faults. Moreover, considering the large-scale fold geometry of Upper Cretaceous reflectors it is most likely that the Budejovice Basin emerged due to post-Cretaceous tilting and the subsequent formation of an angular unconformity between the Cretaceous and the overlying Miocene sediments.

	Wellname	Report Nr.	Depth	Projected from	Crystalline	Upper Cretaceous	Miocene
A	W1	V068630	5,1 m	1230 m SE			2,4 m
B	4H-087c	P119936	168 m	1315 m NW	144,4 m	0,8 m	

Table 4: Wells from Czech Geological Survey (Geofond Prague) displayed in **Fig. 45**.

Fig. 45: Profile P_MU_Munice. From top to bottom: Topographic profile; interpreted, migrated seismic depth section; uninterpreted seismic section and diving wave velocity profile. Top of pre-Cretaceous basement marked as dashed, yellow line. Base Miocene marked as dashed, orange line. Reference level for seismic processing was picked at 400 m above sealevel.

4.4. Profile Dasny (P_DA_Dasny)

Sections P_DA_Dasny and P_MD_Mydlovary crossing the Zbudov Fault show a completely different picture than the previously described sections across the Hluboká Fault (**Fig 46 & Fig. 47**). Located in the basin lowlands, both sections depict two sub-vertical, nearly symmetrical faults.

P_DA_Dasny shows two steeply dipping planer faults, which converge to depth of about 330 m apparently merging into a principal displacement zone (PDZ) below the top of the pre-Cretaceous basement. The converging faults are clearly shown by the terminating and offset reflectors in the Upper Cretaceous and the offset basement reflectors. Fault 1 is also indicated by a marked step in the diving wave velocity profile. Larger offset of lower reflectors compared to smaller offset at shallow reflectors suggest the presence of a flower structure.

Intersecting with the upper layers at geophone 256 (1) and 305 (2), both faults are located close to the Zbudov scarp striking NE-SW (**Fig. 42**). Faults do not coincide with the mapped fault at the contact of Miocene and Upper Cretaceous sediments in the geological map at geophone 197 (**Fig. 13**).

The migrated seismic section displays a strong basement reflector slightly dipping from 200 m in the southwestern part to 250 m in the northeastern part showing vertical offsets of about 10 m at both faults. Concerning the overlying sediments, which are defined by sub-horizontal, slightly SW-dipping reflectors of medium amplitudes, it is hard to discern between Upper Cretaceous and Miocene strata, although at least the upper section seems to be composed of Miocene sediments of the Mydlovary Formation according to borehole information. Therefore, Miocene to post-Miocene fault activity would be indicated by the slight offset of shallow reflectors along the fault zone.

In the sedimentary successions on both sides of the Zbudov Fault, no growth strata geometries have been found (**Fig. 46 & Table 4**).

	Wellname	Report Nr.	Depth	Projected from	Crystalline	Upper Cretaceous	Miocene
A	SG29	P058157	31 m	586 m NW		27 m	0,5 m
B	4H-085c	P118880	195 m	830 m SE		47,5 m	2,5 m
C	HP-IX	P025997	199 m	830 m SE	195 m	14 m	1,8 m
D	4H-086b	P119935	60 m	830 m SE		48,7 m	2,4 m

Table 4: Wells from Czech Geological Survey (Geofond Prague) displayed in **Fig. 45**.

Fig. 46: Seismic Profile P_DA_Dasny. From top to bottom: Topographic profile; interpreted, migrated seismic depth section; uninterpreted seismic section and diving wave velocity profile. Top of pre-Cretaceous basement marked as dashed, yellow line. Reference level for seismic processing was picked at 385 m above sealevel.

4.5. Profile Mydlovary (P_MD_Mydlovary)

Section P_MD_Mydlovary depicts two sub-vertical faults associated with the Zbudov Fault, comparable with the flower structure observed in section P_DA_Dasny. Whereas the upper sections of these faults are depicted by slightly disrupted reflectors of the sedimentary succession at geophone 230 (1) and 276 (2), the lower parts terminate a short band of three prominent reflectors at a depth of about 300 m, probably displaying an offset block within the crystalline basement. Structural data recorded in CP_013 next to the seismic profile in the Zliv Formation indicate dextral strike-slip movement as well as post-Miocene deformation age for the Zbudov Fault (**Fig. 13**). As already seen in section P_DA_Dasny, faults do not coincide with position of the mapped fault in the geological map at geophone 196 (**Fig. 13**).

The top of the crystalline basement can be traced along a sub-horizontal band of three parallel reflectors at a depth of 100 m covered by sediments of the Zliv Formation of Lower Miocene age (Ottangian) in the northeastern and probably sediments of the Mydlovary Formation in the southwestern part of the section.

Fig 47: Seismic profile P_MD_Mydlovary. From top to bottom: Topographic profile; interpreted, migrated seismic depth section; uninterpreted seismic section and diving wave velocity profile. Top of pre-Cretaceous basement marked as dashed, yellow line. Reference level for seismic processing was picked at 385 m above sealevel. CP_013 projected from 180 m SE.

4.6. Summary seismic mapping

The absence of growth strata geometries in Upper Cretaceous and Miocene sediments adjacent to the Hluboká and Zbudov faults, which has been observed especially in section P_MU_Munice and P_DA_Dasny (see chapter **4.3.** & **4.4.**), indicates post-Cretaceous (Hluboká) and post - (Lower) Miocene (Zbudov) fault activity, respectively.

Reflectors of Upper Cretaceous sediments in P_US_Usilne, P_HO_Hosin and P_MU_Munice display concave-up, fold-like geometries most likely caused by post-Cretaceous tilting and the formation of an angular unconformity between the Cretaceous and the overlying Miocene sediments

Giving the fact that Hluboká and Zbudov Fault are characterized as dextral strike-slip faults paralleling each other at an average distance of about 3 km, it is most likely that both faults converge into a single principal displacement zone located within the crystalline basement. Moreover, fault geometries in section P_MU_Munice and P_HO_Hosin share geometrical similarities with a flower structure splitting up at higher depths.

Therefore, concerning the Haklovy Dvory Fault, paralleling the Zbudov Fault in southwestern direction at the mapped contact of Miocene and Upper Cretaceous sediments, dextral strike-slip faulting is suggested as well (**Fig.13** & **Fig 42**). Unfortunately, structural or seismic data regarding the Haklovy Dvory Fault was not available.

Although highly speculative, all three faults might as well join into a deep-seated, lateral displacement zone associated with the Jáchymov Fault Zone.

5. 3D-Modeling of the Budějovice Basin

In order to supplement information obtained from seismic mapping, drilling reports of the investigation area were collected from the archive of the Czech Geological Survey (Geofond Prague). The construction of a consistent 3D model of the Budějovice Basin by the integration of information from various sources (seismic mapping, geological map, drilling reports etc.) was guided by two main objectives:

- Modeling of the 3D basin geometry should constrain the thickness and distribution of Upper Cretaceous and Miocene strata in order to identify depocenters, disrupted horizons and faults. Especially the reconstruction of post-Cretaceous and post-Miocene slip history along the Hluboká and Zbudov Fault was of main interest.
- Work should supplement surface information from a terrain, which is rather poor in natural outcrops by integrating subcrop data from drilling reports, in order to gain a better spatial overview of the geological features characterizing the Budějovice Basin.

5.1. Methodology

For computer aided modeling of the geological 3D model two software packages have been used:

- Adoption of geological features was done in an **ESRI ArcGIS 9.3.** project. This included contouring the distribution of formations characterizing the sedimentary basin infill as well as the course of the major fault zones present in the investigation area (Hluboká, Zbudov, Haklovy Dvory and Rudolfov Fault).

- Preliminary and final modeling was done by the means of **Paradigm GOCAD 2009.2**. Modeling included features pre-processed in ArcGIS 9.3. in order to visualize geological objects like faults, folds, sedimentary layers etc. in their spatial relation.

In detail, information that has been used for modeling are as follows:

- Topography based on the digital elevation model compiled within the framework of AIP by Dana Homolova (10 m ground resolution).
- Vectorized map items including mapped faults, contours of Upper Cretaceous and Miocene strata as well as Quaternary terraces adopted from the Czech geological maps (1:25000; map sheets: 22-434 "Netolice"; 22-443 "Hluboká nad Vltavou"; 22-444 "Ševětín"; 32-212 "Nová Ves"; 32-221 "České Budějovice"; 32-222 "Lišov"; 32-223 "Kamenný Újezd" & 32-224 "Borovany").
- Digitalized information obtained from 994 drilling reports from the Czech Geological Survey (Gefond Prague) containing geological information like sedimentological descriptions and stratigraphic interpretations (well list included in attachment part 4: Drillings for database).
- Five depth-converted, interpreted seismic cross-sections (see chapter 4) pre-processed by the Technical University of Vienna.

Out of 994 drillings, which are mostly located in the eastern part of the basin near the Hluboká Fault (**Fig. 48/a**), 981 reached the base of Quaternary terrace sediments of the Vltavou and Malše river, 212 the top of Miocene strata, 472 top of Upper Cretaceous sediments and 137 the top of the crystalline basement. Modeling of the base of Quaternary terrace sediments was included in the preliminary 3D model but not further processed as inaccuracies proofed to be too large for modeling a layer as thin as the Quaternary terrace deposits with a maximum thickness of only 10 m. Therefore, only 679 drillings remained in the model database including information on Upper

Cretaceous, Miocene and Crystalline units. Point informations of layer boundaries were calculated from the coordinates/elevations of drillings at the surface and the formation tops recorded in the well reports. The points were exported to GOCAD as XYZ-point files fitting the regional coordinate system, manually sorting out drillings not located within the crystalline basin border as well as borehole data with unlikely values caused by insufficient or wrong geological description. Data from drillings were further integrated with marker layers from seismic sections generating a triangulated surface depicting the boundary layers of Upper Cretaceous, Miocene and Crystalline units. In another step, surface edges were stitched with mapped geological contacts between different formations (**Fig. 48/b & Fig. 49**). Finally, generated surfaces were smoothed manually by deleting or relocating outliers of nodes from the triangulated surface.

Fig. 48: **a)** Hillshade model derived from DEM of the Budějovice Basin showing drillings used for 3D-modeling as well as seismic sections depicted as green lines. **b)** Distribution of Upper Cretaceous (green), Miocene (orange) and Quaternary terrace sediments (yellow) characterizing the basins infill (adopted from geological map 1: 25 000). **c)** Wellpaths showing depth of Geofond drillings in the basin (Vertical exaggeration of 1:12 in **b** and **c**).

Fig. 49: Map views showing the distribution of drillings that have been used for modeling the subsurface horizons of crystalline, Upper Cretaceous and Miocene units. **a)** Crystalline outline of the Budějovice Basin (red), seismic sections (light blue) and drillings reaching the crystalline basement **b)** Upper Cretaceous sediments cropping out at the surface (yellow areas) and drillings reaching the top of cretaceous sediments. **c)** Miocene deposits at the surface (green areas) and drillings reaching the top of Miocene sediments.

5.2. Top Crystalline Basement

Fig. 50: Horizon Top Crystalline Basement depicting basin flanks of medium dip at SW and NW border and high-angle dips at SE and NE border (Vertical exaggeration: 1:5. Color bar denotes elevation in meters above sealevel).

The top of the crystalline basement clearly depicts the asymmetry of the Budějovice Basin (**Fig. 50**). The basin floor gently plunges towards the eastern border of the basin with a dip of approximately 5° . At the northeastern margin of the basin the Hluboká Fault steeply offsets crystalline basement units for up to about 380 m, indicating that the basins formation was mainly influenced by the activity of the Hluboka Fault.

The southeastern corner of the Budějovice Basin is highlighted by the termination of the Hluboká Fault at the southwestern end of the Lhotice Basin (see chapter 2.4. and 4.1.) splitting up into several splay faults, all of which depicted by minor morphological scarps partly bending to SW and merging with the NNE-striking Rudolfov Fault (see also chapter 3.1.4.). The depocenter of the Budějovice Basin is located in the southeastern

part of the basin (ca. 390 m below surface) adjacent to the intersection of the NNE-striking Blanice-Kaplice-Rodl-Fault zone and the Hluboká Fault zone.

5.3. Top Upper Cretaceous

Fig.51: Horizon Top of Upper Cretaceous sediments (Vertical exaggeration: 1:5. Color bar denotes elevation in meters above sealevel).

According to the regional geological maps (1:25 000), Upper Cretaceous sediments of the Klikov Formation crop out at the eastern and southern corner of the basin, but also cover large areas close to the southwestern and northeastern basin margin (**Fig. 51**). The constructed sub-surface horizon - mostly corresponding to the base of Miocene sediments - covers the area around the Vltavou and Malše river (**Fig.13**). The main depression of the horizon Top Upper Cretaceous is located between the Zbudov and Haklovy Dvory Fault at about 320 m a.s.l. The depression is filled with Miocene sediments reaching up to the surface. Another, much smaller depression is located near

seismic profile P_MU_Munice (see chapter 4.3.) to the NW of Hluboka nad Vltavou, probably related to a previous Tertiary fluvial channel, also called the “northern river channel”) passing from E to W to the north of the Hluboká hill (Špaček at al., 2011; Fig. 52).

Fig. 52: Tertiary “northern channel” connecting the Budějovice Basin in the west with the ox bow of the Vltavou north of Hluboka nad Vltavou in the east.

5.4. Top Miocene

Fig.53: Horizon Top of Miocene sediments (Vertical exaggeration: 1:5. Color bar denotes elevation in meters above sealevel).

Miocene sediments crop out at the surface mostly in a 3 km broad zone between the Zbudov Fault in the NE and the Haklový Dvory Fault in the SW (**Fig. 53**). Well data and information obtained from seismic sections P_MD_Mydlovary and P_DA_Dasny further indicate that Miocene sediments - mostly belonging to the Mydlovary Formation - completely fill up the northwestern part of this area down to the crystalline basin floor, also known as Pištin Ditch. In general, Miocene sediments are restricted to the central areas of the Budejovice Basin with the deepest part located in the northeastern section around Hluboka nad Vltavou.

The average thickness of Neogene strata is about 20 to 30 m. Neogene and Quarternary deposits therefore contribute only minor volumes to the basin fill.

5.5. Summary 3D-Modeling

The sedimentary infill of the Budějovice Basin mostly consists of Upper Cretaceous sediments of the Klikov-Formation increasing in thickness from west to east, predominantly overlain by Lower to Middle Miocene sediments of the Mydlovary Formation in the Pištin Ditch and, with lower thickness, in the Vltava and Malše flood plain area. The asymmetric basin shape geometry shown by the horizon Top Crystalline Basement in some ways resembles a terrestrial half-graben with comparable sediment forming conditions, which are divided into a high energy sedimentary facies (alluvial fans at the eastern margin) and a low energy sedimentary facies with lacustrine and fluvial sediments in the center of the Budějovice Basin. Another typical feature for such kind of setting is the presence of lakes and/or draining rivers in the area of the basin associated with the largest subsidence rate. In case of the Budějovice Basin this scheme is given by the course of the river Vltava and its tributary, the river Malše, entering the basin from the south and running close to the eastern part to the north, abandoning the basin east of Hluboká nad Vltavou.

With respect to the rhombic crystalline outline geometry, the Budějovice Basin most likely developed as a fault bounded basin along the right-lateral, NW-striking Jáchymov Fault Zone (**Fig. 54**). In this context, the Pištin Ditch could have been developed as a smaller, interior sub-pull-apart basin which opened later on during the Lower Miocene, filled with sediments of the Mydlovary Formation. This assumption would also imply that the Zbudov and Haklový Dvory Fault would have to be regarded younger than the Hluboká and Dubné Fault, delimiting the basin to NE and SW. A comparison of the seismic profiles P_MU_Munice and P_DA_Dasny (see chapter 4.3. & 4.4.) shows that the Hluboká Fault terminates below Miocene deposits near Munice, whereas the Zbudov Fault clearly disrupts Miocene sediments at the surface. Unfortunately, fault characteristics for the Haklový Dvory and Dubné Fault could not be acquired. Concerning the Rudolfov Fault at the southeastern margin of the basin normal faulting is strongly assumed from the image given in seismic section P_US_Usilne (see chapter 4.1.) and from the apparent dip of the crystalline basement between 50° to 60° shown in the 3D basin model.

Fig. 54: Fault map of the Budějovice basin with the main sedimentary formation indicated in blue (Upper Cretaceous Klikov Fm.) and brown (Lower to Middle Miocene deposits).

6. Conclusion

In the course of this master thesis the following conclusion have been made:

The Hluboká Fault developed parallel to pre-existing Variscan ductile foliation and folds, which are characterized as deformation **D₁**. The first movement of the Hluboká Fault took place in late-Variscan times under low to very low greenschist facies metamorphic conditions (**D_{2c}**). Late-Variscan tectonics at low metamorphic conditions further include two extensional deformations with distinct stretching directions (**D_{2A}** - NW-SE-directed extension; **D_{2B}** - NE-SW-directed extension). No consistent age relations could be established between these deformations and ductile strike-slip faulting.

Ductile deformation structures are overprinted and reactivated by the following brittle structures:

- Brittle, NW-striking normal faults provide evidence for dominantly SW-directed extension (**D₃**). The ages of deformed sediments from field and seismic investigation suggest post-Cretaceous to pre-Miocene age for **D₃**.
- Sub-vertical, dextral strike-slip faults striking parallel to the Hluboká fault (**D₄**). Faults correlated to this deformation occur in crystalline basement units, Permian deposits as well as in the Upper Cretaceous and Miocene basin fill suggesting post-Miocene age for **D₄**.

Structures generally proof polyphase brittle deformation between the late Variscan orogeny and post-Miocene times. Structural data characterize both, the Hluboká and Zbudov Fault as dextral strike-slip faults.

Seismic data depict the Hluboká Fault as a sub-vertical, steeply SW-dipping strike-slip fault with a large component of normal displacement, offsetting crystalline basement units for up to 380 m. The fault offsets Cretaceous strata, which are folded into a large-scale asymmetrical syncline adjacent to the fault (P_HO_Hosin and P_US_Usilne). Seismic data provide no evidence for Cretaceous growth strata. The sections further exhibit a marked angular unconformity between the folded Cretaceous sediments and the overlying horizontal Miocene strata. Section P_MU_Munice shows that the main fault

branch of the Hluboká Fault terminates at the Cretaceous-Miocene unconformity, not offsetting overlying Miocene sediments.

Sections across the parallel Zbudov Fault (P_DA_Dasny, P_MD_Mydlovary) display flower structures with two symmetrical fault branches cutting the Miocene sedimentary fill of the Budějovice Basin. These faults apparently converge into a single displacement zone within the crystalline basement. The migrated seismic depth sections prove that the Zbudov Fault is younger than Miocene. Evidence for the displacement of Miocene sediments at the Hluboká Fault has not been observed. The analyzed geological data indicates that the main subsidence in the eastern part of the Budějovice Basin occurred due to post-Cretaceous tilting.

3D-Modeling of lithological and lithostratigraphical boundaries resulted in the construction of three surfaces (Top Crystalline Basement, Top Upper Cretaceous, Top Miocene), which are correlated across the entire Budějovice Basin. The horizon Top Crystalline Basement delineates an asymmetrical basin with a smooth basin floor gently dipping with about 5° towards NE and E. The NE basin margin is formed by the sub-vertical Hluboká Fault, the SE basin margin coincides with the Rudolfov Fault. Modeling indicates that the latter dips with about 50° towards the basin. Comparison of the horizons Top Upper Cretaceous and Top Miocene indicates that most of the basin fill is made up by Cretaceous strata. Miocene sediments reach their maximum thickness of about 80 m in the NNE-trending Pistin Ditch, which is delimited by the Zbudov and Haklový Dvory Fault to the NE and SW, respectively.

Considering the spatial fault geometries of the Hluboká and Zbudov strike-slip faults, which parallel each other at distance of about 3 km, it appears likely that both faults join into a single deep-seated, right-lateral displacement zone associated with the Jáchymov Fault Zone.

Persönliche Daten

Geburtsdatum: 18.08.1984
Geburtsort: Wien
Familienstand: ledig
Staatsbürgerschaft: Österreich

Schul- und Hochschulbildung

1991-2003	Rudolf-Steiner Schule Wien Mauer
2003-2004	BORG Anton-Krieger Gasse Liesing Matura mit ausgezeichnetem Erfolg
2004-2005	Ableistung des Wehrdienstes von 8 Monaten beim Bundesheer (Garde)
2005-2009	Studium der Erdwissenschaften in Wien, Abschluß mit Bakk. rer. Nat. Bakkalaureatsarbeit: „Sandstein- und Konglomeratpetrographie der Nierental-Formation im Profil Groisbach (NÖ)“
2009-2011	Masterstudium Erdwissenschaften Masterarbeit: „Tectonic Evolution of the Budejovice Basin (Czech Republic), with special focus on the Hluboka-Fault“

Weitere Ausbildungen und Kenntnisse:

Führerschein B

Ausbildung zum Sprengbefugten gem. § 6 der Verordnung BGBl Nr. 441/1975

Vertiefende PC-Kenntnisse: MS-Office, ESRI ArcGIS, Corel Draw, GoCAD, Tectonics FP

Grundkenntnisse: Petrel,

Berufserfahrung:

2007	Bengt Karlsson
2008-2009	Ferialjob Jugend am Werk
2009-2011	EGU General Assembly – Student Assistant
1.8. 2010-2011	Anstellung als Projektmitarbeiter beim Projekt „AIP [Austrian Interfacing Project]: Paleoseismology of Temelin’s Near-Regional Faults“ im Zuge der Masterarbeit

Tutorentätigkeit:

SS 2010	Tutor im Rahmen der Lehrveranstaltung „Strukturgeologie und Tektonik“
SS 2011	Tutor im Rahmen der Lehrveranstaltung „Kartierung im Gelände“

Konferenzbeiträge:

2011	EGU General Assembly 2011 Clemens Porpaczy, Dana Homolova & Kurt Decker: A 3D basin model of the Budějovice Basin (southern Bohemia) with a special focus on the Hluboká-Fault Zone (Poster)
2011	CETEG 2011 – 9 th Meeting of the Central European Tectonic Groups Clemens Porpaczy, Dana Homolova & Kurt Decker: Slip-History of the Hluboká Fault derived from structural data and 3D modelling of the Budejovice Basin (Vortrag)
