1 Introduction

1.1 M-Type Stars

When searching for habitable planets outside the Solar System, stars below two solar masses are the best candidates, as their lifetimes are long enough for the evolution of life. About 95% of stars between 0.1 and 2 M_{\odot} are M-type stars (*Scalo et al.* 2007, and references therein). Although M star masses are so small, they make up about half of the total mass of all stars in the Milky Way (*Reid & Hawley*, 2005).

M-type stars are very small and faint, ranging in mass from about 0.075 to 0.6 solar masses. In the Hertzsprung-Russell diagram they lie between K-type stars and brown dwarfs. A consequence of their very low masses are relatively low temperatures, which are between about 2300 K and 3800 K (e.g. *Reid & Hawley*, 2005). Furthermore, stars of spectral type M are divided into three subgroups: early-type (M0-M3), mid-type (M3.5-M6) and late-type (M6.5-9.5).

Looking at an M star's spectrum, the titanium oxide (TiO) absorption bands are the defining features. For a long time it was believed that M dwarfs are the lowest extremities of the hydrogen-burning main sequence. But photometric surveys have become more sensitive and led to the discovery of even fainter and cooler stars, which have spectral characteristics that do not fit spectral class M. Hence, a new spectral class was defined, class L. This class is separated from M dwarfs through decreasing strength of TiO. Early-type L stars seem to be a mixture of brown dwarfs and hydrogen-burning stars, despite their very low masses. In addition, spectral class T was established. Objects of this spectral class are brown dwarfs with substellar masses. Their temperatures are too low to initiate hydrogen burning.

A distinctive feature of M-type stars is not only their large number but also that this spectral class of stars is the only one below 2 M_{\odot} (AFGKM) that has two different modes of energy transport depending on their mass. From M0-M3.5 they behave similar to the Sun, having a radiative zone surrounded by a convective envelope.

Between these zones there exists what *Barnes* (2003) calls the *interface*, a region comparable to the Sun's tachocline¹. The convective zone increases with decreasing stellar mass until stars below $\approx 0.35 M_{\odot}$ become fully convective (e.g. *West & Basri*, 2009). This means that all M dwarfs later than M3.5 are fully convective, which seems to change their behavior in several ways. This point will be discussed in more detail in section 1.3.2.

As their emission maximum lies in the infrared, M-type stars are also called red dwarfs. In this work the expression “M dwarf” respectively “red dwarf” stands for all stars with absolute visual magnitudes fainter than $M_V > 8$.

Figure 1.1. The relationship between spectral subtype and visual absolute magnitude of all M stars studied in this work.

Figure 1.1 shows the visual absolute magnitudes of the M stars sample studied in this work as a function of spectral subtype. It can be clearly seen, that the later the subtype, the fainter is the star's visual absolute magnitude.

¹ The tachocline is a thin transition region between the Sun's radiative and convective zone. Since the radiative zone exhibits a solid-body rotation and the convective zone rotates differentially, this leads to shear effects that are believed to induce the activity cycle of the Sun.

1.2 Space Weather

The term *space weather* stands for all effects caused by the Sun's activity, that may have an influence on space-born or ground-based technological systems, as well as on organisms. It is also believed that the solar variability, among other effects, might influence changes of the Earth's climate. By observing the Sun, it is attempted to find periodicities in photospheric, chromospheric and coronal events and thus make such events predictable. A further goal is to understand the evolution of the Sun from its birth until the current era.

The Sun continuously emits a stream of charged particles, known as the solar wind. These charged particles form a bubble around the Solar System, the heliosphere. It protects the Solar System from energetic cosmic rays coming through the local interstellar medium. Due to the activity of the Sun, the solar wind is variable and hence also the size of the heliosphere. As the solar wind is modulated by the Sun's activity, its strength follows the well-known eleven year solar cycle.

In addition to the solar wind, there are many other solar activity phenomena, e.g. prominences, faculae, coronal holes, etc., but for this work the most interesting effects of space weather are sunspots, flares and coronal mass ejections (CME) as they can also be observed on other stars. The mentioned phenomena occur in the stellar atmosphere, which is composed of the photosphere, the chromosphere and the corona.

Sunspots are dark areas on the Sun's photosphere (Fig. 1.2). When referring to other stars than the Sun they are called starspots. They often arise in groups. Concerning the Sun, they only appear at lower latitudes on both sides of the equator but never close to the poles (*Hanslmeier, 2007*). This is different for stars of spectral class M (*Mullan, 1974*). Starspots are darker than the rest of the star's surface due to their lower temperature. The darkest region is in their centers, the umbra. The penumbra surrounds this region and is less dark. These two regions are embedded a little deeper into the surface of the surrounding plasma. This phenomenon is called the *Wilson depression* (*Hanslmeier, 2007*).

Through the observation of starspots one can determine a star's rotation period, a parameter that is of highest interest concerning the star's age and activity (see section 1.4).

Fig.1.2. Sunspot seen from SOHO satellite in September 2000 with the relative size of the Earth for comparison. Taken from <http://sohowww.nascom.nasa.gov/gallery/images/sunspot00.html> (January 19th, 2012).

As starspots are cooler than the rest of the stellar surface and temporary phenomena, their existence changes the radiation emitted by the star in different periods of time, which means that planets orbiting the star are exposed to varying radiation intensities.

The origin of starspots is the rise of a magnetic flux tube due to magnetic buoyancy. When the flux tube emerges at the photosphere, a spot becomes visible. Hence this stellar activity phenomenon is related to a star's magnetic activity (*Hanslmeier, 2007*). The number of starspots changes with a period of time, whereupon the Sun is the only star with an identified periodicity, namely eleven years. To study starspots on the photosphere, the Ca II K spectral line can be used as an indicator.

Above the photosphere lies the chromosphere, which has a much higher temperature. This layer is the source of flares, which are eruptions that release large amounts of energy within minutes and thus suddenly brighten a star's surface (Fig. 1.3). During a stellar flare radiation of all wavelengths, from radio waves to gamma rays, is produced, but especially short-wavelength radiation such as UV and X-ray. This strong short-wavelength radiation ionizes molecules in a planet's atmosphere, which can further be eroded by stellar winds if the planetary field is weak, meaning that the planet could lose its atmosphere and would be no longer protected from ionizing short-wavelengths which can be harmful for life.

Figure 1.3. Solar flare seen by the SOHO satellite. Taken from <http://spacefellowship.com/news/art23691/scientists-unlock-the-secrets-of-exploding-plasma-clouds-on-the-sun.html> (January, 19th, 2012)

Flares appear in regions of higher activity around starspots. To determine the activity of a star's chromosphere, the emission lines H (396.8 nm) and K (393.4 nm) of singly ionized Ca (Ca II) can be used. These lines appear stronger in a star's spectrum when the activity is at maximum (*Hanslmeier*, 2007). Another suitable spectral line to observe the chromosphere is the spectral line H α (656.3 nm), which will be explained in more detail in section 1.3.2.

The outermost layer of a stellar atmosphere is the corona, which can extend to several solar radii. Its shape changes depending on the solar activity cycle, being more spherical at an activity maximum (*Hanslmeier, 2007*). In this layer the so-called coronal mass ejections (CME) can be observed (Fig. 1.4). A coronal mass ejection is another highly energetic phenomenon, where enormous amounts of stellar material are ejected into a planetary system. Until the 1970's they were unknown because of their poor visibility. The invention of the coronagraph made it possible to cover the solar disk and thus making coronal phenomena observable. At the moment it is not known whether CMEs are connected to flares or not, as CMEs partly appear after a foregone flare, but also separately.

Figure 1.4. Coronal mass ejection seen by SOHO satellite blocking out the light of the solar disk to make the corona visible. Relative size of the Sun shown. Taken from <http://sohowww.nascom.nasa.gov/gallery/images/c2eitnov800.html> (January, 19th 2012)

1.3 M-Type Stars and their Space Weather

Actually the term *space weather* was created to describe effects caused by the Sun's variability, having an influence on planets in the Solar System's habitable zone². But today, where Earth-like planets are intensively searched and wide-ranging discussions about their habitability are held, space weather becomes also very important for all other stars than the Sun, which are orbited by extrasolar planets. In this work the space weather of M-type stars is examined carefully, which consequently means that their activity depending on their mass, age and spectral subtype was studied.

1.3.1 Internal Structure of M Dwarfs

To understand the different activity phenomena of M-type stars, one has to examine their internal structure. Early-type M stars up to about spectral subtype M3 or stellar masses between 0.35-0.6 M_{\odot} have a quite similar structure when compared to the Sun (Fig. 1.5). In the center there is a core, which is surrounded by a radiative zone and generates the energy output. Above this layer is the convective envelope, separated from the radiative interior by a transition region, the interface (*Barnes, 2003*). In the convective zone a MHD-dynamo produces a magnetic field, which provokes the heating of the stellar atmosphere that lies above the convective zone and causes various activity phenomena (*Hartmann & Noyes, 1987*, and references therein).

Similar to the Sun, the stellar atmosphere is composed of the photosphere, the chromosphere and the outermost layer, the corona. Between the chromosphere and the corona exists a transition region.

It is believed that all red dwarfs later than M3-M3.5 are fully convective, which means that all energy produced in the core is transported to the outermost layer of the star by convection. Early-types (M0-M3) may have a small radiative core.

² The so-called habitable zone is a circumstellar region around a star, where liquid water can be maintained on a planet's surface (*Kasting et al., 1993*).

Full convection means further, that helium, which is produced by nuclear fusion of hydrogen, does not accumulate at the core, as it is presumed to happen in Sun-like stars. This leads to a much slower evolution of the star and constant luminosities for hundreds of billions of years. In comparison to the expected long lifetime of M stars, the age of the universe is small. So even when observing an M star older than twelve billion years, it means that the star is investigated somewhere during its initial period on the main sequence.

The point of full convection varies slightly depending on the author. For example, *Barnes (2007)* states that stars become fully convective below $0.3 M_{\odot}$, *West & Basri (2009)* below $0.35 M_{\odot}$. In addition, there exist other theories, that place this boundary for young stars with strong magnetic fields and fast rotation around spectral subtype M6-M7 as it is presumed that this behavior can block the transition to full convection (*Chabrier et al., 2007*). Above this zone the stellar atmosphere is composed in the same manner as in early-type M stars.

1.3.2 Activity of M Dwarfs

Ejnar Hertzsprung was the first, who published an article about M dwarf variability in 1924, where he reported about changes in the brightness of these stars. It took decades to determine that these changes were caused by activity phenomena. Until 1970 about 50 stars showing the same behavior were known and endowed with the term *flare star*. *Gurzadyan* (1970) noticed that almost all of these stars belonged to spectral class M, more precisely mid and late M-type stars.

Stellar activity is always connected with the presence of a magnetic field. *Parker* (1955) was the first, who postulated a theory about magnetic field generation in the convective zone of the Sun. His theory of the dynamo mechanism is now known as the $\alpha\Omega$ dynamo. α and Ω are two processes in the generation of magnetic fields.

Reid & Hawley (2005) summarize these processes as follows:

An initial poloidal field generates a toroidal field through shearing forces at the interface. This process is known as the Ω effect. The toroidal field generates through its cyclonic motions a new poloidal field, known as the α effect. Both effects Ω and α are caused by stellar rotation. The twisted magnetic flux lines of the toroidal field occur due to the turbulences in the convective zone. Such magnetic flux lines gathered together build flux tubes, which rise to the surface by magnetic buoyancy and emerge as loop-like structures. The areas, where this happens, are active regions on a stellar surface and can be observed as starspots. M dwarfs' photospheres can be covered with long-lived starspots over a significant fraction of their surface (*Tarter et al.*, 2007, and references therein). In this region the strength of toroidal magnetic fields seems to be amplified and organized causing starspots on the photosphere (*Browning et al.*, 2010). The current belief is that all M stars with masses higher than $0.3 M_{\odot}$ generate such a magnetic dynamo at the interface (*Parker*, 1993; *Browning et al.*, 2010, and references therein) as they have a similar internal structure as the Sun (see section 1.3.1).

There are indications that the magnetic field generation differs below the fully convective mass limit as the magnetic dynamo cannot work (*Browning et al.*, 2010). Another mechanism must exist that explains the existence of a magnetic field.

These authors add that there is evidence of a change in the atmospheric heating mechanism as well.

Bercik et al. (2005) show that the magnetic field of fully convective stars can be generated by turbulent dynamos. This topic is not properly understood at the moment. *Tarter et al.* (2007) claim that there is no obvious transition in the activity behavior of M dwarfs around M3-M4, which is right at the mass where the radiative zone disappears. Several other authors support this presumption that the level of activity is not influenced at the transition from partly to fully convective stars (e.g. *Kiraga & Stéprien*, 2007, *Delfosse et al.*, 1998). *West et al.* (2008), however, observed a transition when the stars become fully convective at M3-M4. Firstly, they show that the activity lifetimes are dependent on the spectral subtype and therefore stellar mass. Secondly, he illustrates a dramatic increase in the lifetimes of atmospheric activity below the mass limit of the fully convective model. A similar effect was also noticed in the studied M stars' sample in this work (see section 3.4-3.6).

Several activity properties of M dwarfs are well-studied. M stars at young ages can generate very strong magnetic fields, some of them much stronger than the solar magnetic field (up to several kG), covering almost the entire star (*Tarter et al.*, 2007). The stronger a magnetic field, the more intense are space weather phenomena like flares. M stars are known to have extremely strong flaring events, which can brighten the star's surface several times within minutes, emitting X-ray and strong UV radiation. It is still unclear how long the violent flaring period of M dwarfs lasts. The current belief is that younger stars are more likely to flare. *Selsis et al.* (2007) have shown that the duration of intense ionizing radiation, a sign of high activity, increases with decreasing stellar mass.

Rotation and magnetic activity seem to be connected. High stellar activity seems to be linked with rapid rotation (*Kiraga & Stéprien*, 2007). *Reiners & Basri* (2009) state that coronal and chromospheric activity saturate at high rotation rates. Furthermore, this relation shows a mass dependency. From early- to mid-type M dwarfs chromospheric and coronal emission is correlated with rotation (*Browning et al.*, 2010).

In addition, *Mohanty & Basri* (2003) demonstrated that at mid- and late-type M dwarfs (M5-M9) there appears to be a threshold value where the chromospheric emission is more or less independent from the rotation period. But not all M dwarfs show chromospheric emission, only the more active fraction, which has its maximum around M7 (*West et al.*, 2004). It is still unclear in which way the rotation rate is connected to the strength of dynamo-generated magnetic fields.

In 1972, *Skumanich* claimed that stars rotate rapidly at very low ages and slow down with time through the loss of angular momentum, caused by stellar winds. This process is called rotational braking. The duration depends on the strength and geometry of the stellar magnetic field and thus is linked to the rotation period of the star (*Matt & Pudritz*, 2008). Observations let one presume that the spin down time is strongly connected with stellar mass (*Barnes*, 2003). *Mohanty & Basri* (2003) discussed this topic for M dwarfs and come to the conclusion that for lower mass late-type stars the time needed to spin down is longer than for early-type M stars.

Indicators for stellar activity are the spectral lines in X-ray, EUV, the H α line, the H and K lines of Ca II and Mg II (*Hanslmeier*, 2007). The ratio between the luminosity in the H α line and the bolometric luminosity, $L_{H\alpha}/L_{bol}$, is a good indicator of chromospheric activity (e.g. *Reid & Hawley*, 2005). *Browning et al.* (2010) add some concerns in using H α as an activity proxy as they claim that no observable H α emission can stand for two different activity levels, namely no activity or a moderate amount of activity, as H α first appears in absorption and then with increasing activity appears in emission. A solution for this problem could be the chromospheric Ca II K and H lines' emission but, as they lie blueward of the most CCD sensitivities, this becomes especially difficult for already faint M-type stars. The corona is formed of high-temperature gas surrounding the star's chromosphere. To determine the coronal activity level, one has to calculate the ratio between the luminosity emitted at X-ray wavelengths and the bolometric luminosity, L_X/L_{bol} (e.g. *Reid & Hawley*, 2005).

Stellar activity leads to variability of the emitted radiation. This variability has long, but also short timescales. Several programs concentrate on long-term changes in chromospheric activity.

On the long-term side, it is presumed that luminosity changes can be caused through stellar mass loss by stellar winds and coronal mass ejections. The short-term variability is mainly caused by starspots and flares.

Today it is well-known that stars other than the Sun also have activity cycles, but not as precisely determined as that of the Sun (*Soon et al.*, 1993).

1.4 Age Determination for Red Dwarfs

Age is one of the most fundamental parameters of a star. Stellar ages are necessary to gain further knowledge about the star's evolution over time and consequently its activity, but it is especially interesting, for investigating the evolution of a planetary system. The more precise a host star's age can be determined, the more can be concluded about the planets orbiting the star. But estimating the ages of M-type stars is still connected with several challenges and problems. Because of their small masses and consequently slow evolution an extremely long lifetime of up to 200 Gyr or even more can be expected. Most of this time they spend on the main sequence burning hydrogen to helium. As a consequence of their very small masses this process lasts much longer than for stars like the Sun and leads to the presumption of their long lifespan. Nevertheless, it has been attempted to find methods to estimate the ages of M-type stars. There are several methods which are well accepted despite their disadvantages. These methods and their associated problems will be discussed in the following.

Within the last years more than 40 exoplanets orbiting M-type stars have been discovered. Consequently the question arises whether these small, red stars could be hosts for habitable planets. There are several concerns pertaining to their habitability, for example their long-lasting highly ionizing short-wavelength radiation. Further, such planets are exposed to flaring events and other space weather phenomena like coronal mass ejections and strong stellar winds (see section 4.1). Therefore, it is crucial to ascertain more about their evolution over time and how activity parameters change with it. This can be done by estimating the ages of these stars and comparing stars with similar masses at different ages.

1.4.1 Chromospheric Activity- Age Relation

Noyes et al. (1984) showed a relationship between chromospheric emission and age. This method concentrates on the star's chromospheric activity and thus is also known under the term *activity age*. *Donahue* (1998) calculates the chromospheric age t [Gyr] calibrated on stars from G0-K7 as follows:

$$\log t_{chromo} = 10.725 - 1.334R_5 + 0.4085R_5^2 - 0.0522R_5^3 \quad (1.1)$$

where $R_5 = 10^5 R'_{HK}$. R'_{HK} is the ratio between the flux of Ca II H and K lines (corrected for the photospheric contribution) and the bolometric flux (*Noyes et al.*, 1984).

Stellar activity declines with age. Depending on the stellar mass, this happens faster or slower. Thus this method is more useful for stars $> 1 M_{\odot}$, as they evolve faster and so long-term changes in their chromospheres can be studied. The advantage of this method is, that only the chromospheric emission in the Ca II H and K lines has to be measured and can be transformed into age without any additional information. Concerning M-type stars, this age-activity-relation leads to several problems as various authors calibrate it for stars for different spectral types, for example *Mamajek & Hillenbrand* (2008) for F7-K2. Using chromospheric emission as an age indicator, one has to consider that several measurements of the same star are essential to compile an average and thus exclude variability from stellar cycles or the rotation itself (*Barnes*, 2007).

1.4.2 Moving Group Ages

This method makes use of the similar kinematics of the individual members of known moving groups, formed in the same star forming region and hence being nearly coeval. Since not many old moving groups are known, this age determination method should be preferred for young stars. Estimating stellar ages with the moving group method can be problematic as stars with different ages having the same kinematics can share a moving group and lead to errors in determining ages, so the membership has to be carefully evaluated (*Lopez-Santiago et al.*, 2009).

1.4.3 Isochrone Method

Changes in luminosity and temperature are the primary indicators of isochrone age determination. Therefore, one criterion is to know the exact stellar distances, which leads to inaccuracy in this method when used on field stars (*Barnes, 2007*). For M-type stars this method is generally rather unsuited as their luminosity does not measurably change over a long period of time and hence is more qualified for faster evolving stars.

1.4.4 Rotation-Age Relation

The last age determining method mentioned here, seems to be the most interesting concerning at least a fraction of M dwarfs and will be explained in more detail as all age estimation calculations in this work were done by using this method. It is called *Gyrochronology* and uses the effect, that rotation declines with age (*Barnes, 2007*). This method can be used for low-mass, Sun-like stars (FGKM) on the main sequence, which support a solar dynamo (*Barnes, 2003*).

Barnes (2007) states that the most important activity-related parameter of a star is the rotation period. Firstly, because it is independent of the star's distance. Secondly and even more important, several studies have shown that it orderly changes with time and this change can actually be predicted. This fact is of the highest interest for late-type main sequence stars, for which the isochrone method is not really suitable.

Another advantage of this method is, that rotational periods of stars can be measured rather exactly even for late-type stars with very faint visual luminosities. For example, *Irwin et al. (2011)* give a measured rotation period for a star of spectral class M8, with a mass of about only $0.08 M_{\odot}$ and at a distance of more than 14 pc.

Barnes (2007) suggests that the rotation period primarily depends on stellar age and mass. Therefore, all stars are classified into two groups (Fig. 1.6): fast/convective/C and slow/interface/I, whereupon he also mentions that there is actually a third group called "g" (gap) that represents stars in transition from I to C. He calls these groups "varieties" and claims that each of them has an individual mass and age dependency.

Variety I (interface sequence stars) is associated with *Skumanich* (1972) and is used in his article to demonstrate the gyrochronology method. *Skumanich* (1972) presented a ratio of a solar-type star's rotational velocity to its age, known as the Skumanich law ($v \sin i \propto 1/\sqrt{t}$). Because of the generally unknown angles of inclination i , this method can lead to large errors in the estimated ages.

The lower a star's mass, the thicker is its convective zone. *Barnes* (2003) presumes that fully convective stars, which do not have an interface, have to be of variety C as they are not able to induce an interface dynamo and thus cannot transform to an I sequence star. Mid- and late-type M stars must have a turbulent dynamo as mentioned in section 3.1.2.

Figure 1.6. Plot taken from *Barnes* (2007) illustrating varieties I and C/g from the *Pizzolato et al.* (2003) stars' sample. The solid line separates the stars of variety I from variety C/g and represents a rotational isochrone for 100 Myr, while the dotted line shows the color at which stars are believed to become fully convective ($B-V = 1.6$).

Barnes (2003) accentuates that an advantage of gyrochronology is the fact, that rotation periods can be determined with great precision and is only limited by differential rotation of a stellar surface.

The rotation rate can be measured by observing changes in a star's light curve induced by starspots on the surface of solar- and late-type stars (*Barnes, 2003*).

High activity stars seem to be more spotted producing stronger light variations when photometrically studied. That makes it easier to determine their precise rotation periods. Determining the rotation periods of stars can also lead to problems, as the same method is used for detecting extrasolar planets by the transit method. How fast a star spins down seems to depend on its mass. Stars with lower masses spin down faster and higher mass stars spin down slower (*Barnes, 2003*).

It seems to be that estimating stellar ages by using the rotational period leads to the best results. Comparing calculated gyrochronological and chromospheric ages, *Barnes (2007)* and *Odert et al. (2010)* come to the conclusion that these methods are in pretty good agreement in contrast to isochrone ages, where deviations are quite common. Nevertheless, *Barnes (2007)* emphasizes that such a comparison is only then significant and reasonable when the chromospheric emission was measured repeatedly over a longer period of time and only measured and not calculated rotational periods were used without exception.

As a fact, many more rotational periods have to be measured from all different kinds of M dwarfs (from high to low activity levels, from the upper to the lower mass limit, from M0 to M9.5, from both varieties C and I and from slow to fast rotators) to make significant statements possible. The space missions *Kepler* and *CoRoT* were designed to detect exoplanets by using the transit method but also yield the rotation periods of planetary host stars as it is a side effect of all planetary transit missions and thus a large quantity of rotation periods can be expected in the near future.

Of course, there are several more methods for stellar age determination. The above methods were explained as they were mentioned respectively used in this work. For further information concerning this topic *Soderblom (2010)* gives a detailed overview.

2 Data and Methods

2.1 Compiling the Sample

A sample consisting of 355 M-type stars was taken from the PhD thesis "Activity of M-type stars and the influence on planetary atmospheres" (Odert 2012, in preparation). From this catalog the stars' names and their trigonometric parallaxes were taken and sorted by increasing right ascension. These stars are all single objects, which are within 15 parsec (pc) of the Sun as measured by trigonometric parallaxes. Using the parallaxes the distances in parsec were calculated by dividing 1000 by the parallax in mas.

Their coordinates were taken from *2MASS*³ (Skrutskie *et al.*, 2006). Furthermore, the exact spectral subtype (M0-M9.5) was found on *Simbad*⁴, where all stars were confirmed as spectral type M. Also the radiation fluxes in apparent magnitudes m in the passbands U, B, V, R and I were taken from *Simbad*. Since *Simbad* does not list a magnitude for each star in each wavelength, additional catalogs were searched to make the sample as complete as possible. All available references will be given in the next chapter. For the photometric bands J, H, and K the apparent magnitudes m were taken from *2MASS* (Cutri *et al.*, 2003), as this catalog contains data for every single star in these three bands.

Additionally the short-wavelengths NUV, FUV, EUV and X-ray as well as the emission of the spectral line H α were of great interest for this work. NUV and FUV values were taken from *GALEX*⁵, EUV from the *EUV Master Catalog*⁶, X-ray from Odert (2012, in preparation) and finally H α emission values out of several articles, referenced later.

³ *2MASS* stands for Two Micron All Sky Survey and was a mission running from 1997-2001 using two telescopes located in the northern and southern hemisphere to cover the entire sky in the three near-infrared passbands J, H and K.

⁴ <http://simbad.u-strasbg.fr/> (October 14th, 2011)

⁵ *GALEX* stands for Galaxy Evolution Explorer and is an ultraviolet space telescope measuring in NUV and FUV ranges launched in 2003 and still in operation. Data products see: <http://galex.stsci.edu/> (November 2nd, 2011) Using the stars' coordinates, *GALEX* objects in GR6 (*GALEX* Data Release 6) within 6" were correlated with stars in the sample as long as no other stellar objects were within 12" of these coordinates. Objects with a distance greater than 6" in GR6 were further correlated with the position of the stars in data from SDSS DR8 (Sloan Digital Sky Survey Data Release 8) and taken, when a *GALEX* object was within 6" of the SDSS coordinates.

⁶ <http://heasarc.nasa.gov/W3Browse/all/euv.html>

In addition, rotational periods were needed to calculate stellar ages by applying gyrochronology relations. To compare these results, ages determined by the chromospheric activity method were taken from *Odert* (2012, in preparation).

For comparison of the collected M stars' parameters, as well as their calculated ones, a sample of solar-type stars was compiled. Therefore, *Simbad* was used to search for stars with spectral type G2V within 30 pc of the Sun. Twenty-eight stars were found, from which some were not included in this work, because of the fact that only data in two wavelengths was available or the spectral type was not clearly identified. After rejecting those, a list with 22 stars remained. These stars are all included in the HD catalog⁷ and are also sorted by increasing right ascension. The aim was to use them in representation of our Sun to compare the radiation and activity differences to M-type stars.

Due to the relatively close distances of all stars in this sample, the effects of interstellar medium absorption and reddening were neglected in all calculations hereafter.

2.2 Calculating Luminosity

2.2.1 Luminosity in the Passbands UBVRIJHK

The apparent magnitudes⁸ m were transformed into absolute magnitudes M by using the following formula:

$$M = m + 5 - 5\log_{10}(r) \quad (2.1)$$

where r is the distance in pc. The absolute magnitudes M were needed to determine the stars' luminosities L . Therefore two other parameters had to be calculated, flux density f and frequency range ν .

⁷ Henry Draper Catalog

⁸ Many apparent magnitudes in R and I were derived from the USNO-B catalog (*Monet et al.*, 2003), a photographic plate sky survey. Use of this data is problematic. Due to a lack of alternatives to convert these values to Johnson UBV, they were processed as described above as other authors have done this as well (e.g. *Schuh et al.*, 2003).

Flux density f is given by (*Reid & Hawley, 2005*):

$$f = f_0 \times 10^{-(M/2.5)} \quad (2.2)$$

where f_0 is the flux density in Jansky⁹ at magnitude 0 produced by a star with spectral class A0 and is different for every passband. These f_0 values¹⁰ were also obtained from *Reid & Hawley (2005)*.

Frequency range ν was calculated as follows (e.g. *Reid & Hawley, 2005*):

$$\Delta\nu = c/\lambda_{\max} - c/\lambda_{\min} \quad (2.3)$$

where c is the speed of light and λ_{\max} resp. λ_{\min} are the upper and respective lower limits of each filter's FWHM¹¹. The λ values¹² are listed in *Reid & Hawley (2005)*.

After computing f and ν in the passbands UBVRIJHK, the luminosities L were calculated. Usually this is done with the formula $L = 4\pi r^2 f$ (e.g. *Karttunen et al., 2007*).

In this case the formula had to be expanded by ν [Hz] as the flux density f was calculated in the units of Jansky but the result was needed in Watt. Hence the following formula was used:

$$L = 4\pi r^2 f \nu \quad (2.4)$$

to calculate the luminosities in all mentioned wavelengths, where r is 10 pc in meters. Finally, the results were multiplied by 10^7 to receive the units [erg s⁻¹].

For both, M and G stars, data processing was executed with the same method.

⁹ 1 Jansky = 10^{-26} W m⁻² Hz⁻¹

¹⁰ f_0 : U=1181; B=4520; V=3711; R=3180; I=2460; J=1568; H=1076; K=650. All values in Jansky.

¹¹ FWHM stands for Full Width at Half Maximum and is an expression of the bandwidth, where less than half of the maximum signal is obtained.

¹² λ_{\min} : U=325; B=390; V=500; R=565; I=730; J=1160; H=1490; K=2000. All values in nm.
 λ_{\max} : U=395; B=490; V=590; R=725; I=880; J=1350; H=1800; K=2300. All values in nm.

2.2.2 Luminosity in the Passbands NUV and FUV

Data from *GALEX* was collected in the form of apparent AB magnitudes¹³. To convert AB magnitudes to luminosity [erg s^{-1}], the magnitudes were transformed into microJansky by calculating the flux density f . For this purpose the formula from Oke (1974) $AB = -2.5 \log_{10} f - 48.6$ was transformed to:

$$f = 10^{(23.9-AB)/2.5} \quad (2.5)$$

Further, the frequency range ν was determined as it was done in 2.2.1 using equation (2.3). The values¹⁴ for λ_{max} and λ_{min} were calculated using the pivot wavelength¹⁵ \pm FWHM/2 given in the *GALEX* observer's guide¹⁶ and finally converted into Jansky by multiplying by 10^6 . Using the same formula (2.4) as above, led to the luminosities L [erg s^{-1}] in NUV and FUV. The only difference was, that for r the individual stellar distances [m] were taken, as the initial AB magnitudes had not been converted into absolute values which correlate to the magnitudes at a distance of 10 pc. M and G stars were processed in the same manner.

2.2.3 Luminosity in the Passband EUV

The data in EUV was mainly taken from the *EUV Master Catalog*, which is a compendium of EUV source catalogs, and completed with data from *Hodgkin & Pye* (1994). The *EUV Master Catalog* contains data taken for this work, derived from *EUVE*¹⁷ (filter Lexan/B) and *ROSAT*¹⁸ (filter S1).

¹³ AB magnitudes differ from the classical magnitude system, in that 0 magnitude in each passband is not defined on the basis of a reference star, i.e. Vega, but rather on the basis of the magnitude zero-point being equivalent to 3631 Jansky. This eliminates possible fluctuations in the luminosity of reference stars and defines the zero-point as an energy level instead of a natural source, and allowing easier calculation of flux densities.

¹⁴ λ_{min} : FUV=138.95; NUV=198.9. All values in nm. λ_{max} : FUV=165.85; NUV=260.5. All values in nm.

¹⁵ Pivot wavelength is the wavelength of the effective transmission of a filter in a source independent manner and is the same whether expressed in wavelength or frequency.

¹⁶ <http://galexgi.gsfc.nasa.gov/docs/galex/documents/galexobserverguide.pdf> (November 2nd, 2011)

¹⁷ EUVE stands for Extreme UltraViolet Explorer and was the first satellite mission especially for radiation between 7-76 nm (*Unsöld & Baschek*, 2001). Running from 1992-2001, one of the main goals was to make an all-sky survey in EUV. Lexan/B is a filter sensitive in the range 5.8 - 17.4 nm (*Christian et al.*, 1999).

In certain cases this led to two values in EUV for the same star. All values were given in counts per second [ct s⁻¹]. Using conversion factors¹⁹ (*Hodgkin & Pye*, 1994 for S1; *Wood et al.*, 1995 for Lexan/B), the flux density f was calculated, which transformed the former unit directly to [erg cm⁻² s⁻¹]. Hence calculating the frequency range ν was not needed in this case.

Finally the luminosity L in EUV was determined applying (e.g. *Karttunen et al.*, 2007):

$$L = 4\pi r^2 f \quad (2.6)$$

where r is the individual stellar distance in centimeters [cm]. These calculations were performed identically for M and G stars.

2.2.4 Luminosity in the Wavelength Range X-ray

Since the calculated X-ray luminosities for the studied M stars' sample were available from *Odert* (2012, in preparation), these values were adopted.

For the G2V stars the data given in [ct s⁻¹] was derived from *ROSAT* bright and faint source catalogs (*Voges et al.*, 1999; *Voges et al.*, 2000). The transformation to [erg cm⁻² s⁻¹] was performed in the same manner as above (2.2.3) using the conversion factor²⁰ from *Simon et al.* (1995). Applying equation (2.6) the luminosity L in [erg s⁻¹] was determined.

2.2.5 Luminosity of the Emission Line H α

The M stars' H α luminosities were calculated using the equivalent widths in Ångström [Å] of the emission lines. Spectral lines in absorption were not further used. The values were taken from different articles, which will be referenced later.

¹⁸ ROSAT stands for Röntgensatellite and was a mission running from 1990-1999 designed to make an all-sky survey in the wavelength ranges X-ray and EUV. Filter S1 is sensitive in the range 6-14 nm (*Pye et al.*, 1995).

¹⁹ Conversion factor for S1 (*Hodgkin & Pye*, 1994): 5×10^{-11} erg cm⁻² ct⁻¹
Conversion factor for Lexan/B (*Wood et al.*, 1995): 1×10^{-10} erg cm⁻² ct⁻¹

²⁰ Conversion factor for X-ray (*Simon et al.*, 1995): 6×10^{-12} erg cm⁻² ct⁻¹

Walkowicz et al. (2004) give two equations to calculate $\log(\chi)$, which is the ratio between the flux at H α ($f_{\text{H}\alpha}$) and the bolometric flux (f_{bol}).

For this case equation (1) from *Walkowicz et al.* (2004) was chosen as it includes the term $(I-K)$ instead of $(V-I)$ (equation (2) in *Walkowicz et al.*, 2004) as there were more K magnitudes than V magnitudes available for the M stars sample allowing more completeness.

$$\log(\chi) = -5.73342 + 3.07439(I - K) - 1.58615(I - K)^2 + 0.274372(I - K)^3 - 0.0154537(I - K)^4 \quad (2.7)$$

The ratio $f_{\text{H}\alpha}/f_{\text{bol}}$ was converted to the ratio of $L_{\text{H}\alpha}/L_{\text{bol}}$ by multiplying χ with the equivalent width (*Walkowicz et al.*, 2004). The calculation of the bolometric luminosity L_{bol} follows in section 2.4.

As the χ -factor was only calibrated for M-type stars, the G2V H α luminosities were processed differently. This was performed using the surface fluxes $F'_{\text{H}\alpha}$, referenced later, with equation (2.6) and setting the radius for all G2V stars equivalent to $1 R_{\odot}$.

2.3 Calculating Bolometric Magnitude

The bolometric magnitude is needed to calculate the bolometric luminosity. There are different ways to determine the bolometric magnitude. *Veeder* (1974) gives the following equation:

$$M_{\text{bol}} = 1.12 + M_K \times 1.81 \quad (2.8)$$

where M_K is the absolute magnitude in passband K. *Reid & Hawley* (2005) refer to another equation:

$$M_{\text{bol}} = BC_{\lambda} + M_{\lambda} \quad (2.9)$$

where BC_{λ} is the bolometric correction factor and M_{λ} the absolute magnitude at a certain passband.

Depending on the star's spectral subtype there are different methods to determine the bolometric correction factor. *Reid & Hawley* (2005) give three equations to calculate BC using either the V, I or K band.

$$BC_V = 0.27 - 0.604(V - I) - 0.125(V - I)^2 \quad (2.10)$$

$$BC_I = 0.02 + 0.575(V - I) - 0.155(V - I)^2 \quad (2.11)$$

$$BC_K = 0.42 + 1.486(I - K) - 0.22(I - K)^2 \quad (2.12)$$

But these can only be used for the spectral subtypes M0-M6. For subtypes M6.5-M9.5 *Golimowski et al.* (2004) show another relation:

$$BC_K = 3.9257 - 0.3833SpT + 0.053597SpT^2 - 0.002655SpT^3 + 0.000040859SpT^4 \quad (2.13)$$

where SpT stands for the spectral subtype (i.e. M6.5: $SpT = 6.5$).

It was decided to use the following approach:

For all early- and mid-type M stars (M0-M6), which had a value in both passbands, I and K, equation (2.12) from *Reid & Hawley* (2005) was applied to calculate the bolometric correction factor BC , because its standard deviation (σ) is the smallest of the three presented equations and values in K were available for all stars. Equation (2.9) was then used to calculate the bolometric magnitude M_{bol} for these stars.

For those stars without data in passband I, equation (2.8) (*Veeder*, 1974) was applied and finally for all late-type stars (M6.5-M9.5) equation (2.13) (*Golimowski et al.*, 2004) was taken.

Determining the G2V stars' bolometric magnitudes required using the formula (2.9) (*Flower*, 1996):

$$M_{bol} = M_V + BC$$

where M_V is the absolute visual magnitude. The bolometric conversion factors BC are listed in *Flower* (1996). Using $(B-V)$ color, the matching bolometric correction factor could be found in the referenced article and the bolometric magnitude M_{bol} could be determined.

2.4 Calculating Bolometric Luminosity

After calculating the bolometric magnitudes, the modified formula²¹ (e.g. *Reid & Hawley, 2005*) was used to determine the bolometric luminosities L_{bol} for both, M and G stars:

$$L_{\text{bol}} = L_{\text{bol}\odot} \times 10^{-(M_{\text{bol}} - M_{\text{bol}\odot})/2.5} \quad (2.14)$$

where the values $3.8503 \times 10^{33} \text{ erg s}^{-1}$ for $L_{\text{bol}\odot}$ (e.g. *Oderl 2012*, in preparation) and 4.72 for $M_{\text{bol}\odot}$ (e.g. *Karttunen et al., 2007*) were applied.

With these calculated parameters, the logarithmic ratios between the luminosity in each passband and the bolometric luminosity were compiled ($\log L_{\lambda}/L_{\text{bol}}$) for the diagrams presented in chapter 3.

2.5 Determining Stellar Mass

To determine a star's mass there are several methods. *Delfosse et al. (2000)* give five different mass-luminosity relations employing different passbands, which can be used for all stars with masses smaller than 0.6 solar masses. The following two equations were both applied to compare the results (*Delfosse et al., 2000*):

$$\log_{10} (M/M_{\odot}) = 10^{-3} \times (1.6 + 6.01M_J + 14.888M_J^2 - 5.3557M_J^3 + 0.28518 \times M_J^4) \quad (2.15)$$

$$\log_{10} (M/M_{\odot}) = 10^{-3} \times (1.8 + 6.12M_K + 13.205M_K^2 - 6.2315M_K^3 + 0.37529M_K^4) \quad (2.16)$$

The comparison showed, that the calculated results did not differ until the second decimal place, which is not especially surprising as the passbands lie near to each other. However, interesting was, that nearly all (except three) values calculated using the K passband were smaller than those calculated with J.

²¹ Original formula (e.g. *Reid & Hawley, 2005*): $M_{\text{bol}} - M_{\text{bol}\odot} = -2.5 \log_{10}(L_{\text{bol}}/L_{\text{bol}\odot})$

Ultimately, all M star masses in this work were determined using equation (2.16) as *Delfosse et al.* (2000) come to the conclusion, that the smallest dispersion around the mean relation was observed using the K band.

In particular cases this calculation method led to masses bigger than 0.6 solar masses, which should actually be the upper mass limit for stars of spectral type M.

Taking a closer look, it showed that these stars with masses $> 0.6 M_{\odot}$ are either of spectral subtype M0 or M0.5 (with one exception: M2), where there is a good chance that those stars are in fact of spectral type K.

The same happened at the other end of the mass limit for M stars which lies at about $0.075 M_{\odot}$. Nine stars of the sample lie below this limit, the lowest having a mass of $0.068 M_{\odot}$. Potentially these stars could be brown dwarfs.

However, regardless of these concerns the mentioned stars were retained in the sample as different mass calculation methods lead to different results and a certain grade of deviation is acceptable.

The G2V stars' masses were calculated differently, using a relation which is especially applicable for stars with masses between $0.43 M_{\odot} - 2 M_{\odot}$ (*Duric*, 2004):

$$L_{\text{bol}}/L_{\text{bol}\odot} = (M/M_{\odot})^4 \quad (2.17)$$

where for M_{\odot} the value 1 was inserted.

2.6 Estimating Stellar Age

As mentioned in 1.4 age determination is still problematic, especially for M-type stars, which evolve extremely slow. In this work the so-called gyrochronology method by *Barnes* (2007) was used. He shows an improved way of using a star's rotation period connected with its color (B-V) as a clock.

Therefore, rotational periods P_{rot} were collected for both M and G stars from several articles which will be referenced later.

The M and G stars' ages were estimated applying the following formula (*Barnes, 2007*), but with different parameter values²² in a , b , c and n for the G2V stars (*Mamajek & Hillenbrand, 2008*):

$$\log t [\text{Myr}] = \frac{1}{n} [\log P_{\text{rot}} - \log a - b \log(B - V - c)] \quad (2.18)$$

as they have revised the parameters of *Barnes (2007)* especially for late F to early K stars and mainly tested them on G stars, which seems to work better for the G2V stars in this sample. *Barnes (2007)* states that his parameters are valid for solar-type (FGKM) stars.

The parameters a and b are fitted constants, c is called the "color singularity" and n represents the time-dependent power law index (*Mamajek & Hillenbrand, 2008*).

The difficulty in using both formulas is that there are many limitations on their use. First *Barnes (2007)* claims that this age determination method is valid for solar-type stars (FGKM), but mentions later in his article that it can only be applied for stars that have an interface and hence are not fully convective, which implies that ultrafast C sequence rotators are excluded. Further, it means that it only works for M stars with masses higher than $\approx 0.35 M_{\odot}$. The rotation-age relationship for fully convective stars is not well studied yet.

Furthermore, he limits the use of his formula to stars with $B-V$ smaller than 1.55 as in one of his studied samples there are no slow rotators redwards of this color. However, recently *Irwin et al. (2011)* presented new measured rotation periods which showed the opposite, e.g. for the star GJ 1072 (member of the M stars sample studied here) which has a $B-V$ value of 1.95 but a rotation period of 147 days. Additionally, there are eleven other stars with $B-V > 1.55$ and long rotation periods (> 50 days, most of them above 100 days) in the M stars' sample used here.

²² *Barnes (2007)*: $a = 0.7725$, $b = 0.601$, $c = 0.40$, $n = 0.5189$.

Mamajek & Hillenbrand (2008): $a = 0.407$, $b = 0.325$, $c = 0.495$, $n = 0.566$.

Finally, he adds that his formula is not functional until a stellar age of at least 100 Myr is reached, as it takes approximately this time for Sun-like stars to switch from the C- to the I-sequence. This is due to the variability of rotation periods in young stars as they converge during their later evolution.

Mamajek & Hillenbrand (2008) present a different calibration valid for spectral classes from late F till early K type stars.

Concluding it seems that the parameters a , b , c , and n must be defined even more accurately for different stellar mass ranges.

Despite the awareness of many limits to the gyrochronology formula from *Barnes* (2007), it was applied to all stars with rotation periods in the M stars sample as there were only 40 out of 355 available. It demonstrated good correlation with chromospheric ages for the stars that were within the criteria outlined by *Barnes* (2007), but also was able to give crude estimates for young stars or stars with very low masses. All ages estimated by this method, even those where the stars do not meet all criteria, were in good agreement with chromospheric ages and a potential age proxy which will be discussed later.

Out of interest the M stars' ages were also estimated with the parameters given by *Mamajek & Hillenbrand* (2008), which led to many results that were clearly older than the current age of the universe. This cannot be correct but also happened in four single cases when using the parameters given in *Barnes* (2007).

Taking a closer look at these four stars showed that their spectral types are in fact M3.5, M4 or M5, which is right at the border between early- and mid-type M stars and represents a stellar mass around the point where several authors (*Reid & Hawley*, 2005; *Barnes*, 2007; *West & Basri*, 2009) presume the changeover to a fully convective energy transfer, which would mean that these stars are not on the I-sequence and thus making the formula from *Barnes* (2007) not suitable for these stars.

Another reason for the impossibly large ages could be, of course, erroneous rotation periods or errors in measurement of the B or V magnitude.

However, these stellar ages estimated with the parameters of *Barnes* (2007) were kept in the M stars' sample and also included in the compiled diagrams which are presented in the next chapter as there currently exists no dependable gyrochronological method to estimate stellar ages for fully convective stars.

For comparison M star ages calculated with the chromospheric method were taken from *Odert* (2012, in preparation) and can be compared to the gyro ages in Table 2.1 and several diagrams. Furthermore, G2V stars' ages calculated with the isochrone method were taken from *Holmberg et al.* (2009) as only two rotational periods were available and so only for two stars the ages could be estimated using gyrochronology.

Concluding this chapter, Table 2.1 for M-type stars and Table 2.2 for G2V stars summarize fundamental stellar parameters which were either taken from literature or calculated as described above. Included - as far as available - are: number (col. 1), name (col. 2), spectral type (col. 3), right ascension (col. 4), declination (col. 5), parallax (col. 6), B-V (col. 7), bolometric magnitude (col. 8), bolometric luminosity (col. 9), stellar mass (col. 10), rotational period (col. 11), ages calculated using different methods (col. 12 and 13) and references (col. 14).

Table 2.2: lists the names, positions and distances of the used G2V stars' sample as well as several stellar parameters which were either taken from the given references or calculated. (*) in [deg] and taken from *Van Leeuwen 2007*; (°) taken from *Holmberg et al. 2009*; (1) *Barnes 2007*, (2) *Gray et al. 2006*, (3) *Koen et al. 2010*, (4) *Montes et al. 2001*, (5) *Torres et al. 2006*, (6) *White et al. 2007*, (7) *Zuckerman & Song 2004*; (~) taken from *Simbad* (October 14th, 2011). All other values were calculated as explained in chapter 2.

3 Results and Discussion

The electromagnetic radiation of 355 M-type stars was studied in twelve different wavelengths and compared to the radiation of 22 Sun-like (G2V) stars. These wavelength ranges are X-ray, EUV, FUV, NUV, U, B, V, R, I, J, H and K. Furthermore, the emission of the spectral line H α was investigated.

The most interesting ranges concerning M-type stars and their space weather are, of course, the short-wavelengths ranges (X-ray, EUV, FUV and NUV) and the emission in the spectral line H α . The longer wavelengths are included for completeness and will be explained first, before the most significant part will be treated in detail.

Finally the examination of the M- and G-type stars' H α emissions will be discussed. H α is a very important proxy concerning a dwarf star's chromospheric activity and thus can be used as an indicator of the intensity of chromospheric events such as flares.

For each wavelength range at least two diagrams²³ were compiled, one plotting the stellar masses against the luminosity of the studied wavelength, the second plotting the stellar masses against the ratios of the particular filter's to the bolometric luminosity. In the diagrams on the following pages the M-type stars are marked as red diamonds, while the G2V stars are green. This applies for all upcoming diagrams, unless other descriptions are given.

Additionally the luminosities of the short-wavelength ranges, as well as of the spectral line H α , were not only investigated in terms of the stellar masses, but also as a function of the stars' spectral subtypes and their ages.

In summary, this work presents an almost complete coverage of the electromagnetic radiation emitted by 355 M-type stars as well as 22 Sun-like (G2V) stars over a wavelength range from 0.5 to 2300 nm and thus illustrates the characteristics over a large part of the electromagnetic spectrum.

²³ There is a prominent outlier clearly below all other stars in all diagrams where magnitude I was used for calculations. This star is GJ 398 (No. 164), which has a far too high value in this passband (*Monet et al.*, 2003; I=17.9). It was kept in the sample for completeness. Further discussions about outliers do not concern this one.

3.1 The Johnson UBV

3.1.1 The U Band

The U filter is sensitive to ultraviolet rays in a wavelength range from 325-395 nm (*Reid & Hawley, 2005*). The M-type stars' apparent magnitudes in U were available for 124 stars and mainly taken from *Simbad* (except two values). As far as reference papers²⁴ were stated, they are quoted below. The G2V stars' apparent magnitudes in U were available for 3 stars and also taken from *Simbad*. The corresponding references²⁵ are cited below as well.

Figure 3.1. The relationship between mass and luminosity in passband U for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

In Figure 3.1 (right) the amount of radiation in U compared to the bolometric only slightly increases with increasing stellar mass. Further it can be seen that Sun-like stars have higher U luminosities than M-type stars, which is clear as they are more luminous in the blue part of the spectrum. In the left diagram in Fig. 3.1 there is an obvious linear relationship between mass and the log of U filter luminosity. The outliers in both Figures could represent bad data and/or flaring stars as flares are a phenomenon of chromospheric activity and the main amount of the chromosphere's radiation consists of UV radiation (*Hanslmeier, 2007*).

²⁴ **M stars:** *Henry (2002)*: Stars no. 139, 146, 150; *Koen (2010)*: Stars no. 1, 10, 18, 22, 25, 31, 34, 35, 41, 43, 45, 47, 48, 60, 70, 74, 76, 78, 80, 82, 86, 88, 89, 91, 93, 94, 99, 105, 111, 112, 116-118, 123, 140, 141, 143, 145, 149, 151, 153, 157, 159, 161, 162, 167, 171, 173, 175, 177, 179, 181, 182, 188, 195, 196, 198, 199, 201, 210, 215, 216, 219, 220, 224, 227, 229, 230, 234, 236, 237, 239, 242, 244, 251, 253, 254, 257, 259, 261, 263-265, 268, 270, 273, 283, 285, 286, 296, 298, 304, 306, 307-310, 313, 317, 319, 322, 324, 325, 331, 333, 335, 337, 338, 342, 346, 352, 353; *Oja (1985)*: Star no. 174; *Samus (2003)*: Stars no. 27, 126, 130, 164, 170, 202, 311, 320.

3.1.2 The B Band

The B filter is sensitive to blue light and covers a wavelength range from 390-490 nm (*Reid & Hawley, 2005*). The M-type stars' apparent magnitudes in B were available for 347 stars and taken from *Simbad*. As far as a reference paper²⁶ was stated, it is quoted below. The G2V stars' apparent magnitudes in B were available for all 22 stars and also taken from *Simbad*, referenced²⁷ below as far as available.

Figure 3.2. The relationship between mass and luminosity in passband B for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

Figure 3.2 shows clearly that the amount of B radiation in M dwarfs increases with increasing mass and is obviously less than in the compared Sun-like stars. Besides, it demonstrates a steep increase of radiation in B at the lower mass end of M-type stars. Compared to Figure 3.1, the intensity of B filter luminosity at the lower mass end illustrates the higher chromospheric activity in U present in late M-type stars lower than $0.2 M_{\odot}$, as there is a significant break-point in Figure 3.2, but a rather flat slope in Figure 3.1.

²⁶ **M stars:** *Bessell (1990)*: Star no. 240. *Casagrande (2008)*: Stars no. 44, 241. *Hog (2000)*: Stars no. 26, 28, 110, 114, 142, 212, 245, 255, 334. *Kharchenko (2001)*: Stars no. 12, 58, 90, 127, 148, 176, 185, 204, 205, 213, 280, 320. *Koen (2010)*: Stars no. 1, 10, 18, 25, 31, 34, 35, 41, 43, 45, 47, 48, 60, 70, 74, 76, 78, 80, 82, 86, 88, 89, 91, 93, 94, 99, 105, 111, 112, 116-118, 123, 140, 141, 143, 145, 149, 151, 153, 157, 159, 161, 162, 167, 171, 173, 175, 177, 179, 181, 182, 188, 195, 196, 198, 199, 201, 210, 215, 216, 219, 220, 224, 227, 229, 230, 234, 236, 237, 239, 242, 244, 251, 253, 254, 257, 259, 261, 263, 264, 265, 268, 270, 273, 283, 285, 286, 296, 298, 304, 306-310, 313, 317, 319, 322, 324, 325, 331, 333, 335, 337, 338, 342, 346, 352, 353. *Lasker (2008)*: Star no. 249. *Mermilliod (2006)*: Star no. 15. *Monet (2003)*: Stars no. 3, 4, 21, 22, 37, 57, 59, 62, 68, 72, 77, 102, 119, 136, 138, 152, 156, 164, 178, 200, 214, 225, 228, 247, 260, 267, 269, 278, 279, 281, 282, 293, 305, 355. *Oja (1985)*: Star no. 174. *Oppenheimer (2001)*: Star no. 20. *Reid (2004)*: Stars no. 36, 103, 122, 124, 294. *Space Telescope Science Institute (2001)*: Star no. 284.

²⁷ **G2V stars:** *Hog (2000)*: Stars no. 10, 19; *Koen (2010)*: Stars no. 2, 4; *Oja (1991)*: Star no. 6.

3.1.3 The V Band

The V filter is sensitive to visual light and ranges from 500-590 nm (*Reid & Hawley, 2005*). The M-type stars' apparent magnitudes in V were available for 350 stars and mainly taken from *Simbad*. Because of the importance of V values for several calculations, additional catalogs were searched, to find even more values in V. The G2V stars' apparent magnitudes in V were available for all 22 stars and taken from *Simbad*. As far as reference papers^{28,29} for these values were stated, they are quoted below.

Figure 3.3. The relationship between mass and luminosity in passband V for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

Passband V, like the other visual passbands B and R, demonstrates the same break-point at 0.2 M_⊙. This is the last filter range going redwards, where the ratio of the filter to bolometric luminosity is unambiguously higher for the G2V stars than for the M stars. Again a steep increase of the M stars luminosity from the lower mass limit up to 0.2 M_⊙ can be seen in both diagrams of Fig. 3.3, which afterwards flattens its slope.

²⁸ **M stars:** *Bessell* (1990): Star no. 240. *Casagrande* (2008): Stars no. 2, 32, 44, 136, 166, 180, 183, 193, 241. *Costa* (2005): Stars no. 14, 38. *Costa* (2006): Star no. 340. *Hog* (2000): Stars no. 26, 28, 110, 114, 142, 212, 245, 255, 334. *Jao* (2011): Star no. 289. *Jenkins* (2009): Stars no. 5, 9, 13, 16, 27, 52, 55, 57, 65, 83, 98, 104, 107, 108, 120, 121, 144, 152, 160, 165, 168, 170, 186, 187, 189, 190, 194, 202, 221, 232, 238, 266, 272, 275, 300, 332, 349, 351. *Kharchenko* (2001): Stars no. 12, 58, 90, 127, 148, 176, 185, 204, 205, 213, 280, 320. *Koen* (2010): Stars no. 1, 10, 18, 22, 25, 31, 34, 35, 41, 43, 45, 47, 48, 60, 70, 74, 76, 78, 80, 82, 86, 88, 89, 91, 93, 94, 99, 105, 111, 112, 116-118, 123, 140, 141, 143, 145, 149, 151, 153, 157, 159, 161, 162, 167, 171, 173, 175, 177, 179, 181, 182, 188, 195, 196, 198, 199, 201, 210, 216, 219, 220, 224, 227, 229, 230, 234, 236, 237, 239, 242, 244, 251, 253, 254, 257, 259, 261, 263-265, 268, 270, 273, 283, 285, 286, 296, 298, 304, 306-310, 313, 317, 319, 322, 324, 325, 331, 333, 335, 337, 338, 342, 346, 352, 353. *Lépine* (2009): Stars no. 3, 59, 77, 178, 225. *Mermilliod* (2006): Star no. 15. *Oja* (1985): Star no. 174. *Patterson* (1998): Star no. 206. *Reid* (2004): Stars no. 7, 36, 85, 103, 122, 124, 130, 228, 274, 178, 294, 301. *Riedel* (2010): Stars no. 33, 147, 303, 314. *Van Altena* (1995): Stars no. 4, 6, 19-21, 23, 30, 37, 40, 46, 50, 66-68, 72, 92, 96, 119, 131-134, 137, 138, 156, 163, 164, 169, 172, 191, 200, 214, 226, 231, 233, 235, 247-249, 252, 267, 269, 277, 282, 292, 293, 297, 305, 318, 321, 328, 329, 336, 347, 350, 355. *Van Belle* (2009): Star no. 215.

3.2 An Extension into the Red

3.2.1 The R Band

Passband R is sensitive to red light and ranges from 565-725 nm (*Reid & Hawley, 2005*). The M-type stars' apparent magnitudes in R were available for 332 stars and mainly taken from *Simbad* but also from other references. The G2V stars' apparent magnitudes in R were available for 9 stars and taken from *Simbad*. As far as reference papers^{30,31} were stated, they are quoted below.

Figure 3.4. The relationship between mass and luminosity in passband R for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

As in filters B and V, Figure 3.4 shows a significant break-point at 0.2 M_⊙. This break-point demonstrates the redshift of a star's spectrum at lower masses, and when compared with the U filter, the higher chromospheric activity of these stars. At this point the G2V stars luminosity ratio, right diagram, approaches that of the M stars.

³⁰ **M stars:** *Casagrande (2008)*: Stars no. 2, 16, 32, 44, 136, 139, 146, 166, 180, 183, 193, 241. *Costa (2005)*: Stars no. 17, 38, 92, 133. *Costa (2006)*: Stars no. 344, 345. *Cvetkovic (2011)*: Star no. 150. *Henry (2006)*: Stars no. 24, 42, 61, 83, 197, 323. *Jao (2005)*: Stars no. 11, 71, 158, 203, 206, 222, 288, 299, 312, 315, 348. *Jao (2011)*: Stars no. 87, 289. *Koen (2010)*: Stars no. 1, 10, 18, 22, 25, 31, 34, 35, 41, 43, 45, 47, 48, 60, 70, 74, 76, 78, 80, 82, 86, 88, 89, 91, 93, 94, 99, 105, 111, 112, 116-118, 123, 140, 141, 143, 145, 149, 151, 153, 157, 159, 161, 162, 167, 171, 173, 175, 177, 179, 181, 182, 188, 195, 196, 198, 199, 201, 210, 215, 216, 219, 220, 224, 227, 229, 230, 234, 236, 237, 239, 242, 244, 251, 253, 254, 257, 259, 261, 263-265, 268, 270, 273, 283, 285, 286, 296, 298, 304, 306-310, 313, 317, 319, 322, 324, 325, 331, 333, 335, 337, 338, 342, 346, 352, 353. *Lasker (2008)*: Star no. 14. *Liebert (2006)*: Stars no. 7, 231, 340. *Monet (2003)*: Stars no. 3, 4, 5, 6, 9, 12, 13, 19, 21, 26, 28, 29, 30, 36, 37, 39, 40, 46, 49, 52, 53, 55, 56, 57, 58, 59, 62, 64, 65, 68, 72, 77, 79, 85, 90, 95, 96, 98, 100, 102, 104, 106-110, 113, 114, 119-121, 124, 126, 127, 129, 130, 132, 135, 137, 138, 142, 144, 148, 152, 154-156, 160, 163-165, 169, 170, 172, 174, 176, 178, 187, 189, 191, 192, 194, 200, 202, 204, 205, 208, 211-213, 217, 221, 225, 226, 228, 232, 238, 245-248, 252, 255, 256, 258, 262, 266, 267, 269, 271, 272, 275-282, 291-295, 297, 300, 305, 320, 330, 332, 341, 343, 349-351, 354, 355. *Norton (2007)*: Star no. 334. *Patterson (1998)*: Star no. 168. *Reid (2004)*: Stars no. 27, 69, 75, 81, 84, 103, 122, 185, 186, 190, 274, 287, 290, 301, 302. *Reid (2007)*: Star no. 128. *Riedel (2010)*: Stars no. 33, 51, 97, 101, 125, 147, 184, 218, 303, 314. *Wheatley (2008)*: Stars no. 243, 250. *Zacharias (2009)*: Stars no. 15, 20, 207, 209, 214, 223, 240, 249, 260, 284, 336.

³¹ **G2V stars:** *Cutri (2003)*: Star no. 9. *Koen (2010)*: Stars no. 2, 4. *Monet (2003)*: Stars no. 6, 7, 11, 14, 15, 17.

3.2.2 The I Band

Passband I is sensitive to radiation that ranges from 730-880 nm (*Reid & Hawley, 2005*). The M-type stars' apparent magnitudes in I were available for 326 stars and mainly taken from *Simbad* but also other catalogs. All available references³² are cited below. The G2V stars' apparent magnitudes in I were available for 8 stars and taken from *Simbad*, referenced³³ below.

Figure 3.5. The relationship between mass and luminosity in passband I for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

Figure 3.5 illustrates that the break-point, that was at 0.2 M_⊙ in the visual passbands, has moved to stellar masses of about 0.1 M_⊙. Independent of the stellar mass and spectral type (M or G), the radiation amount in I compared to the bolometric remains at the same level except for stars with masses lower than 0.1 M_⊙, where a short decrease can be seen in Figure 3.5.

³² **M stars:** *Casagrande* (2008): Stars no. 2, 32, 44, 136, 139, 146, 166, 183, 193, 241. *Costa* (2006): Stars no. 344, 345. *Cvetkovic* (2011): Star no. 150. *Henry* (2002): Star no. 38. *Henry* (2006): Stars no. 24, 42, 61, 83, 197, 323. *Jao* (2005): Stars no. 11, 71, 92, 158, 203, 206, 299, 315, 348. *Jao* (2011): Stars no. 87, 289. *Koen* (2010): Stars no. 1, 10, 18, 22, 25, 31, 34, 35, 41, 43, 45, 47, 48, 60, 70, 74, 76, 78, 80, 82, 86, 88, 89, 91, 93, 94, 99, 105, 111, 112, 116-118, 123, 140, 141, 143, 145, 149, 151, 153, 157, 159, 161, 162, 167, 171, 173, 175, 177, 179, 181, 182, 188, 195, 196, 198, 199, 201, 210, 215, 216, 219, 220, 224, 227, 229, 230, 234, 236, 237, 239, 242, 251, 253, 254, 257, 259, 261, 263-265, 268, 270, 273, 283, 285, 286, 296, 304, 306-310, 313, 317, 319, 322, 324, 325, 331, 333, 335, 337, 338, 342, 346, 352, 353. *Lasker* (2008): Star no. 15. *Leggett* (1992): Stars no. 52, 55, 121, 133, 134, 168, 170, 311, 329, 339. *Liebert* (2006): Stars no. 7, 231, 288, 340. *Monet* (2003): Stars no. 3, 5, 6, 9, 12, 13, 16, 19, 21, 28, 30, 36, 37, 39, 40, 46, 49, 53, 56-59, 62, 64, 65, 68, 72, 77, 85, 90, 95, 96, 98, 100, 102, 104, 106-110, 113, 114, 119, 124, 126, 127, 129, 132, 135, 142, 144, 152, 154-156, 160, 163-165, 172, 174, 176, 178, 187, 189, 191, 194, 200, 202, 204, 205, 208, 211, 212, 217, 221, 225, 226, 228, 232, 238, 245-248, 252, 255, 256, 258, 262, 266, 267, 269, 271, 272, 275-279, 281, 282, 291-295, 297, 300, 305, 320, 330, 332, 334, 341, 343, 349, 350, 354, 355. *Oppenheimer* (2001): Star no. 20. *Reid* (2004): Stars no. 27, 69, 75, 81, 84, 103, 122, 130, 185, 186, 190, 274, 287, 290, 301, 302. *Riedel* (2010): Stars no. 51, 97, 101, 125, 147, 184, 207, 218, 223, 303, 314. *Smart* (2007): Stars no. 4, 138, 169, 180, 192, 222, 336. *The Denise Consortium* (2005): Stars no. 14, 33, 209, 214, 240, 244, 249, 260, 284, 298, 312. *Wheatley* (2008): Star no. 250.

3.3 An Extension into the Near-Infrared

The passbands JHK are an extension of the Johnson UBV system to near-infrared wavelengths.

3.3.1 The J Band

Passband J is sensitive in the wavelength range from 1160-1350 nm (*Reid & Hawley, 2005*). The apparent magnitudes in J were available for all 355 M-type stars as well as for all 22 G2V stars and were taken from *Cutri et al. (2003)*.

Figure 3.6. The relationship between mass and luminosity in passband J for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

In Figure 3.6 the M stars show almost no scatter or deviation along the curve, as this is to be expected in the H and K bands as well. This is due to the fact, that all measurements were obtained using the same instrumentation in the same mission, and the K band, which lies near resp. next to passbands J and H, was used to determine the stellar masses for all M stars. The luminosity ratio in the right diagram illustrates the opposite behavior as in the previous passbands, UBVRI, namely a negative slope. Going redwards the Sun-like stars, G2V, for the first time show a smaller fraction of total luminosity in this passband than all M stars in the sample. All in all the luminosity ratio demonstrates, that with increasing stellar masses the luminosity in J as a fraction of the bolometric decreases.

3.3.2 The H Band

Passband H is sensitive to wavelength ranges from 1490-1800 nm (*Reid & Hawley, 2005*). The apparent magnitudes in H were available for all 355 M-type stars as well as for all 22 G2V stars and were taken from *Cutri et al. (2003)*.

Figure 3.7. The relationship between mass and luminosity in passband H for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

As already mentioned in 3.3.1, Figure 3.7 shows a smooth curve with almost no scatter as was expected. The gap between red dwarfs and Sun-like stars would be the position for stars of spectral type K as well as for mid- and late-type G stars. Despite this gap, it can clearly be seen that the G2V stars' luminosity in H follows exactly along the same curve defined by the M stars.

As opposed to previous luminosity ratio diagrams, the ratio of H band luminosity to bolometric shows a slight increase at the very end of the lower M star masses at 0.1 M_⊙. Figure 3.7 illustrates even clearer, that in passband H the G2V stars have a smaller fraction of total luminosity than the red dwarfs. This is in agreement with the well-known fact that red dwarfs are literally redder than yellow dwarfs and the chosen sample of M stars conforms perfectly with this fact.

3.3.3 The K Band

Passband K is sensitive for wavelength ranges between 2000-2300 nm (*Reid & Hawley, 2005*). The apparent magnitudes in K were available for all 355 M-type stars as well as for all 22 G2V stars and were taken from *Cutri et al. (2003)*.

Figure 3.8. The relationship between mass and luminosity in passband K for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

Since the M star's masses were determined using the K band it was no surprise that the result of plotting stellar mass against luminosity in K revealed a smooth curve with no scatter at all (Figure 3.8, left diagram), while the G2V stars, calculated using a different method, show a little scatter. Nevertheless, the Sun-like stars follow the same direction that the M stars have shaped, demonstrating that the higher a star's mass the higher its luminosity in K. The right diagram illustrates results very similar to the previous luminosity ratio in passband H with a slight increase at 0.1 solar masses followed by a smooth trend for the M-type stars and a fractionally lower K versus bolometric luminosity ratio.

3.4 The Short-Wavelengths

The wavelength ranges NUV, FUV, EUV and X-ray are arranged at the bluer end of the visible spectrum and are short-wavelengths. Down from about 150 nm they become ionizing, which might impact habitable planetary atmospheres in different ways. For example, strong ionizing radiation could erode a planet's atmosphere through stellar winds. From all main sequence stars, M dwarfs are one of the most luminous at short-wavelengths (*Reid & Hawley, 2005*).

3.4.1 NUV - Near Ultraviolet

The NUV passband of *GALEX* is sensitive to radiation from 175-280 nm (*Hanslmeier, 2009*). All used values in NUV were given in AB magnitudes and taken from *GALEX*³⁴. Altogether 200 values for the M stars' sample and 15 values for the G2V stars' sample were available.

Figure 3.9. The relationship between mass and luminosity in passband NUV for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

In comparison to all previous passbands, NUV shows two differing groups of M stars (Figure 3.9, left diagram), which are separated at approximately 0.2 M_⊙. In the first group of very low mass stars there seems to be no apparent relationship between mass and radiation in NUV. The second group demonstrates a linear relationship with mass above which the stars in the first group show large scatter. This phenomenon is even more obvious in the diagram on the right.

³⁴ Data products see: <http://galex.stsci.edu/> (Data release GR6)

The scattering above both groups could be caused by flaring events or general activity. Possible explanations for the existence of these two groups will be discussed later.

In Figure 3.9 the ratio of NUV to bolometric luminosity demonstrates that almost all M stars have lower values than the G2V stars. Even the most active M stars at very low mass, first group, show a lower ratio of about three times than all G stars in the sample. The M star outlier slightly above [-2] on the y-axis is most likely a measurement during a strong flaring event. As it is clear to which masses these two groups belong, it is necessary to inspect the corresponding spectral subtypes.

Figure 3.10. The relationship between spectral type and the NUV luminosity ratio defined by M stars from the sample.

Figure 3.10 illustrates the luminosity ratio in NUV versus the spectral subtype only for the M stars sample. Taking a closer look, it shows a transition around spectral class M4. From M0-M4 there is a downwards trend, but after the minimal turning point the curve increases strongly and even passes the highest NUV ratio level at M0. This leads to the presumption that the more massive early-type M stars belong to the second group from above. Those stars of the first group appear to belong to spectral types M3.5 and later, which exactly correlates with the stellar mass, where stars change from a radiative zone surrounded by a convective envelope to a fully convective energy transport.

The previous figures in NUV (Fig. 3.9 and Fig 3.10) showed different activity levels depending on mass and spectral subtype. To make a statement about activity changes during stellar evolution, age is a fundamental parameter.

Therefore, estimated stellar ages using different methods were plotted against the NUV luminosity ratio (Figure 3.11), which showed that there is a correlation between fractional NUV emission and stellar age. This can be seen for the ages estimated by chromospheric as well as by gyrochronological method, which are in good agreement, especially for ages above several million years. The G2V stars do not show such a behavior as they scatter around the same level through billions of years. However, this could be caused by the domination of the NUV flux by the photospheric emission or the uncertainties of the isochrone method discussed in chapter 1.4.3.

Figure 3.11. The relationship between age and NUV luminosity ratio. M star ages estimated by the chromospheric method are marked pink while the gyrochronological ages are illustrated in light and dark blue. The dark blue stars represent those that roughly fulfill the criteria given by *Barnes* (2007). G2V star ages estimated by the isochrone method are marked green.

3.4.2 FUV - Far Ultraviolet

The FUV passband from *GALEX* is sensitive in a wavelength range from 135-175 nm (*Hanslmeier, 2009*). All values in FUV were given in AB magnitudes and taken from *GALEX*³⁵. Overall 92 values for the M and 15 values for the G2V stars were available.

Figure 3.12. The relationship between mass and luminosity in passband FUV for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

Compared to the results in NUV, Figure 3.12 illustrates that the linear mass-luminosity relationship of the second group has dispersed. Still the presence of two groups in FUV with a separation at around $0.3 M_{\odot}$ can be observed. Apparently at higher energy radiation there is a larger scatter when compared to lower energy bands, i.e. NUV and U.

The diagram on the right of fig. 3.12 demonstrates a higher FUV emission for lower mass stars, which decreases with increasing stellar mass. At this wavelength G stars and less active M stars scatter around the same level.

Due to a lack of data in FUV for stars later than M6 it is difficult to demonstrate the presumption of two existing groups with different activity levels based on spectral type (Figure 3.13). Nevertheless, a trend starting between M3.5 and M4 can be noticed, where later stars seem to be more active in FUV.

³⁵ Data products see: <http://galex.stsci.edu/> (Data release GR6)

Figure 3.13. The relationship between spectral type and the FUV luminosity ratio defined by M stars from the sample.

Concerning FUV emission over time, Figure 3.14 illustrates that there is a very high activity for stars younger than 500 million years. Older stars appear to be less active in FUV. A reason for this could be that estimating stellar ages by the chromospheric method requires measurements of the Ca II K line, which lies within the bluer end of passband B. As demonstrated in Figure 3.2, the B luminosity of low mass ($< 0.2 M_{\odot}$) stars is very faint and thus could be a reason why/that there are no measurements of Ca II K for these stars.

Figure 3.14. The relationship between age and FUV luminosity ratio. M star ages estimated by the chromospheric method are marked pink while the gyrochronological ages are illustrated in light and dark blue. The dark blue stars represent those that roughly fulfill the criteria given by *Barnes* (2007). G2V star ages estimated by the isochrone method are marked green.

In fact, when plotting the stellar masses against chromospheric ages (Figure 3.15) it showed that there is a mass-age dependence. Whether this has to do with limitations of the chromospheric method or that only for young early-type M stars, ages can be determined as their activity is lower than that of later-type M stars anyway and even decreases further with increasing age.

Figure 3.15. The relationship between mass and chromospheric age of the here studied M stars' sample.

Another rather unlikely explanation could be a gradient in stellar evolution within 15 pc of the Sun, namely that there are only young early-type and old late-type M stars. However, the comparison between M and G stars illustrates (Figure 3.14), that Sun-like stars have higher FUV emissions than coeval red dwarfs.

3.4.3 EUV - Extreme Ultraviolet

The passbands in EUV are sensitive in wavelength ranges from 5.8-17.4 nm (Lexan/B EUVE) (*Christian et al.*, 1999) and 6.0-14.0 nm (S1 ROSAT) (*Pye et al.*, 1995). All EUV values were given in counts per second and mainly taken from the EUV Master Catalog³⁶, supplemented with the catalog from *Hodgkin & Pye* (1994).

Figure 3.16. The relationship between mass and luminosity in passband EUV for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

As there were very few measurements in EUV available for the complete sample, it is difficult to draw a conclusion. Nevertheless, Figure 3.16 in EUV shows the same existence of two groups as the other short-wavelengths did before. One being more active at lower masses and another with lower activity at higher masses. However, in the second group there are only three data points. This might be due to the limits of the instruments' sensitivity as stars in this sample later than M6.5 have no corresponding EUV data (see Figure 3.17). These three stars in the lower activity group belong to early-type M stars as Figure 3.17 identifies.

Again, the M stars demonstrate a clearly higher activity than the G2V stars, except the lower activity group. Besides, this confirms the trend of lower mass M dwarfs radiating a comparatively higher fraction of their bolometric luminosity in the higher energy ranges than the G2V stars.

³⁶ The EUV Master Catalog is a compendium of seven catalogs from which the six following were used in this work: EUVEBSL (*Malina et al.* 1994), EUVECAT2 (*Bowyer et al.* 1996), ROSWFC2RE (*Pye et al.* 1995), ROSATXUV (*Kreysing et al.* 1995), EUVERAP2 (*Christian et al.* 1999) and EUVEXRTCAT (*Lampton et al.* 1997).

3.4.4 X-ray

The X-ray detector from *ROSAT* (PSPC) is sensitive to a wavelength range from 0.52-12.4 nm (Voges *et al.*, 1999). The X-ray luminosities [erg s^{-1}] for the M stars' sample were already calculated and taken from Odert (2012, in preparation). The X-ray values [cts s^{-1}] for the G2V stars were derived from *ROSAT* bright and faint source catalogs (Voges *et al.*, 1999; Voges *et al.*, 2000) and available for 11 G2V stars.

Figure 3.19. The relationship between mass and luminosity in X-ray wavelength for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

In the preceding mass-luminosity figures of short-wavelengths, the existence of two groups might have been difficult to notice. Coming to the shortest wavelength range studied in this work, X-ray, their existence can no longer be doubted. Taking a look at Figure 3.19, two strong concentrations of stars can be seen immediately and prove that the M stars in the here studied sample contain two groups of different activity.

Comparing stars of spectral type M and G, it shows that many M-type stars have a much higher energy output at X-ray wavelengths relative to their bolometric, especially those at the lower mass end. Reid & Hawley (2005) claim that X-ray luminosity when compared to the visual (L_X/L_V) can reach a ratio of 10% in M dwarfs and this is about 1000 times higher than the G star ratio. Figures 3.3 and 3.19, when compared, perfectly confirm this statement. Kiraga & Stéprien (2007) state that the most active M-type stars show a ratio of L_X/L_{bol} of about 10^{-3} , which is in very good agreement with Fig. 3.19, right diagram.

Concluding, it turns out that later-type M stars have a relatively higher coronal emission than G stars. This is also illustrated in Figure 3.20, where the spectral subtype is plotted against the luminosity ratio in X-ray wavelengths. Beginning at approximately M3.5 the stars almost exclusively belong to the higher activity group.

Figure 3.20. The relationship between spectral type and the X-ray luminosity ratio defined by M stars from the sample.

When comparing the X-ray luminosity ratio to age, there is no significant dependence observable at ages higher than a few hundred million years (Figure 3.21). In contrast to the previous age figures, the M and G stars scatter at the same levels.

Figure 3.21. The relationship between age and X-ray luminosity ratio. M star ages estimated by the chromospheric method are marked pink while the gyrochronological ages are illustrated in light and dark blue. The dark blue stars represent those that roughly fulfill the criteria given by *Barnes* (2007). G2V star ages estimated by the isochrone method are marked green.

3.5 The Spectral Line H α

The spectral line H α is the strongest line of ionized hydrogen with a wavelength of 656.28 nm. When an electron falls from the third to the second lowest energy level, the H α line emission occurs, emitting red light. To detect this released emission, special H α filters or spectroscopy are used to visualize the structure of the chromosphere. The equivalent widths of H α emission were available for 59 M stars and derived from several catalogs³⁷, referenced below. The surface fluxes in H α for 10 G stars were found in several articles³⁸. However, as the I band was needed to calculate H α luminosities for the M stars (see section 2.2.5) and data was not available in this band for all stars with an equivalent width in H α , only 52 M stars could be processed.

Figure 3.22. The relationship between mass and luminosity in H α for the studied M and G stars sample in this work. M stars are marked red as the G stars are green.

The examination of the H α emission of stars is of prime importance when trying to get information about a star's chromospheric activity. In the figures of the previous short-wavelength ranges two groups could be identified probably based on different activities. Looking at Figure 3.22, it seems that one group is missing. This can be easily explained as only the emission of H α was studied, while stars with H α in absorption were excluded.

³⁷ **M stars:** *Gizis et al.* (2002): Stars no.: 2, 18, 27, 30, 36, 40, 75, 83, 95, 108, 118, 119, 126, 132, 137, 168, 170, 173, 192, 194, 202, 218, 274, 275, 281, 283, 292, 294, 302, 320, 328, 347, 349, 351. *Mohanty & Basri* (2003): Stars no.: 231, 329. *Panagi & Mathioudakis* (1993): Stars no.: 181, 188, 196. *Shkolnik et al.* (2009): Stars no.: 26, 130, 176, 204, 237, 332, 334. *Walkowicz & Hawley* (2009): Stars no.: 88, 160, 163, 164, 198, 201, 250, 271. *West et al.* (2008): Stars no.: 67, 155, 253. *West et al.* (2011): Stars no.: 190, 233.

³⁸ **G2V stars:** *Herbig* (1985): Stars no.: 13, 14. *Lyra & Porto de Mello* (2005): Stars no.: 10, 12, 15, 18, 19, 21. *Martinez-Arnaiz et al.* (2010): Stars no.: 4, 7.

Further, it illustrates that the G2V stars are on the same level as the more active M stars' group, which is probably explained through taking measurements during or shortly after flaring events as G stars normally absorb in H α and only emit during strong flares. When viewed against spectral subtype one can conclude that the vast majority of H α emitting stars belong to M3 and later (Figure 3.23).

Figure 3.23. The relationship between spectral type and the H α luminosity ratio defined by M stars from the sample.

Even the comparison with age (Figure 3.24) allows no significant statement of H α evolution with age, as there were too few stars with H α emission and corresponding age available.

Figure 3.24. The relationship between age and H α luminosity ratio. M star ages estimated by the chromospheric method are marked pink while the gyrochronological ages are illustrated in light and dark blue. The dark blue stars represent those that roughly fulfill the criteria given by Barnes (2007). G2V star ages estimated by the isochrone method are marked green.

3.6 Why look far when the good is so NEAR?

The two groups of M dwarfs in this sample can be seen in NUV, FUV, EUV and X-ray wavelengths. These two groups seem to separate the sample into active late-type stars and inactive early-type stars. This could simply indicate the length of time necessary for late-type M dwarf star evolution. As an example, if the rate of star formation is independent of the subtype, then more stars of late-type will remain active before scaling down to less activity. A further explanation could be that at different times different subtypes formed. Also the two groups could have formed within a short period of time at some point in the past and evolve in different time frames.

Irrespective of these thoughts, there is a dramatic change in activity at or around the point at which the full-convective model begins, and this significant shift can only be explained by large differences in the periods of stellar evolution, with early-types taking hundreds of millions of years to reach a point when the activity scales down, whereas later types require billions of years.

The discussion above clearly shows how urgent an accurate age determination method is needed to estimate ages from very young up to very old M dwarfs precisely. All current age determinations existing for M-type stars do not achieve satisfying results as they are connected with too many limitations.

As there was a good agreement between chromospheric and gyrochronological ages in NUV (see Fig. 3.11), the idea of using NUV as an age proxy came to mind. Since a dependency between age, activity and mass seems to exist, it was attempted to find a color which would give satisfying results as an age proxy. Hence the K band was included as it was used to determine the stellar masses for the M stars' sample, and demonstrates a reverse relationship to mass compared to the NUV passband.

Searching through the literature did not show anything comparable to this idea besides one article by *Findeisen et al.* (2011), where NUV-J is used to predict ages. In their work very young stars from moving groups are chosen for calibration. This method was not tried on M-type stars but only on earlier spectral classes (B8-K5).

Findeisen et al. (2011) come to the conclusion that there exists a correlation between NUV flux and activity or age. However, they describe this effect as slight, particularly for stars older than 1 Gyr.

As opposed to *Findeisen et al.* (2011), the here presumed proxy demonstrates a correlation between NUV-K and chromospheric ages from hundreds of millions to billions of years (Figure 3.25). A correlation between activity and NUV-K can be seen in the short-wavelength ranges FUV and X-ray as well as in the emission line H α . Due to a lack of data in EUV the existence of such a correlation could not be proved. However, it is believed that one exists as it is embedded between X-ray and FUV wavelengths.

Figure 3.25. The relationship between NUV-K and the short-wavelengths FUV resp. X-ray as well as the spectral line H α (upper diagrams and lower left). Lower right: Relationship between NUV-K and chromospheric ages. All data points are stars of the M stars' sample.

NUV emission can be related to the magnetic field of stars. *Vazquez & Hanslmeier* (2006) state that the largest proportion of chromospheric heating is accomplished by the magnetic fields of the star. Through heating of the chromosphere, UV radiation is emitted. These low energy wavelengths of UV radiation could be indicative of long-term heating of the chromosphere, since their generation does not require high energies as shorter wavelengths do. Therefore, NUV could be an indicator of long-term magnetic field strength in dwarf stars. Accounting for mass-specific influences, this could be a strong proxy of baseline magnetic field strength through activity and therefore age. Of course, this theory must be tested, e.g. with moving group ages.

4 Red Dwarfs as Host Stars

Already in the 1980's, the first extrasolar planets were discovered but wrongly classified as brown dwarfs. In 1992, the existence of two or more exoplanets orbiting the pulsar star PSR 1257+12 was published (*Wolszczan & Frail*, 1992). In 1995, the first exoplanet hosted by a Sun-like star was discovered by Michel Mayor and Didier Queloz using the radial velocity method (*Mayor & Queloz*, 1995). Since then the search for planets orbiting other stars than the Sun is one of the most pulsating topics in modern astronomy.

First the focus was laid on F, G and K stars, which means stars with spectral classes like the Sun, as well as one subclass up and down. Since more and more exoplanets have been found orbiting M-type stars - especially small, terrestrial planets - they finally have become targets for exoplanetary search missions and topic for theories discussing the possibility of a planet's habitability around such a red dwarf.

4.1 Habitability of Exoplanets Orbiting M-Type Stars

The importance of M dwarfs as host stars for habitable planets had been neglected for a long time as there were many considerations that argued against them.

The smaller a star, the closer is its habitable zone. Calculations for determining the extensions of habitable zones were made by *Kaltenegger et al.* (2010). Since M dwarfs have such low masses, their habitable zones are located much closer to the star. For spectral subtype M0, the perfect orbit for liquid water on a planet's surface is 0.1-0.35 AU and moves even closer to the host star with later M-types (*Tarter et al.*, 2007). M-type stars' habitable zones may remain stable clearly longer than the Solar System's HZ as the star does not change its luminosity significantly due to its slow evolution. Further, this means that a larger fraction of this zone is continuously habitable, wherein a planet could remain for up to 100 Gyr (*Tarter et al.*, 2007).

Despite this, one of the main concerns is the fact that planets orbiting their host stars at very close distances can become tidally locked.

This means that one side of the planet is always facing the host star receiving X-ray and UV emission over a long time scale and the other side is dark and cold. If water exists on the planet, then it is probably frozen on the nightside. *Tarter et al.* (2007) state that not all close-in planets become tidally locked, as a large initial eccentricity or a third body that perturbs the orbit could prevent the planet from becoming that.

Besides, different theories of heat transport and heat dissipation already exist, which attempt to explain how heat can be transported to the frozen side of the planet to become habitable (*Selsis et al.*, 2007). *Haberle et al.* (1996) presented a solution based on an energy-balance model. These authors argued that atmospheric heat-transport in the form of strong cloud coverage could prevent the planet's dark side from freezing. Further, they showed that a pure CO₂ atmosphere of 150 mbar could be sufficient to transport heat to the dark side of a tidally locked planet to maintain temperatures above the freezing point of CO₂. For liquid water 1-1.5 bar would be necessary.

Similar ideas derive from *Joshi & Haberle* (1997). They claim, that a dense and opaque atmosphere in the IR could transport heat to the dark side of the planet. Another method of heat transport, and thus preventing the planet's dark side from freezing, is the idea of a global ocean. Further, *Joshi et al.* (1997) presented a three-dimensional simulation of exoplanets' atmospheres, where it was attempted to estimate the climate of a tidally locked planet around an M-type star. Several factors were taken into account, for example the presence of clouds. In conclusion, *Joshi* (2003) claims that even synchronously rotating planets are suitable for life as long as they reside in the habitable zone around their host star.

But there is a further concern about tidally locked planets as it is not clear whether non-rotating planets can generate magnetic fields. *Lammer et al.* (2007) presumed that a reduced magnetic field can lead to the loss of the planetary atmosphere. This low magnetic moment, as well as the continuous impacts of CMEs experienced by the planet over a very long period of time, would lead to the exposure of these planets to a dense flow of CME plasma (*Khodachenko et al.*, 2007). This would cause strong erosion of the planet's atmosphere within the very close HZ of active M-type stars (*Khodachenko et al.*, 2007).

On the other hand, *Lammer et al.* (2007) claim that even weak magnetic moments of exoplanets can prevent major erosion of the atmosphere. Further, *Lammer et al.* (2007) state that an Earth-like exoplanet orbiting an M-type star with $0.5 M_{\odot}$ can preserve its atmosphere if its orbit is less than or equal to 0.1 AU and the EUV radiation is not higher than 50-70 times that of the Sun. The crucial parameter for atmospheric loss is the EUV flux exposure as well as the thermal heating and expansion that would take place. Larger planets could be more effective at protecting their atmospheres against erosion (*Lammer et al.*, 2007).

As M dwarfs are smaller than Sun-like stars, their protoplanetary disks are less massive. Therefore, it is expected that planets orbiting such stars are Neptune-sized and smaller (*Oshagh et al.*, 2010). Observations of protoplanetary disks have shown that M dwarfs also have such disks with sufficient material to form Earth-sized planets (*Andrews & Williams*, 2005). Nevertheless, it is not known whether small planets are preferably formed around M-type stars or more massive ones. Regardless of this discussion, with the current detection methods it should be easier to discover small planets around M-type stars than around stars of the more massive spectral classes.

Another concern besides tidal locking, is the magnetic activity which, among other things, becomes noticeable through heavily spotted surfaces, strong flares and powerful CMEs. M dwarfs are covered by much more starspots than Sun-like stars (e.g. *Reid & Hawley*, 2005). The heavy covering can lead to a radiation decrease of up to 40 % (*Joshi et al.*, 1997) and an M star flare can double the incoming radiation in several wavelengths within minutes (*Tarter et al.*, 2007, and references therein). During all these space weather phenomena, strong short-wavelength radiation is emitted and planets in the close-in habitable zone would be exposed to it.

This raises the question, how long the high activity period for M-type stars lasts. Although the magnetic dynamo is not fully understood, especially for fully convective stars, it is well-known that the level of activity and its duration depend on the stellar mass and further, that young stars are more likely to flare. That means, if focusing on early-type M stars with ages higher than one billion years, similar conditions to that of the young Sun could be expected.

Later-type M stars should be excluded as they show chromospheric activity levels too high, even at higher ages, as their magnetic dynamo scales down more slowly. This statement is also supported by different authors (e.g. *Turnball & Tarter*, 2003). However, *Segura et al.* (2005) presume that atmospheric ozone could defuse the strong radiation coming from flaring events and this ozone can be produced abiotically.

So if we want to say something about a planet's habitability, it is crucial to understand the effects of space weather. The magnetic dynamo has to be understood and also the size of a star's astrosphere has to be taken into account, which turns out to be very complicated, as even the precise extensions of the heliosphere are not yet known.

Discussing the pros and cons of M-type stars as hosts for habitable planets, it must not be forgotten how adaptable life is to the extremest conditions. On earth such organisms are called extremophiles and biologists are surprised each time anew when unknown species existing under incredible conditions are discovered. Several exoplanetary search missions require lists for so-called "Habstars", in which all nearby early M-type stars with ages higher than one billion years should be absolutely included.

4.2 M-Type Stars of this Sample Hosting Exoplanets

Since 1995, there exists an online catalog which is called "The Extrasolar Planets Encyclopaedia" by Jean Schneider³⁹. It contains 716 exoplanets⁴⁰, which were detected either by radial velocity, astrometry, transit, microlensing, imaging or timing method. Within this catalog 14 of the 355 M stars in this sample are listed to date as host stars with a total number of 21 exoplanets.

The following table (Table 4.1) lists the names of these stars, the stars' spectral subtypes as well as the number of so far detected orbiting planets.

Table 4.1: Exoplanets

Star	SpT	Planets	No. in Tab. 2.1
GJ 176	M2.0	1	78
GJ 179	M3.5	1	80
GJ 317	M3.5	2	131
GJ 433	M1.5	1	182
GJ 436	M3.5	1	186
GJ 581	M5.0	4	236
GJ 649	M2.0	1	251
GJ 674	M3.0	1	259
GJ 832	M1.5	1	313
GJ 849	M3.5	1	324
GJ 876	M5.0	4	335
GJ 1148	M4.0	1	185
GJ 1214	M4.5	1	256
HIP 79431	M3.0	1	244

Table 4.1: lists the stars of the here studied M stars' sample orbited by so far detected exoplanets.

5 Conclusion

The close proximity of M stars in this work, lying within a radius of 15 pc of the Sun, allowed the extensive study of even low mass M dwarfs in a wide wavelength range from X-ray to NIR. Further, it permitted the decrease of biases introduced by limitations in the detection of faint objects. This work attempted to characterize M-type stars over a large range of the electromagnetic spectrum, as well as a dependency of several activity indicators on age.

M-type stars make up the overwhelming majority of stars in the galaxy with lifetimes long enough for habitable conditions to form and life to evolve. Due to concerns about long periods of high activity and tidal locking of planets within the habitable zone, they were neglected for a long time, and exoplanetary search missions largely concentrated on the spectral classes FGK as host stars.

When considering the habitability of exoplanets, one must also consider the "hospitality" of the host star itself. In particular, the long period of initial high activity must be regarded and its potential to erode a planet's atmosphere, where due to tidal locking possibly no protective magnetic field exists.

West et al. (2008) and this work demonstrate that the long lifetimes of high activity in M stars may in fact not necessarily be long enough to erode a planetary atmosphere. Atmospheric erosion models for planets in the habitable zone around red dwarfs have shown this to be the case (*Lammer et al.*, 2009). In *West et al.* (2008) and here, data is presented that shows for at least the early-type M stars up to spectral subtype M3.5 that this lifetime may be about several hundred million years.

Actually, M stars should be treated as two separate groups when considering candidates for habitable exoplanet searches, namely early till mid-type and mid- till late-type stars. The border separating these two is the upper mass limit for a fully convective energy transport. This seems to be, from the data presented here, $0.3 M_{\odot}$, if not in fact lower.

The first group of M dwarfs with short activity lifetimes has a mass range of 0.3-0.6 M_{\odot} , while the second group of high activity stars range from 0.08-0.3 M_{\odot} .

In all mass-luminosity diagrams in the UBVRIJHK passbands, there is an interesting transition beginning at 0.2-0.3 M_{\odot} . This transition can also be observed in the shorter wavelength ranges, X-ray, EUV, FUV and NUV and could be the mass limit for full convection.

All activity indicators plotted against ages demonstrate, at least for early and mid-type red dwarfs, a decrease of activity after several hundred million years. If these lifetimes are as low as shown, then the viability of these stars to host habitable planets has greatly increased, as well as the quantity of potential candidate stars. Therefore, it is very important to improve the age determination methods of early to mid-type M stars to allow an empirical study of their high activity lifetimes and evolution.

Currently, there are no age determination methods specifically for M-type stars. The here presented age proxy (NUV-K) could very well be of interest for at least early-type M dwarfs. Both chromospheric and gyrochronology age determination are hampered by limits even in the most massive M-type stars. As could be observed in Fig. 3.15, the chromospheric ages appear to be mass dependent, indicating the limits of this method.

Continued work must be done to improve the understanding of M-type dwarf evolution. Early and mid-type stars, a large portion of the masses of this spectral class, require more intensive study. Their viability for hosting habitable planets must be determined as their quantity in the galaxy and advantages for exoplanet discovery over more massive stars lend this class to closer examination. Further, much more work needs to be done to understand the transition between the dynamo generation in fully convective and interface stars.

Early-type M stars are extremely interesting in the search for Earth-sized planets in the habitable zones of their host stars.

They have several advantages in terms of mass and luminosity over their more massive relatives for current detection methods, and allow even direct imaging of candidate planets.

With the current exoplanet detection methods it is feasible to discover Earth-sized planets hosted by M stars. Within the coming years presumably many exoplanets around M stars will be discovered thanks to missions like CoRoT, Kepler, Gaia, TESS, PLATO and so on.

If enough importance is given to M-type stars, then the majority of terrestrial exoplanets will likely be discovered around red dwarfs. This also means that studying the influence of space weather phenomena on a planet's potential habitability cannot be taken seriously enough.

The present state of scientific and technical knowledge does not allow precise determination of several fundamental stellar parameters to make explicit predictions concerning the future evolution of red dwarfs. At the current age of the universe it seems that mid and late-type M stars are still too young to offer conditions for life as we know it as their activity and thus their radiation in certain wavelengths is far too strong. But we should always keep in mind that even M stars older than 10 Gyr are still very young compared to their expected lifetimes. Maybe one day, several billions of years in the future, when human beings will have disappeared from Earth and the Sun will have expanded to a red giant, a myriad of M-type stars could be host stars for other livable worlds.

Abstract

The term space weather was originally introduced to describe temporal changes of the Sun's activity and their influence on the planets of the Solar System. Due to numerous discoveries of exoplanets in the past decades, this term is also used today to describe the activity of other stars than the Sun. In the present work a large sample of M-type stars within 15 parsec of the Sun was studied directing the main focus on their activity in comparison to Sun-like stars. In summary, an almost complete coverage of the electromagnetic radiation emitted by 355 M-type stars as well as 22 Sun-like stars over a wavelength range from 0.5 to 2300 nm was performed and thus illustrates their characteristics over a large part of the electromagnetic spectrum. It turned out that the high activity lifetime of ionizing short radiation is not as long as expected, especially for early-type M stars. Furthermore, the mass limit for fully convective energy transport seems to be lower than it has been postulated in earlier articles. Finally, a possibly new age indicator for stars of spectral class M is discussed.

Zusammenfassung

Der Begriff Space Weather wurde ursprünglich eingeführt, um zeitliche Änderungen der Sonnenaktivität und deren Einfluss auf die Planeten des Sonnensystems zu beschreiben. Aufgrund zahlreicher Entdeckungen von Exoplaneten in den vergangenen Jahrzehnten wird dieser Begriff nun auch zur Beschreibung der Aktivität anderer Sterne als der Sonne verwendet. In der vorliegenden Arbeit wurde ein großes Sample von Sternen der Spektralklasse M, die sich in einem Radius von 15 pc um die Sonne befinden, untersucht, wobei der Fokus auf ihre Aktivität im Vergleich zu sonnenähnlichen Sternen gerichtet wurde. Zusammenfassend wurde die elektromagnetische Strahlung von 355 M sowie 22 sonnenähnlichen Sternen im Wellenlängenbereich von 0.5 bis 2300 nm nahezu vollständig untersucht und somit die jeweiligen Besonderheiten über einen großen Teil des elektromagnetischen Spektrums dargelegt. Dabei zeigte sich, dass die hohe Aktivitätszeit der ionisierenden kurzwelligen Strahlung nicht so lange anzudauern scheint wie bislang vermutet. Dies gilt besonders für frühe M Sterne. Des Weiteren scheint die Grenzmasse für einen völlig konvektiven Strahlungstransport niedriger zu sein als sie in früheren Artikeln eingeschätzt wird. Darüber hinaus wird ein möglicher neuer Altersindikator für Sterne der Spektralklasse M diskutiert.

Acknowledgements

I want to thank my supervisor Univ.-Prof. Dr. Arnold Hanslmeier for giving me the chance to work on a combination of two topics that I absolutely wanted to work on. He took the time to discuss several ways and ideas until the perfect match was found. Furthermore, I really appreciate having been taught by such a didactically great professor, who never loses sight of the practical aspects next to a fundamental scientific education. Further, he supports his students in many different ways, for example inviting me to the Central European Solar Physics Meeting V in Bairisch Kölldorf, Austria, where I was allowed to present my first scientific poster. His feedback was always constructive and motivating and so guided me through the process of writing a master's thesis.

I acknowledge Mag. Petra Odert for allowing me access to various calculated results from her PhD thesis in advance of publication. Further, I would like to thank her for advice and many helpful suggestions during the writing of this work. She put so much effort into supporting me and not one single of my numerous e-mails or questions was left unanswered.

There are two other persons, that I would like to quote in particular: David Horner and Barbara Kaschel. Thank you, for accompanying me for the last ten years and that I can always count on you.

In addition, I am very grateful to all my friends, who were truly interested in my master's thesis' topic and never stopped questioning about it. This really helped not to lose the thread. Besides, I would like to thank everyone, who offered valuable comments on this work, supported me in any way or just was understanding when I had no time during the writing process. Listing all your names would fill several pages. Please feel mentioned, remembered and appreciated!

Finally, I want to thank my parents for supporting me financially over the main part of my studies.

CURRICULUM VITAE Traude Rochowanski

PERSONAL INFORMATION

Date, place of birth: September 9th, 1983, Vienna, Austria

E-mail: t.rochowanski@yahoo.de

EDUCATION

10/2008 - 04/2012 University of Vienna, Master of Astronomy (Magisterstudium)
Majors: Stellar Astrophysics, Structure and Evolution of the Milky Way
Master's thesis: M-Type Stars and their Space Weather

10/2004 - 10/2007 University of Vienna, Bachelor of Astronomy (Bakkalaureatsstudium)

09/1993 - 06/2001 Secondary School (AHS), BG VIII, Vienna, Austria
School Leaving Examination (Matura) June 21st, 2001

WORK EXPERIENCE

02/2010 - present Trainer for German as a second and English as a foreign language
Project ISIS, Adult Education Centers of Vienna (VHS). ISIS is a project to support migrant youth. Tasks: Conducting lessons, developing curricula and teaching material, empowerment and motivation

01/2011 - present Project manager for the project uni4you
Private initiative in collaboration with the Adult Education Centers of Vienna
Content: Integration of young immigrants into the higher education sector.
Responsible for selection of staff, conducting workshops, networking and collaborating with project partners (universities, schools, NGOs), development of material, project documentation and evaluation

AWARDS

Project ISIS Austrian National Award for adult education. Section: Integration through education (in the framework of the Dynamo network), 2010

Project uni4you Vielfalter Award. Awarded with 5000€, 2012

VOLUNTARY ENGAGEMENT

09/1989 - present Active scout member at the scout group 23 "St. Calasanz", Vienna, Austria
Since 2009 scout leader. Main tasks: working with 13-16 year old adolescents on different topics (environmental protection, first aid, social behavior, politics etc.), organizing weekly meetings, scout camps and other events

POSTER

10/2011 M-Type Stars and their Space Weather
Central European Solar Physics Meeting V; Bairisch Kölldorf, Styria, Austria
